The change of the magnetic susceptibility of the alloy is to be noted. In the diamagnetic susceptibility of bismuth (and also of antimony), the non-diagonal terms may be primarily important but the Landau diamagnetism is not, since we can estimate that the contribution of the conduction electrons to the Landau susceptibility is less than 20% of the experimental value as follows: First because of small concentration of carrier the contribution to the susceptibility due to the minority carrier should be negligible. This can be deduced from the present band calculation, the value of the effective mass estimated from the cyclotron absorption, and the absence of the de Haas-van Alphen effect. Secondly the ratio of the Landau susceptibility of majority holes to that of electrons is a little smaller than unity, if we approximate the hole surfaces with six or twelve maxima to be ellipsoidal and assume to be $m_\perp^{(h)}/m_\perp^{(e)} \gtrsim 3$ (basing upon the fact that the structure of the cyclotron absorption curve in high magnetic field mentioned above may be due to the majority holes) and $m_\parallel^{(h)} \sim m_\parallel^{(e)}$ in the magnetic field parallel to the bisectrix axis. This hole mass $m_\parallel^{(h)}$ parallel to the field is overestimated, since $m_\parallel^{(e)} \sim m_0$ and there is some evidence for $m_\parallel^{(h)} < m_0$.[5),7)] Then the contribution to the Landau susceptibility due to the holes is overestimated in the above evaluation. On the other hand the Landau susceptibility of the de Haas electrons is only 10% of the experimental value. These are all of the bases of our estimation. By alloying antimony in bismuth, three effects are to be considered. The energy gaps at C and A are broadened monotonically, the relative height varying as mentioned above, and the extrema where the holes are located may move away along the line M. The number of conduction electrons *versus* the concentration of antimony curve has a minimum about 16 atomic %, or there is a narrow region about this concentration in which electrons and holes are missing. The susceptibility due to filled band with small energy gaps at special points in $\boldsymbol{k}$-space may be strongly diamagnetic and may decrease monotonically with the concentration of antimony, because the effect from the points C and A are not probably counterbalanced by the other effect from points such as the maxima along M. If and only if we assume with Heine[9)] that total contribution of the conduction electrons is strongly paramagnetic, we can explain the susceptibility curve in small concentration of antimony given by Shoenberg and Uddin[3)]. In such an assumption, we expect that $-\chi$ curve will have a maximum about the concentration of 16 atomic % antimony, though there is not yet such an experimental report.

The author wishes to thank Professor K. Ariyama for his valuable advice of the manuscript.

Appendix. Basis Functions for Irreducible Representations of Single Groups of $\boldsymbol{k}$

We use the same notation as in I. $\nu = \mathcal{E}\pi/2(1+3\omega)$.

(i) Γ, A: $p=1$ for Γ, $p=-i\exp(-3\nu i)$ for A

$$\left.\begin{matrix}\psi(\Gamma_1)\\ \psi(\Gamma_1')\end{matrix}\right\} = \frac{\sqrt{2}}{2}(z \mp p\bar{z}) ,$$

Internal Friction of Lead, II

By Yosio HIKI

The Government Mechanical Laboratory, Suginami-ku, Tokyo, Japan

(Received February 7, 1959)

The experimental results on the internal friction of lead single crystals were discussed on the basis of the dislocation theory. At low temperatures, the dependences of the internal friction on the strain amplitude and the frequency are well explained with the pinned-down dislocation model. The pinning of dislocations by point defects is also varified to exist through analyzing the change of the amplitude dependence of the internal friction produced by annealing the specimen. The exponential increase of the internal friction with increasing temperature is considered to be due to the thermal break-away of the dislocations from the pinning points. On the assumption that the Cottrell's force acts between the pinning impurity atom and the dislocation, some of the unknown quantities of a crystal can be determined as follows: dislocation density is $1.03 \times 10^8\,\mathrm{cm}^{-2}$, loop length of dislocation network 1.71×10^{-4} cm, and mean distance between impurities on dislocation 2.85×10^{-5} cm. Above a certain temperature (about 300°K) the internal friction decreases with increasing strain amplitude, being the reverse of the behavior at low temperatures. This phenomenon is interpreted as the impurity pinning becomes ineffective at high temperatures and the formation of jogs at the network pinning points of the dislocations contributes to the internal friction.

§ 1. Introduction

The internal friction of lead single crystals has been measured as a function of the strain amplitude, frequency and temperature, and the results were described in the earlier paper$^{1)}$ (hereafter called part I). The following is an analysis of these experimental data by the dislocation theory of internal friction. As will be shown in § 2–§ 5, the behavior of the internal friction at low temperatures is well understood by the "pinned-down" dislocation theory established by Granato and Lücke$^{2)}$. In § 6 and § 7, the temperature dependence of the internal friction will be taken into account and another mechanism will be proposed as an origin of the internal friction at high temperatures. Some transient phenomena will also be discussed briefly (§ 8).

§ 2. Pinned-down Dislocation Theory

The "pinned-down" dislocation theory of internal friction of Granato-Lücke$^{2)}$ can be summarized as follows. Crystalline solid contains a network of dislocations, their intersections being usually immovable. The network loops of dislocations are further pinned down or fixed by point defects which exert forces on the dislocation lines. The internal friction originated from the vibration of dislocation lines may have two types. The first is the dynamic one due to the damping force against the movement of the dislocation. The expression for this internal friction is obtained by solving the equation of motion of a dislocation line segment between pinning points which vibrates under the influence of the external alternating stress. The damping force is assumed to be proportional to the velocity of the dislocation though its origin has not been well understood. The second is one of the static hysteresis type due to the break-away of the dislocation line from the pinning by point defects. The dissipation of energy corresponds to the area of the hysteresis loop in the stress—dislocation strain diagram during one cycle of the external vibration. If the frequency of the external force is in the kilocycle range, the internal friction of a single crystal is expressed as a sum of these two losses, δ_i and δ_h, the former being frequency dependent and amplitude independent while the latter frequency independent and amplitude dependent. When the point defects are arranged randomly along the dislocation lines, these are given by$^{2)}$

$$\delta_i = \frac{5!\,\Omega\Delta_0}{\pi^2 c}\Lambda L_e{}^4 B\omega\ ; \qquad L_e = 3.31 L_c\ , \tag{1}$$

$$\left.\begin{aligned} \delta_h &= \frac{c_0}{\mathcal{E}^{1/2}}\exp(-c_1/\mathcal{E})\ ; \\ c_0 &= \frac{2\Omega\Delta_0}{\pi^2}\left(\frac{F}{bsE}\right)^{1/2}\frac{\Lambda L_n{}^3}{L_c{}^{3/2}}\ , \\ c_1 &= \frac{2F}{\pi bsE}\cdot\frac{1}{L_c}\ . \end{aligned}\right\} \tag{2}$$

There is also an associated change of the elastic modulus. The fractional changes of Young's modulus are given by

$$(\Delta E/E)_i = \frac{6\Omega\Delta_0}{\pi}\Lambda L_c{}^2\ , \tag{3}$$

$$(\Delta E/E)_h = \frac{c_0}{\mathcal{E}^{1/2}}\exp(-c_1/\mathcal{E})\ . \tag{4}$$

In these equations, the main variables are the angular frequency of the vibration ω and the strain amplitude of the specimen $\mathcal{E}$. E is Young's modulus along specimen axis, G shear modulus along slip direction, ν Poisson's ratio, b Burgers vector, Ω orientation factor, s resolved shear stress factor and $\Delta_0 = 4(1-\nu)/\pi^2$, $c = 2Gb^2/\pi(1-\nu)$. In a f.c.c. lattice, $s = \cos\theta\cos\varphi$ and $\Omega = (E/G)(s^2/12)$, where θ is the angle between the specimen axis and the normal to the slip plane, and φ the angle between the specimen axis and the slip direction. Λ is the total length of dislocation lines per unit volume of the specimen, L_n loop length of dislocation network, L_c mean distance between point defects on the dislocation line, F the maximum binding force between point defect and dislocation, and B damping constant for dislocation movement. Among the above quantities, Λ, L_n, L_c, F and B are unknown, which may be determined by comparing the theory with experiments. The value of L_c takes the exponential distribution in the present case while L_n is assumed to be constant throughout a specimen.

§ 3. Qualitative Confirmations of the Theory

At low temperatures, the experimental results on the internal friction of lead are well explained by the pinned-down dislocation theory as follows:

(i) δ increases with increasing $\mathcal{E}$ [Fig. 2 in part I], and there is a linear relationship between $\log \mathcal{E}^{1/2}\delta_h$ and $\mathcal{E}^{-1}$ as shown in Fig. 1, fitting to Eq. (2). The values of c_0 and c_1 can be determined by the intercept and the slope of this straight line, respectively.

(ii) The plots of δ_h against $\mathcal{E}$ for the same specimen measured with different frequencies lie on the same curve [Fig. 3 in I], namely, δ_h is independent of the frequency.

(iii) The fractional change of Young's modulus associated with the change of the strain amplitude, $(\Delta E/E)_h$, is proportional to δ [Fig. 4 in I], as expected by comparing Eqs. (2) and (4).

(iv) In the low temperature region, δ measured with small strain amplitude seems to be proportional to the frequency [Fig. 9 in I], being consistent with Eq. (1).

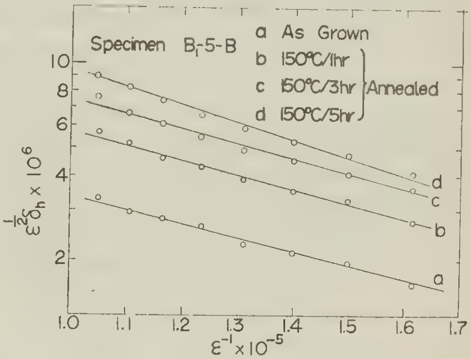

Fig. 1. Analysis of amplitude dependence of internal friction.

§ 4. Migration of Point Defects to Dislocations

In order to inspect the pinned-down model, the effect of annealing upon the amplitude dependence of the internal friction is to be examined. Cottrell and Bilby[3] offered a theory of strain ageing of metals and calculated the migration velocity of impurity atom to dislocation line under the influence of its stress field. According to them, in the early stage of ageing, the number of solute atoms which arrive at the unit length of dislocation line within time t is given by

$$n(t) = \alpha n_0\left(\frac{ADt}{kT}\right)^{2/3}\ , \tag{5}$$

where $\alpha = 3(\pi/2)^{1/3}$, n_0 is the total number of atoms in solution, $A = [4(1+\nu)/3(1-\nu)]Gber^3$, $e = (r-r')/r$, r and r' are the radii of solvent and solute atoms, $D\ (= D_0\exp(-Q/RT))$ is the diffusion coefficient and kT has its usual meaning. Using the theory described in § 2, the following relation is obtained from Eq. (2):

$$n(t)=\frac{1}{L_c(t)}-\frac{1}{L_c(0)}=\frac{\pi bsE}{2F}\,[c_1(t)-c_1(0)]\ ,$$

if there exists one point defect at a pinning point. Combining this with Eq. (5), we obtain

$$[c_1(t)-c_1(0)]=\beta\left[\frac{\exp(-Q/RT)}{T}\right]^{2/3}t^{2/3}\ , \qquad (6)$$

where β is a temperature-independent constant, Q is the activation energy for the diffusion of the point defect and t corresponds to the annealing time.

The amplitude dependence of the internal friction of a lead crystal received successive annealing has been measured at 8°C. From the analysis of the experimental data, the values of c_1 for the crystal as grown and annealed at 150°C for 1, 3 and 5 hours can be determined as shown in Fig. 1. Using these values, $[c_1(t)-c_1(0)]$ are plotted against $t^{2/3}$ in Fig. 2. These lie on a straight line as asserted by Eq. (6). The same specimen was also annealed at 135°C for 1, 3 and 5 hours; at 120°C for 1, 3 and 5 hours; at 105°C for 2, 4 and 7 hours, successively. Similar straight lines are also obtained for each annealing temperature as shown in Fig. 2. The activation energy can be calculated from these results with the usual method as shown in Fig. 3: $Q=26.6\pm0.8$ kcal/mol·deg.

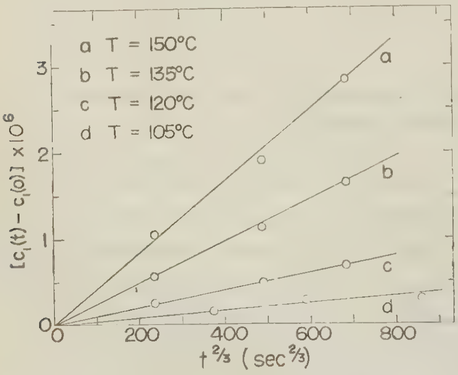

Fig. 2. Analysis of effect of annealing upon amplitude dependence.

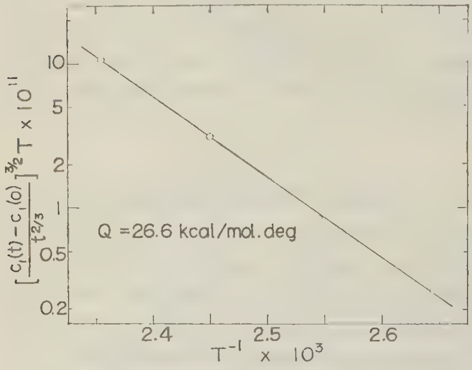

Fig. 3. Determination of activation energy for diffusion of point defect.

It is concluded that, in the present case, the dislocation are certainly pinned down by some point defects. The pinning agents may probably be impurity atoms. This has been suggested from the result of etch pits observation by the present author[4]. The number of etch pits per unit area on the lead single crystal made from the same material increases with increasing annealing time. This is explained by the fact that the impurity atoms migrate to the dislocation with prolonged annealing, because etch pit is considered to be produced by the combination of dislocation with impurity. The impurity atom acting as the pinning agent may be carbon, because it is the main impurity detected in the material [Table I in part I]. Although the direct measurement of the diffusion coefficient of carbon in lead has not yet appeared, the value of the activation energy obtained above ($Q=26.6$ kcal/mol·deg) seems to be quite reasonable. For the purpose of comparison the activation energies for diffusion of various elements determined by usual method are listed in Table I.

Table I. Activation energies for diffusion of various elements in lead. (in kcal/mol·deg)

§ 5. Numerical Evaluation of Unknown Quantities

The quantities appearing in Eqs. (1) and (2), A, L_n, L_c, F and B, can be calculated using some assumptions.

The crystal is considered to be broken up into blocks, dislocation lines forming the edges of these blocks. It is assumed that there is one dislocation per block face. This is fairly confirmed by X-ray experiments in the case of well-annealed crystals[5]. In this case, the following relation holds:

$$A=3L_n^2\ . \qquad (7)$$

Further assumptions are that the pinning agents are carbon atoms in the present case and that the force between the pinning atom and the dislocation line is that of Cottrell's⁶⁾. The binding energy between an impurity atom and a dislocation line is given by

$$U_0=\frac{4}{3}\frac{(1+\nu)}{(1-\nu)}\frac{Gber^3}{r_0}=A/r_0\ , \tag{8}$$

where A is the same constant as that in Eq. (5), and r_0 is the distance between a dislocation line and an impurity atom at the equilibrium position, being several times the Burgers vector. The maximum binding force between a dislocation line and an impurity atom is also given by

$$F=(3\sqrt{3}/8)A/r_0^2\ . \tag{9}$$

From the amplitude dependence of the internal friction of the specimen B₁–5–B annealed at 150°C for 60 hours, c_0 and c_1 in Eq. (2) are determined as stated in § 3. Inserting these values together with the value of δ_i at low temperatures into Eqs. (1), (2), (7) and (9), and regarding r_0/b as a parameter, the values of A, L_n, L_c, F and $B\,(\equiv B_1+B_2T)$ can be calculated. The value of δ_i in the region where the internal friction increases slightly with increasing temperature is used in the present case. The value of U_0 is also known from Eq. (8). The results are listed in Table II.

§ 6. Effect of Temperature

The temperature dependence of the internal friction was not taken into account explicitly until now. At low temperatures, the internal friction of lead increases slightly with increasing temperature. This can be explained by the change of the damping constant B with temperature. As temperature is raised further, the internal friction increases steeply [Fig. 6 in part I], and this has been also observed by Bordoni *et al.*⁷⁾ and Weertman *et al.*⁸⁾ The phenomenon can be found in other metal single crystals, and some theories have been proposed to interpret it, by taking account of thermal motion of dislocations⁹⁾,¹⁰⁾.

The experimental results on the temperature dependence of the internal friction of lead will be analyzed as follows. The temperature-dependent part of the internal friction δ_T measured with small strain amplitude varies as $\exp(-U/RT)$, as shown in Fig. 4. The values of U of some specimens are listed in Table III. This behavior is considered to be due to the rate-controlling process so that the dislocations are thermally activated and broken away from the impurity pinning. Then U corresponds to the work to tear away the dislocation loop between network pinning points from impurity atoms. When the interaction between them is of Cottrell type, U is approximately U_0 times the number of impurity atoms on the dislocation loop, namely,

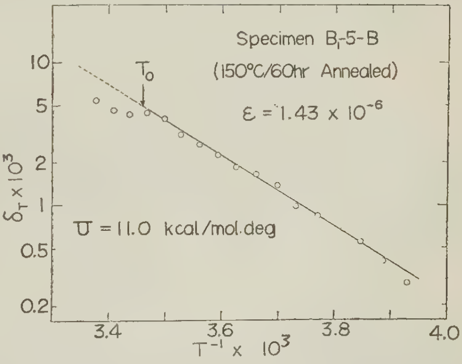

Fig. 4. Temperature dependence of internal friction at $T<T_0$.

$$U=U_0\times\left(\frac{L_n}{L_c}-1\right)\ . \tag{10}$$

As can be seen in Table III, the values of U

Table III.

n 1 (poly.)	Merk C.P.	machined	26.2	8.57	400	1.3×10^{9}	7)

are different in different specimens, probably due to the different impurity contents. In the same specimen, the value of U increases by prolonged annealing, as expected from the migration of the impurities to the dislocations.

In the above discussion, it is assumed that the concentration of the impurity atoms on the dislocation line, a/L_c, does not change during the measurement (a means the lattice parameter). This assumption seems to be reasonable because the migration velocity of the impurity is small even at 150°C [cf. §4]. The measuring temperature is lower than 70°C and long time is not wanted for measurement. On the contrary, if sufficient time is allowed for the atomic migration to occur, the concentration of impurities on dislocation is given by[6)]

$$C=C_0\exp(U_0/RT)\ , \qquad (11)$$

where C_0 is the average concentration in the crystal. From Eqs. (1) and (11), it is derived that δ_i is proportional to $\exp(-4U_0/RT)$. But this argument is not available to the analysis of the present experiment.

At higher temperatures, impurity atoms cannot pin down the dislocation line effectively. This occurs when the time required for a dislocation loop is broken away from impurity pinning by thermal fluctuations becomes smaller than the period of the external alternating stress, as stated by Weertman[11)], namely,

$$f\leqq\nu_0\exp(-U/RT)\ , \qquad (12)$$

where f is the frequency of the external stress, ν_0 the frequency of the thermal vibration of the dislocation loop. The critical temperature which corresponds to the equality in Eq. (12) may be the anomalous temperature T_0 which appears near 300°K in Figs. 6 and 7 in part I. This can be understood from the fact that δ decreases with increasing ε at temperatures higher than T_0. At lower temperatures, on the other hand, δ increases with increasing ε and this is the characteristic feature of the internal friction originated from the pinned-down dislocations [Fig. 8 in I]. The similar anomalous point can also be seen in the δ *vs* T curves observed by other authors [Figs. 6 and 11 in Weertman's[8)] and Fig. 2 in Bordoni's[7)]]. The reversal of the amplitude dependence near that temperature, however, did not seem to be examined by them. The frequency ν_0 can be calculated by Eq. (12), using the experimental values of U and T_0. These are summarized in Table III. The values of ν_0 are in the range between 10^9 and 10^{13}, which are in agreement with the usually accepted values of the frequency of the thermal vibration of dislocation.

Using the results obtained in §5 and Eq. (10) together with the experimental value of U, the various quantities for the specimen B_1-5-B, annealed at 150°C for 60 hours, can be determined without any undetermined parameter:

$$A=1.03\times10^{8}\ \mathrm{cm}^{-2}\ ,$$

$$L_n=1.71\times10^{-4}\ \mathrm{cm}\ ,$$

$$L_c=2.85\times10^{-5}\ \mathrm{cm}\ ,$$

$$F=8.25\times10^{-7}\ \mathrm{dyne}\ ,$$

$$B=(1.38\times10^{-2}+2.46\times10^{-5}T)\ \mathrm{gr/sec\cdot cm}\ ,$$

$$U_0=2.21\ \mathrm{kcal/mol\cdot deg}=0.093\ \mathrm{eV}\ ,$$

$$r_0=1.17\times10^{-7}\ \mathrm{cm}=3.33\times b\ .$$

The values of A, L_n and r_0 seem to be quite reasonable.

If the impurity atoms are in thermal equilibrium in the crystal, the average concentration of the impurity in the specimen can be calculated through inserting the values of U_0, $C=a/L_c$, and the annealing temperature $T=$

423°K into Eq. (11). It follows that $C_0=1.25\times10^{-4}$ while the concentration of carbon in lead determined by chemical analysis is 1.2×10^{-3}. This discrepancy may be explained as follows. (i) The solubility of carbon in lead is small and solute atoms are only a little part of the total carbon atoms. (ii) The specimen is not annealed perfectly yet. (iii) The material is purified in the course of making the single crystal.

Regarding the damping constant B, Leibfried[12] has analyzed the mechanism of damping, considering the scattering of phonons which impinge on the moving dislocations. From his formula, $B=9.5\times10^{-6}T$ is obtained for lead. Damping mechanisms proposed by other authors offer smaller values of B.

§ 7. Higher Temperature Region

As shown in Fig. 5, the internal friction in the temperature region higher than T_0 is expressed as

$$\delta=\delta_0+K/\mathcal{E}\ . \tag{13}$$

δ_0 is amplitude-independent and almost temperature-independent and K is sensitively dependent on temperature. The factor K varies as $\exp(-U'/RT)$ as shown in Fig. 6. The value of U' for the specimen B$_1$–5–B is found to be 13.5 kcal/mol·deg. These experimental facts will be explained as follows.

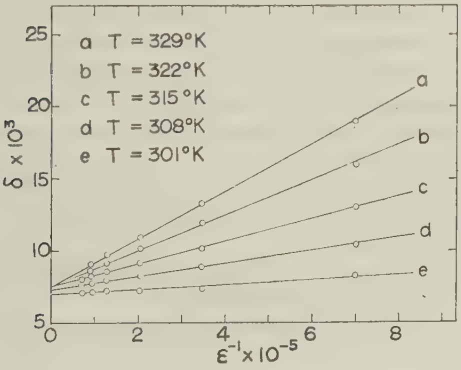

Fig. 5. Amplitude dependence of internal friction at $T>T_0$.

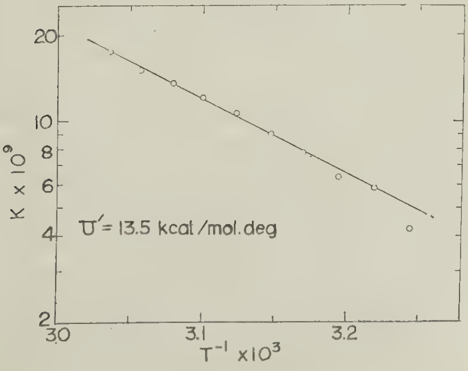

Fig. 6. Temperature dependence of factor K.

At temperatures higher than T_0, dislocations are not effectively pinned down by impurity atoms but pinned only by the intersections with other dislocation lines. The dislocation loop vibrates rather freely and produces a jog at the intersecting point. The formation of the jog is essentially an irreversible process of energy dissipation, since interstitial atoms or vacancies must be created and destroyed. According to Cottrell, the activation energy to form a jog is given by[13)]

$$U_0'=\gamma Gb^3-\sigma(t)L_n b^2\ , \tag{14}$$

where $\sigma(t)$ is the resolved shear stress of external force and γ is a constant of the order unity. The total increment of shearing strain produced by dislocation in the time interval dt is given by

$$d\mathcal{E}=K'\exp(-U_0'/RT)\,dt\ , \tag{15}$$

where K' is proportional to the frequency of vibration of dislocation and also depends on the geometry of dislocation. By definition, the internal friction is calculated as

$$\delta=\Delta W/2W=\int_{\text{cycle}}\sigma\, d\mathcal{E}/(\sigma_0^2/E)\ , \tag{16}$$

where σ_0 is the maximum shear stress. In the present case, the second term in U_0' given by Eq. (14) is estimated to be negligible in comparison with the first. Accordingly, the internal friction can be calculated from Eqs. (14), (15) and (16):

$$\delta=(K''/\mathcal{E})\exp(-U_0'/RT)\ , \tag{17}$$

where K'' is a constant. This conclusion is in good agreement with the experimental facts. If the value of U' is compared with U_0', γ is calculated to be about 0.3.

§ 8. Transient Phenomena

The internal friction of single crystal is markedly structure-sensitive and affected by slight cold-work. The change of the internal friction just after mounting the specimen [Fig. 1 in part I] may be due to recovery process associated with some unstable imperfections produced by handling the crystal. The large peak, which is also observed in the case of other pure metals[14], may be caused by the rearrangement of unstable dislocations. The smaller peak appearing in the earlier stage of the recovery of the quenched specimen may be originated from other kinds of imperfections.

Some of the irreproducible peaks at low temperatures on the internal friction *vs.* temperature curves, which vanish away when the specimen is annealed well [Fig. 6 in I], may be the result of "avalanche" process, namely, sudden movements of unstable dislocations provoked by the external vibrating stress[15],[16].

The apparent hysteresis in the internal friction *vs.* strain amplitude curve and the relating recovery-like phenomena [Fig. 5 in I] cannot be explained by the impurity-pinning model of dislocations. The model predicts that the dislocations, which break away from the impurity-pinning points and bow out during the increasing part of the stress cycle, collapse completely and are again pinned down by impurities in the other half-cycle. There must be one-to-one correspondence between the internal friction and the strain amplitude, being in disagreement with the present experimental facts. The activation energy of the recovery can be estimated from the curve of Fig. 5(b) in I. The value obtained is 8.8 kcal/mol·deg, being nearly one third of the activation energy for the self-diffusion of lead. The recovery may be attributed to the migration of vacancies[17] and these phenomena may be related to the vacancies formed by the vibrating dislocations.

Acknowledgements

The author wishes to express his sincere gratitudes to Dr. T. Kawada for his encouragement during the course of this work. He is also greatly indebted to Professor Y. Tomono and Professor R. R. Hasiguti for their kind advices. Thanks are also due to Mr. A. Hikata for his valuable discussions.

Precipitation Process of Carbon in Alpha-Iron

By Tetsuro SUZUKI* and Yuzo TOMONO

Department of Physics, Faculty of Science, Tokyo University

(Received February 7, 1959)

The precipitation process of carbon in alpha-iron was studied by measuring the internal friction, and by observing the precipitates by electron microscope. The experimental results are expressed fairly well by the formula which expresses the sum of the two processes, one being the absorption of carbon atoms by the precipitates by way of dislocations and the other being the absorption of carbon atoms through the surfaces of the precipitates by the diffusion-limited process. The observation of the precipitates supports this explanation of the precipitation process.

§ 1. Introduction

The internal friction of alpha-iron containing carbon and nitrogen as solute atoms has been exhaustively studied by Snoek[1)] and Dijkstra[2)]. They have found that the internal friction arising from the stress-induced interstitial diffusion of solute atoms has a maximum at the temperature, at which the jumping frequency of interstitial atoms coincides with 2/3 of the measuring frequency, and that the amount of the maximum internal friction is proportional to the number of atoms in solid solution. By measuring the internal friction caused by the jumping of solute atoms, it is possible to estimate the amount of solute atoms at each stages of the aging treatment.

We have estimated the fraction of precipitated carbon atoms from the measurement of the internal friction, and have observed the shape of the precipitates by means of electron microscope.

§ 2. Aging Experiment on Wire Specimens

The specimens in the form of wire about 1 mm in diameter and 14 cm in length were used in this experiment. In order to eliminate both carbon and nitrogen atoms completely from the initial specimens, they were heated at 800°C for a few days within an atmosphere of dry hydrogen. Wert[3)] has shown that the precipitation process of carbon is correlated intimately with the precipitation of nitrogen if nitrogen is present. Therefore, it is necessary to check the nitrogen content in studying the precipitation process of carbon. For this purpose, the internal friction was measured at various temperatures. In case the peak of internal friction caused by the diffusion of carbon or nitrogen was detectable, decarburizing and denitriding treatment was repeated. By this procedure the contents of carbon and nitrogen were reduced to less than 5×10^{-4} wt. per cent. In the next step, the specimen was heated up to 700~800°C in an atmosphere of dry hydrogen and cyclohexane and then was quenched from 720°C on a copper plate, in order to dissolve appropriate amount of carbon atoms into the specimen.

The specimens containing carbon atoms about 0.009 wt. per cent in solid solution were cold-worked by 0, 0.93, 2.2, 3.3 and 4.3 per cent respectively after quenching. These specimens were aged at 100°C. The internal friction, the magnitude of which is proportional to the amount of carbon in solid solution, was measured at proper aging intervals by torsion pendulum. We can thus obtain the quantity q, the relative amount of carbon atoms which has precipitated during the aging

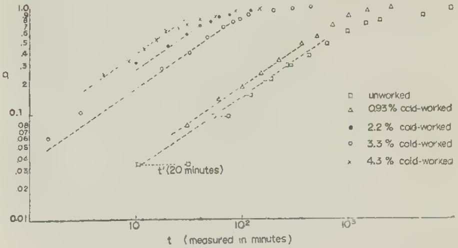

Fig. 1. Aging of cold-worked and unworked specimens at 100°C.

---

[*] Present address: The Toshiba Transistor Plant. 1, Komukai-Toshiba-cho, Kawasaki-shi, Kanagawa-ken, Japan.

time t. $\log q$ vs. $\log t$ is plotted in Fig. 1. In the worked specimens, q was found to be proportional to $t^{2/3}$ in the initial stages of the precipitation process. On the other hand, in the unworked specimens, q was found to be proportional to $(t-t')^{2/3}$, where t' is constant, in the initial stages of the precipitation process.

§ 3. Analysis of the Aging Experiment

If the precipitation process is to be described as the formation of Cottrell atmosphere[4)], the relative amount of precipitated carbon atoms, as Harper has shown[5)], will be given by the formula

$$q=1-\exp\left[-3L\left(\frac{\pi}{2}\right)^{1/3}\left(\frac{ADt}{kT}\right)^{2/3}\right] \tag{1}$$

where L is the dislocation density, D is the diffusion coefficient of interstitial carbon atoms in alpha-iron and A is a constant that depends on the elastic constants of the matrix, on the volume change caused by a solute atom, and on the magnitude of the Burgers vector of the dislocation. For the initial stages of the precipitation process, Eq. (1) reduces to

$$q\sim 3L\left(\frac{\pi}{2}\right)^{1/3}\left(\frac{ADt}{kT}\right)^{2/3}$$

As shown in Fig. 1, this $t^{2/3}$ law for the precipitation process holds for the worked specimens in the initial stages of the precipitation process. Also for the unworked specimen, if the effective aging time is taken to be $t-t'$, where t is the aging time and t' is about 20 minutes, the relative amount of precipitated carbon atom q is proportional to $(t-t')^{2/3}$ in the initial stages of the precipitation process.

If the experimental results obey Eq. (1), $\ln(1-q)$ plotted vs. t will be on a straight line. In our experiment, the experimental results of the unworked specimen plotted in $\ln(1-q)$ vs. $(t-t')^{2/3}$ are nearly on a straight line. However, the experimental results of the worked specimen plotted in $\ln(1-q)$ vs. $t^{2/3}$ are not on a straight line, but on a curved line concave downwards. This fact indicates that the precipitation rate becomes faster than Eq. (1) indicates in the later stages of the precipitation process.

According to Eq. (1), the rate of precipitation will be given as follows:

$$\left.\begin{aligned}\frac{1}{1-q}\frac{dq}{dt}&=\frac{2}{3}\frac{1}{\tau_d}\left(\frac{t}{\tau_d}\right)^{-1/3}\\ \tau_d&=(3L)^{-3/2}\left(\frac{\pi}{2}\right)^{-1/2}\frac{kT}{AD}\end{aligned}\right\} \tag{2}$$

Taking into account that the Cottrell atmosphere will be saturated with carbon atoms of 10^{-4} wt. per cent for density of dislocation as high as 10^{10}, the carbon atoms gathered by the attractive force of the dislocations are considered to be absorbed by the precipitates nucleated at some favourable point on the dislocation lines, for example at dislocation jogs. The carbon atoms absorbed by the dislocation will be drifted to the precipitates in negligible time which absorb carbon atoms also directly through their surfaces by the rate as is given by the following expression[6)]:

$$\left.\begin{aligned}\frac{1}{1-q}\frac{dq}{dt}&=\frac{3}{2}\frac{1}{\tau_c}q^{1/3}\\ \tau_c&=\left(\frac{3}{4\pi N}\right)^{2/3}\frac{1}{2D}\left(\frac{n_0-n_1}{n_\infty(0)-n_1}\right)^{1/3}\end{aligned}\right\} \tag{3}$$

where N is the density of precipitates nucleus and n_0, $n_\infty(0)$ and n_1 are the concentration of solute carbon in precipitates, in alpha-iron before aging and in alpha-iron after aging process has completed itself, respectively. Although the shape of the precipitate is assumed to be spherical in this expression, the shape of the precipitate is found not to be spherical but plate-like as described in § 4. The exact relation describing the growth of the plate-like precipitate by the diffusion limited process is not known, but Eq. (3) is expected to be the approximate expression for the rate of precipitation process due to absorption of carbon atoms by the precipitates through their surfaces.

Then, the total rate of precipitation is given by the sum of right hand sides of Eq. (2) and Eq. (3) as follows:

$$\frac{1}{1-q}\frac{dq}{dt}=\frac{2}{3}\frac{1}{\tau_d}\left(\frac{t}{\tau_d}\right)^{-1/3}+\frac{3}{2}\frac{1}{\tau_c}q^{1/3} \tag{3}$$

Assuming proper value of τ_c and τ_d, and integrating the differential equation numerically, the experimental plots for the worked specimens are fitted by the calculated curve. These plots are shown in Fig. 2. The experimental data are fairly reproduced by the calculated curve. From τ_c and τ_d, the density of precipitates and the density of dislocations in the worked specimens were estimated as shown in Table I. For the unworked specimen, effective aging time is taken to be $t-t'$, where t' is a constant and Eq. (4) was integrated for this effective aging time, and was fitted to the experimental plots as shown also in Fig. 2. In this procedure, τ_c and τ_d for the unworked specimen were calculated and also shown in Table I.

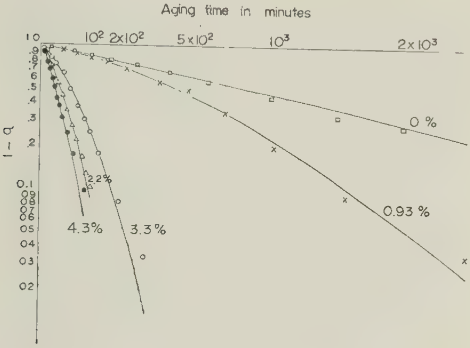

Fig. 2. log $(1-q)$ plotted *vs.* $t^{2/3}$.

Table I.

Cold-work (%)	τ_d (minutes)	τ_c (minutes)	dislocation density (lines/cm²)	precipitate density (1/cm³)
0	1500	27100	2.1×10^9	1.7×10^{11}
0.93	1480	1380	2.1×10^9	1.6×10^{13}
2.2	70	106	1.7×10^{10}	6.3×10^{14}
3.3	160	149	1.0×10^{10}	4.4×10^{14}
4.3	40	100	2.2×10^{11}	7.3×10^{14}

§ 4. Observation of Precipitates by Electron Microscope

It was found difficult to prepare replicas for electron microscope observation from wire specimens. Specimens in the form of rectangular bars 0.2 cm in thickness, 2 cm in width and 18 cm in length were prepared for the convenience of replica technique. Decarburizing and denitriding treatments and solution treatment of carbon of these specimens were performed by the same method as that of wire specimens.

The internal friction of specimens of this type was measured by suspending the specimen at the node of fundamental mode of flexual vibration. The vibration of the specimens was detected by using the circuit as shown in Fig. 3. The frequency of fundamental mode of flexual vibration of the bar is about 600 cps. The internal friction peaks due to diffusion of carbon and nitrogen appear at 110°C and 100°C, respectively, in this measuring frequency.

The aging treatment of these specimens were carried out by keeping them at the temperature of internal friction peak and this peak value of internal friction was measured

at appropriate intervals. The internal friction of the worked and the unworked specimen was plotted vs. aging time in Fig. 4. The relatively low value of the internal friction in the initial stages of the aging process is due to the fact that it takes several minutes for the temperature of the specimen to attain to 110°C, at which the internal friction due to solute carbon is maximum.

As shown in Fig. 4, the precipitation process of the 4.5 per cent worked specimen have finished within 150 minutes. On the other hand, the precipitation process of the unworked specimen have scarcely begun within 150 minutes.

The photomicrographs of the specimens were taken by electron microscope using acetyl-cellulose-carbon replicas. The photo-

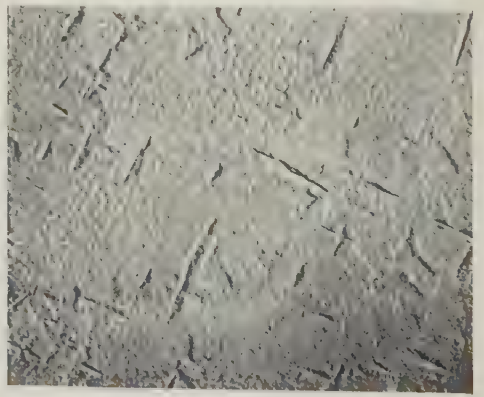

Fig. 11. Precipitates on (100). ×15000.

micrographs of the specimens aged for 150 minutes after 4.5 per cent cold-working and without working were shown in Fig. 5 and Fig. 6, respectively. In Fig. 5, there are a number of small plate-like precipitates and in Fig. 6 there are a relatively small number of precipitates. The photomicrographs of the specimens aged for 870 minutes after 4.5 per cent cold-working and without working were shown in Fig. 7 and Fig. 8, respectively. In Fig. 8, there are larger plate-like precipitates compared with the precipitates shown in Fig. 5. The precipitates in the unworked specimen were quite the same shape as published by W. Pitsch[7].

The photomicrographs of the specimens aged for 1800 minutes at 110°C without working were shown in Fig. 9, Fig. 10 and Fig. 11. The surfaces of the specimens shown in Fig. 9, Fig. 10 and Fig. 11 are (111), (110) and (100) planes, respectively. From these photomicrographs, it may be concluded that the carbon atoms in alpha-iron aged at about 100°C precipitate in plate-like shape on the (100) plane of the matrix iron.

§ 5. Discussions

As shown in Table I, the density of precipitates estimated from τ_c of Eq. (4) increases with the degree of the cold-working. The photomicrographs of the specimens also show that the density of the precipitates is higher in the cold-worked specimen than in the unworked specimen. On the other hand, it is known that the dislocation jogs increase due to intersection of dislocation lines in the course of plastic deformation. The density of the precipitates on the dislocation lines estimated from τ_c and τ_d is 3.32×10^4 per cm for the 4.5 per cent cold-worked specimen and 8 per cm for the unworked specimen. These value are not unreasonable value to be taken as the density of dislocation jogs. These data suggest that the precipitates nucleate at dislocation jogs.

In § 3, for the unworked specimen the effective aging time was taken to be $t-t'$. Hence, the precipitated fraction of carbon atoms q, in the unworked specimen was expressed to be proportional to $(t-t')^{2/3}$ in the initial stages of the precipitation process. However, as many authors have found[8],[9], q would be taken to be proportional to t^{α} in the initial stages of the precipitation process, where α is a constant between 1 and 1.15. This expression may be rather natural. By writing that q is proportional to $(t-t')^{2/3}$ in the initial stages of the precipitation process, we suggest that the precipitation process in the unworked specimen proceed also by way of dislocations and t' means a incubation time for the formation of precipitation nuclei. The density of dislocation lines estimated by assuming that the effective aging time is given by $(t-t')$ in the unworked specimen is the order of 10^9 lines/cm^2. This value of the dislocation density is not to be unexpected for the unworked specimen. It may be not unreasonable to consider that major part of the precipitation process of carbon in the unworked specimen also proceed by way of dislocation short circuit, because the mean distance between precipitation nuclei is too large for carbon atoms to be directly absorbed.

Acknowledgement

The authors wish to express their sincere gratitude to Prof. S. Kaya for his constant encouragement and discussions. The authors are also indebted to Dr. T. Taoka for his interests to this work and to Mr. S. Sakata for his cooperation in electron microscope technique.

Electronmicroscopic Observations of the KCl Single Crystal Irradiated with Ultra-Violet Light

By Tetsuhiko TOMIKI*
The Research Institute for Steel, Iron and other Metals,
Uuiversity of Tohoku
and Masayasu UETA
Department of Physics, The Faculty of Science,
University of Tohoku, Sendai

(Received November 21, 1958)

Electronmicroscopic observations were made for the KCl single crystal which was irradiated with light emitted from a hydrogen discharge tube, using the replica technique. Growth of crystallites occurred on the irradiated surface, and the irradiated effects could also be detected inside the crystal to the depth of 5 to 7 microns beneath the irradiated surface. It was confirmed experimentally that the growth of crystallites was induced by the ionic motions inside the irradiated crystal. The mechanism by which crystallites were formed is discussed in relation to the action of excitons.

§ 1. Introduction

The exciton has been one of the outstanding interests for both experimental and theoretical workers since Hilsch and Pohl measured at first the fundamental absorption bands of alkali-halides in the ultra-violet region. Hilsch and Pohl have found that the fundamental absorption bands of an alkali-halide crystal in a form of thin film consist of a series of relatively sharp bands[1),2)], and that free electrons are not produced by irradiating the crystals in the tail of the first fundamental absorption band when they are uncoloured[3)]. These facts indicate that the particles produced by this excitation are neutral. This neutral particle is believed as an electron coupled with a positive hole, and is called as an "*exciton*". Smakula[4)] has also observed that colour centres are produced in the alkali-halide crystals by irradiation with light lying in the tail of this band with quantum yield of unity at the initial stage. The numerous extensions of these measurements have been accumulated[5)]. Recently, Apker and Taft[6),7)] measured the photoelectric emission of alkali-halide crystals (both of single crystals and of thin films) and confirmed that the peak of photoelectric yield appears in the spectral region of the first fundamental absorption band, if the crystal contains F centers. This phenomenon was interpreted in a way that electrons associated with F centers are freed as a result of collision with excitons produced with light in this band, and are ejected outside the crystal. Thus, an exciton has a dual property to produce or destroy F centres.

On the other hand, Hibi and his coworkers have found electronmicroscopically that the growth of crystallites occurs both on the surfaces and in the inner parts of the alkali-halide crystals, when they are irradiated with X-ray[8)] or coloured with excess metal[9)].

The present article concerns with the growth of crystallites of the KCl single crystal that was illuminated with ultra-violet light. The observations were also made with an electron microscope using replica technique. The growth of crystallites was observable on the irradiated outer (001) surface and some effects induced by irradiation could be detected in the interior beneath the irradiated surface. These phenomena are discussed in relation to excitons.

§ 2. Experimental Methods

2.1 *Irradiation with ultra-violet light*

The (001) surface of the KCl single crystal cleaved from the block was illuminated in the open air with light from the hydrogen discharge tube through the LiF window. The separation between the (001) irradiated surface and the LiF window was chosen to be either 1 mm or 3 mm. According to optical measurements, the first fundamental absorption band of the KCl crystal has a peak at 1,625 A[1] at the room temperature and the long wavelength tail of the first fundamental absorption band of LiF single crystal rises steeply from the wavelength of nearly 1,500A*. In addition to these affairs, since the oxygen molecules in the air absorb strongly the ultraviolet light of which wavelength is shorter than 1,800 A, it could safely be concluded that the light quanta absorbed by the KCl crystal are those of long wavelength tail of the first fundamental band (exciton band).

---

* The present address: *Department of Physics, The Faculty of Science, University of Tohoku, Sendai.*

2.2 *Preparation of replicas*

The procedures for the preparation of replicas have been described in the previous papers[8)-10)]: The electron microscopic object is a replica of the crystal surface to be examined. The replica is the obliquely deposited Chromium film reinforced subsequently with Carbon film in a high vacuum. Here, the direction of chromium beam was parallel to the ⟨100⟩ of the KCl crystal and made an angle $\theta=\tan^{-1}(1/3)$ to its (001) surface.

Since it is considerable that the irradiation effects will be introduced most markedly into the interior directly beneath the irradiated surface, we made one sheet of replica which casts both the irradiated (001) surface and the fresh (010) cleavage plane of the crystal obtained after the illumination, when the inner parts of the crystal are to be examined[10)].

2.3 *The purity of KCl crystal*

The optical absorption spectra of the KCl single crystal employed show a slight impurity band whose absorption peak is located at 2,500 A.

§ 3. Experimental Results

In this section, the descriptions are given for the fresh {100} cleavage surface, the (001) surface irradiated with light emitted from a hydrogen discharge tube, and the interior beneath the irradiated surface of the KCl single crystal.

3.1 *The {100} plane*

Many investigators[11)] have been interested in the process of cleaving the crystal and the numerous observations have been made for the relation between the pattern of cleavage steps and the imperfections of the crystal. These works are mainly achieved with an optical microscope. Here, there is no need to describe them in detail, but it is sufficient to call attentions to the general feature of the freshly cleaved {100} plane: When the cleavage crack either propagates across a twist boundary or ceases to propagate during the crack front seals the loops of dislocation into the crystal (these regions were called as "deformation zones" by Forty[12)]), the new cleavage steps are formed at screw dislocations lying in this boundary or the "deformation zone"[12),13)]; however, between these zones, the cleavage crack propagates steadily with a constant velocity leaving straight cleavage steps on the cleavage plane.

Electronmicroscopically, on the other hand, the fresh {100} planes of KCl single crystal are flat and smooth and have straight cleavage steps whose crystallographic directions can be assigned to the ⟨100⟩, ⟨110⟩, ⟨120⟩, ⟨130⟩ and ⟨230⟩ directions[9)], when the crystal is perfect. The feature of this plane can be represented by Fig. 1(a). However, on the "deformation zone" the pattern of these cleavage steps turns into the complicated one. Since these zones occupy, as a whole, only small portions of the cleavage plane obtainable in usual cleaving processes, so general features of the freshly cleaved plane are well illustrated by Fig. 1(a) and these can be refered as the initial state of the irradiated surface of KCl single crystal.

For observations of an interior of a crystal, it has been usual to make the replica of a fresh cleavage plane which was produced by cutting the crystal plate normal to its (001) plane[8)9)]. In order to unify the experiment, however, it is necessary to observe an interior of a crystal by means of a replica which has informations both of the (001) and of the (010) cleavage surface (cf. § **2.2**). Fig. 1(b) is the electron micrograph obtained with such a replica. The (001) outer plane corresponds to the right half and the (010) plane to the left half of the photograph. The latter is flat and smooth, except for the straight cleavage steps running quite parallel to the intersection, marked with arrows, of the two cleavage planes, i.e. the [100] direction. This feature is also served as the initial state of an interior of the KCl crystal irradiated with light from a hydrogen discharge tube.

---

* Absorption of the LiF crystal, which was purchased from the Harshaw Chemical Company, was measured with the spectrophotometer constructed in our laboratory.

3.2 *The (001) outer surface of the KCl crystal irradiated with light from the hydrogen discharge tube*

Fig. 2 is the electron micrograph of the (001) outer surface of the KCl single crystal which was illuminated with light emitted from hydrogen discharge tube for 15 minutes. In this case, the crystal was apart 3 mm from the light source. It can be seen that crystallites appear densely all over the irradiated surface. When a crystal was placed at the distance of 1 mm from the hydrogen discharge tube and was illuminated with it for 15 minutes, appearances of the (001) surface turn into those such as shown in Figs. 3(a) and 3(b). The crystallites grow on the irradiated (001) surface with surface density of the order of $5 \cdot 10^7\,\mathrm{cm}^{-2}$, and their edges are directed to the $\langle 110 \rangle$ of the basal plane. In addition to these regular crystallites, we can also observe that tiny droplets of crystallites appear either at random (Fig. 3(a)) or in a regular alignement (Fig. 3(b)) on the irradiated (001) surface. Especially, in the latter case, this regular arrangement of droplets is parallel to the $\langle 110 \rangle$ of the basal plane, and come out either as satellites associated with larger crystallites of the regular shape or independently of them.

Fig. 4 is the (001) surface of the KCl crystal which was illuminated for 30 minutes at distance of 1 mm from the light source. In this case, the shape of crystallites are not so regular as shown in Fig. 3(a). These crystallites are estimated as 0.3 microns or less in heights.

Figs. 2–4 confirm that the crystallites come out on the (001) surface as the illumination with a hydrogen discharge tube proceeds, although it is quite sure that the shape or the growth mode of the grown up crystallites are closely related to both the microgeometry of the irradiated surface and the imperfections included in the interior beneath it, or the irradiation time.

According to the preliminary experiment carried out in vacuum, crystallites grew also on the irradiated surface. In this case, the KCl specimen was illuminated with monochromatic light ($\lambda = 1650$ A) near the peak of the first fundamental absorption band. The intensity of the incident beam was so weak that growth of crystallites was observed after the irradiation for 180 minutes. Fig. 5 shows the crystallites grown on the (001) of KCl specimen illuminated with light of 1650 A in vacuum for 180 minutes. One sees that they appear mainly along cleavage steps of the (001) irradiated surface. This corresponds to the first stage of crystal growth. Thus, it may be concluded that growth of crystallites was caused by the energy of incident light transferred to the crystal, and not by humidity or by atmosphere surrounding the specimen. In other words, these phenomena correspond to what might be termed *volume effect* and not to surface effect merely. These situations may well be illustrated by the phenomena induced inside the crystal by irradiation with ultra-violet light. This is described in the next section.

3.3 *The interior beneath the irradiated (001) surface*

Fig. 6 shows both the irradiated (001) surface and the fresh (010) cleavage plane of KCl crystal. The irradiated surface corresponds to the upper part and the cleavage plane to the lower part of the photograph. Here, irradiation time was 15 minutes and the separation between the crystal and the light source was 1 mm. The feature of the irradiated (001) surface in Fig. 6(a) corresponds to those shown in Fig. 3(a), and the (010) plane has groups of wavy cleavage steps.

The other interesting phenomena induced in the interior of the crystal by irradiation with ultra-violet light are shown in the Fig. 6(b). The crystallites (indicated in the figure with markings **A1** and **A2**) on the (010) plane come out from the interior to the outer (001) irradiated plane. Then, it is quite sure that the growth of crystallites on the (001) surface is induced as a result of the redistribution of ions inside the crystal, as was suggested by Hibi et al[8]. Furthermore, Fig. 6 indicates that the appearance of these wavy steps is a characteristic phenomenon which is associated with growth of crystallites as reported in the earlier paper[8],[9]. In addition to this, the step **BC** is not a cleavage step, because this is perpendicular to the direction of cleavage

(a) (b)

Fig. 6. Electron micrograph both of the irradiated (001) plane and of the (010) plane which was obtained after the illumination with ultra violet-light for 15 minutes at the distance of 1 mm from the light source. **A** (Fig. 6 (a)), and **A1** and **A2** (Fig. 6 (b)) show the crystallites coming out to the outer (001) plane from interior.

steps.

From Fig. 6, it is confirmed that the wavy steps appear on the (010) plane down to the depth of 5 to 7 microns from the intersection of the (010) and (001) planes.

It is interesting to note that growth of crystallites or of the wavy steps did not occur when the KCl crystal was irradiated with X-ray for 60 minutes, even though it was coloured deeply. On the contrary, the results described here were obtained when the crystal was coloured only slightly.

§ 4. Interpretations of Experimental Results

According to the present observations, it is clear that crystallites grow on the (001) irradiated surface and they become larger and larger with irradiation time.

These phenomena have a close relationship to the change inside the crystal. Growth of crystallites have never been observed electronmicroscopically on the alkali halide crystals irradiated with visible light if they did not contain colour centers[8),19)]. Thus, it is conceivable that crystal growth on the irradiated plane and changes inside the crystal are induced by the light quanta absorbed in the tail of the first fundamental absorption band of KCl crystal, i.e. excitons.

4.1 *Changes inside the irradiated crystal*

One of the characteristic features which have been observed so far with an electron microscope is the following: When crystallites grow inside an alkali halide crystal, numerous zigzag steps appear on the fresh cleavage plane, and they are always accompanied both with crystallites at their kink sites and with a bundle of wavy steps[8),9)]. Suggestions were made for the zigzag step in a way that this may correspond to a kind of internal surface[9)].

According to Fig. 6, the same phenomena are also observed: The step **BC** in Fig. 6(b) is quite different from the cleavage step, for it is perpendicular to the direction of cleavage step. Furthermore, the step **BC** is in a form of zigzag only down to the depth of 5 to 7 microns beneath the irradiated surface and becomes then linear on the deeper region where wavy steps vanish. Then it is probable that the step **BC** is a kind of internal surface or a crystal imperfection which has no relation to the cleavage process, and that it turns into the zigzag one as the irradiation proceeds, even though it was originally straight before irradiation. The origin of this change is considered to be the action of excitons, such as thermal spikes, by which the redistribution of ions are induced inside the crystal accompanying the movement of internal surfaces such as the step **BC**. Fig. 6 seems to indicate that these processes are connected to growth of crystallites either along such a step or on the outer surface (see, the crystallite **A1** in Fig. 6(b)). This behaviour is quite similar to the nonconservative motion of dislocation[17),18)]. It is conceivable that crystallites **A** (Fig. 6(a)) and **A2** (Fig. 6(b)) are also resulted from the preferential diffusion of ions through some kind of crystal imperfection—dislocation, though this is not detected electronmicroscopically. These processes are favourable to the production of colour centres by excitons as proposed by Seitz[16)].

The nature of wavy steps is unknown at present. Though it is conceivable that they might indicate the internal stresses caused by the redistribution of ions, the sufficient confirmation is not obtained experimentally yet. They appear only down to the depth of 5 to 7 microns. Though this value corresponds to 1/10 of the minimum value of the penetration depth of incident light employed in this experiment, it may be possible to obtain the information regarding to the diffusion length of migrating exciton[16)], if the experiment is carried out with monochromatic light, especially with light at the peak of the first fudamental absorption band where the penetration depth of light is estimated as several hundreds angstrom.

4.2 *Crystallites on the irradiated surface*

If the above interpretation is correct, it is conceivable that distribution of crystallites on the outer surface must correspond directly to those of emergences of crystal imperfections on the (001). But, it will be rather difficult to accept this idea without restriction, if one sees the appearance of the irradiated plane as shown in Fig. 2. Nevertheless, we cannot deny the preferential diffusion of ions through imperfections as shown in Fig. 6. These peculiar behaviour of the irradiated surface were first discovered by Hibi and Ishikawa[8)] on the KBr and NaCl single crystals irradiated with X-ray and discussed by them [See Fig. 9 in their paper[8], for example]. They observed electronmicroscopically that in earlier stage of colouration of a crystal crystallites appear preferentially along steps, in the next stage crystallites cover uniformly on the irradiated surface and finally, distinct larger crystallites grow on it. Judging from experimental circumstances, it is conceivable that Figs. 5, 2, 3 and 4 show every stage of crystal growth in this order in a schematic representation.

From the present observations, these characteristic behaviours of the irradiated surface may be considered to be caused by the followings:

(i) Mode of crystal growth differs from places to places closely depending both on microgeometry and on the population of imperfections of the irradiated surface. Some evidences appear to support this. (ii) In addition to this, it is also acceptable that surface migration of ions occurred in some stage of crystal growth. This concept was already adopted in the explanation of the peculiar behaviours of the surface irradiated with X-ray by Hibi et al[8], because of the strong similarity to those of aggregation of a deposited film. (iii) The pattern of imperfection including the internal surface may be changed as the irradiation with ultra-violet light proceeds. (iv) Finally, transient departure from the normal composition may be induced locally on the surface by high energy radiation. It is difficult to attempt to make a further detailed explanation on the irradiated surface how these respective mechanisms affect on the every stage of crystal growth. It is considered to be most important and certain that the crystallites appear in the course of irradiation with ultraviolet light as a " volume effect " and become larger and larger with irradiation time.

Acknowledgement

It is a great pleasure to express the authors' thanks to Prof. S. Ogawa who was kindly interested in this experiment and also to Prof. Hibi who gave us the valuable suggestions. One of the authors (T. Tomiki) would like to express his sincere thanks to Prof. S. Ogawa who provided him an opportunity to achieve this experiment.

On the Diamagnetism of Graphite, I. Energy Levels of π-electrons

By Hisanao SATO

Department of Physics, Nagoya University

(Received January 8, 1959)

The energy levels of the conduction electrons in graphite, in the presence of a magnetic field, are calculated by the method of the tight binding approximation, taking into account the effect of band-to-band transitions which is not included in the Landau-Peierls treatment. The present theory is a natural extension of the Luttinger-Kohn and McClure theories for the band structure of graphite. The relation to the diamagnetic susceptibility is discussed.

§1. Introduction

The effect of a uniform magnetic field on the orbital motion of free electrons was first studied by Landau¹⁾. He showed that the magnitude of the diamagnetic susceptibility of the free electron gas is equal to one-third of the spin paramagnetic susceptibility. For the diamagnetic susceptibility from the electrons in the periodic field of the lattice, Peierls²⁾ obtained a formula by a method which did not involve a detailed knowledge of the stationary states. Using wave functions in the tight binding approximation, he deduced the formula:

$$\chi_{\mathrm{dia}}=-\frac{1}{6}\left(\frac{e}{\hbar c}\right)^2\int\left\{\frac{\partial^2 E}{\partial k_x^2}\frac{\partial^2 E}{\partial k_y^2}-\left(\frac{\partial^2 E}{\partial k_x \partial k_y}\right)^2\right\}\frac{\partial f_0}{\partial E}\frac{dk}{(2\pi)^3}\,. \qquad (1)$$

This formula reduces to Landau's result when $E=\hbar^2k^2/2m$. Later Luttinger³⁾ proved the so-called effective mass theory using the Wannier functions. His result is that the Hamiltonian of the quasi-bound electrons is given by changing the argument of the function $E_m(\boldsymbol{k})$, energy of the mth band as a function of the wave vector $\boldsymbol{k}$, into a vector $\bar{\boldsymbol{k}}$ whose components are operators, satisfying the commutation law

$$[\bar{k}_x, \bar{k}_y]=i\frac{eH}{\hbar c}\,, \qquad (2)$$

where H is the magnetic field in the z-direction. The most questionable approximation in the effective mass theory consists in neglecting the interband transitions caused by the magnetic field.

Wilson⁴⁾ deduced the formula (1) by the direct calculation of the density matrix as a power series in H. In his calculation he neglected terms of the order of $kT/(E_m-E_{m'})$ compared with unity; this approximation corresponds to neglecting the interband elements in the effective mass theory. Besides (1), terms arising from the $\boldsymbol{k}$-dependence of the periodic part $u_{\boldsymbol{k}}(\boldsymbol{r})$ of the Bloch functions also contribute to the susceptibility. The magnitude of these terms are not clear since in general we do not have knowledges about $u_{\boldsymbol{k}}(\boldsymbol{r})$.

Adams⁵⁾ criticized the above mentioned theories in the case where two bands are near each other energetically at the same point in $\boldsymbol{k}$-space, and pointed out that the interband elements could make large contributions to the susceptibility.

The band structure of graphite was studied in detail by several authors⁶⁾⁻⁹⁾. Using the Peierls formula (1), Hove¹⁰⁾ calculated the diamagnetic susceptibility on the basis of the Wallace model⁶⁾ and showed that the magnitude of the theoretical susceptibility is about forty times too small. Mase⁹⁾ investigated the band structure by the Bloch tight binding method more precisely than Wallace did. He also found that one cannot explain the diamagnetism of graphite by means of the formula (1). Therefore it seems interesting to clarify the effect of the interband elements on the diamagnetism of graphite, in which the valence and conduction bands are degenerate.

Recently we have had some progress in searching the magnetic energy levels of electrons in the degenerate bands. Because the top of the valence bands for silicon and germanium are degenerate, the interband elements should be included in the theory of the cyclotron resonance of holes. Luttinger and Kohn[11] solved this problem making use of the fact that holes in question have small wave numbers. McClure[12] applied the method of Luttinger and Kohn to the two dimensional graphite layer and succeeded in accounting for the large diamagnetism, but the method is not adequate to the graphite crystal.

Corresponding to Wallace's calculation of the band structure, we shall solve the one electron Schrödinger equation by the tight binding approximation and investigate the effect of the band-to-band transitions caused by the magnetic field. In section 2 we shall discuss our approximations in detail. It is shown that our method gives the same result as McClure's in the case of hexagonal layer. In section 3 we shall apply our method to graphite. In section 4 the method of Luttinger and Kohn will be discussed concerning the application to graphite.

§ 2. Method of Tight Binding for Hexagonal Layer

In our tight binding approximation there is no essential distinction between the two and three dimensions. In this section, however, we shall investigate the energy levels for a hexagonal layer because of the simplicity and clearness of the calculation and for the convenience of comparison of our theory with McClure's one.

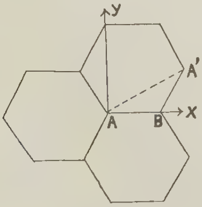

Fig. 1.

Fig. 1 shows hexagonal layer of graphite and our coordinate axes x and y. The unit cell contains two atoms, A and B, the distance between which being $1.42A$. The first Brillouin zone is a hexagon and a corner C indicated in Fig. 2 has $k_x=2\pi/\sqrt{3}\,a$ and $k_y=2\pi/3a$, where $a=1.42\times\sqrt{3}=2.46A$ is the distance between A and A' (Fig. 1). The valence and the conduction bands are degenerate at point C (and other equivalent points).

Assuming that a homogeneous magnetic field H is perpendicular to the plane of the hexagonal layer, we shall choose for the vector potential A

$$A_x=-H_y\,,\qquad A_y=A_z=0\,. \tag{3}$$

with this gause, the Hamiltonian becomes

$$\mathscr{H}=\mathscr{H}_0-\omega y p_x+\frac{m}{2}\omega^2y^2\,, \tag{4}$$

where

$$\omega=\frac{eH}{mc}\,,\qquad p_x=-i\hbar\frac{\partial}{\partial x}\,, \tag{5}$$

and $\mathscr{H}_0$ is the Hamiltonian of an electron in the lattice field. Then the eigen-value problem which we must solve is

$$\mathscr{H}\Psi=E\Psi\,. \tag{6}$$

Let $X(\boldsymbol{r})$ be the normalized $2p_z$ orbital function for an isolated carbon atom, then the wave function in the tight binding approximation becomes the linear combination of $\varphi_1(\boldsymbol{k})$ and $\varphi_2(\boldsymbol{k})$, which are defined by

$$\left.\begin{aligned}\varphi_1(\boldsymbol{k})&=\frac{1}{\sqrt{N}}\sum_A e^{i\boldsymbol{k}\cdot\boldsymbol{r}_A}X(\boldsymbol{r}-\boldsymbol{r}_A)\,,\\ \varphi_2(\boldsymbol{k})&=\frac{1}{\sqrt{N}}\sum_B e^{i\boldsymbol{k}\cdot\boldsymbol{r}_B}X(\boldsymbol{r}-\boldsymbol{r}_B)\,,\end{aligned}\right\} \tag{7}$$

where N is the number of unit cells and the sum is taken over all the equivalent lattice points which are designated by A or B.

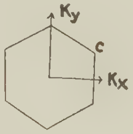

Fig. 2.

In the magnetic field a stationary state of an electron is no longer represented by a point in $\boldsymbol{k}$-space, but an electron forms a wave packet spreading over $\sqrt{eH/\hbar c}$. Therefore, we assume

$$\Psi=\int B_1(\boldsymbol{k}')\varphi_1(\boldsymbol{k}')\,d\boldsymbol{k}'+\int B_2(\boldsymbol{k}')\varphi_2(\boldsymbol{k}')\,d\boldsymbol{k}'\,, \tag{8}$$

the integration being taken over the first Brillouin zone. $B_1(\boldsymbol{k})$ and $B_2(\boldsymbol{k})$ are required to be periodic functions with the periodicity of the reciprocal lattice. The reason why we have neglected higher atomic states in Eq. (8) will be stated later on.

We substitute (8) into (6), multiply it by $\varphi_1{}^*(\boldsymbol{k})$ and integrate over the entire crystal. First let us consider the integral

$$\iint d\boldsymbol{k}'\, d\boldsymbol{r}\, B_2(\boldsymbol{k}')\varphi_1^*(\boldsymbol{k})\mathscr{H}\varphi_2(\boldsymbol{k}')=\mathrm{I}_0+\mathrm{I}_1+\mathrm{I}_2\,, \tag{9}$$

where

$$\mathrm{I}_0=\iint d\boldsymbol{k}'\, d\boldsymbol{r}\, B_2(\boldsymbol{k}')\varphi_1^*(\boldsymbol{k})\mathscr{H}_0\varphi_2(\boldsymbol{k}')\,,$$

$$\mathrm{I}_1=\iint d\boldsymbol{k}'\, d\boldsymbol{r}\, B_2(\boldsymbol{k}')\,\varphi_1^*(\boldsymbol{k})(-\omega y p_x)\,\varphi_2(\boldsymbol{k}')\,,$$

$$\mathrm{I}_2=\iint d\boldsymbol{k}'\, d\boldsymbol{r}\, B_2(\boldsymbol{k}')\,\varphi_1^*(\boldsymbol{k})\left(\frac{m}{2}\omega^2 y^2\right)\varphi_2(\boldsymbol{k}')\,.$$

I_0 may easily be evaluated as follows:

$$\begin{aligned}\mathrm{I}_0&=\int d\boldsymbol{k}' B_2(\boldsymbol{k}')\left(\frac{1}{N}\sum_{A,B} e^{-i\boldsymbol{k}\cdot\boldsymbol{r}_A+i\boldsymbol{k}'\cdot\boldsymbol{r}_B}\int X^*(\boldsymbol{r}-\boldsymbol{r}_A)\mathscr{H}_0\, X(\boldsymbol{r}-\boldsymbol{r}_B)\, d\boldsymbol{r}\right)\\&=\int d\boldsymbol{k}' B_2(\boldsymbol{k}')\left(\frac{1}{N}\sum_{A} e^{-i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{r}_A}\right)\left(\sum_{\rho_{AB}} e^{i\boldsymbol{k}'\cdot\boldsymbol{\rho}_{AB}}\int X^*(\boldsymbol{r})\mathscr{H}_0 X(\boldsymbol{r}-\boldsymbol{\rho}_{AB})\, d\boldsymbol{r}\right)\\&=\mathrm{H}_0^{12}(\boldsymbol{k})B_2(\boldsymbol{k})\,,\end{aligned} \tag{10}$$

where

$$\left.\begin{aligned}\mathrm{H}_0^{12}(\boldsymbol{k})&=\sum_{\rho_{AB}} e^{i\boldsymbol{k}\cdot\boldsymbol{\rho}_{AB}}\int X^*(\boldsymbol{r})\mathscr{H}_0 X(\boldsymbol{r}-\boldsymbol{\rho}_{AB})\, d\boldsymbol{r}\,,\\ \boldsymbol{\rho}_{AB}&=\boldsymbol{r}_B-\boldsymbol{r}_A\,.\end{aligned}\right\} \tag{11}$$

Integral I_1 can be written as a sum of two terms I_1' and I_1'', where

$$\mathrm{I}_1'=-\omega\int d\boldsymbol{k}' B_2(\boldsymbol{k}')\left(N^{-1}\sum_{A,B} e^{-i\boldsymbol{k}\cdot\boldsymbol{r}_A+i\boldsymbol{k}'\cdot\boldsymbol{r}_B}\int X^*(\boldsymbol{r}-\boldsymbol{r}_A)(y-y_B)\,p_x X(\boldsymbol{r}-\boldsymbol{r}_B)\, d\boldsymbol{r}\right),$$

the magnitude of which may be of the order of $\omega B_2 a(\hbar/a)$. The other term I_1'' can be transformed into a simple form:

$$\begin{aligned}\mathrm{I}_1''&=\int d\boldsymbol{k}' B_2(\boldsymbol{k}')\left(N^{-1}\sum_{A,B} e^{-i\boldsymbol{k}\cdot\boldsymbol{r}_A+i\boldsymbol{k}'\cdot\boldsymbol{r}_B}\int X^*(\boldsymbol{r}-\boldsymbol{r}_A)(-\omega y_B p_x)X(\boldsymbol{r}-\boldsymbol{r}_B)\, d\boldsymbol{r}\right)\\&=-\omega\int d\boldsymbol{k}' B_2(\boldsymbol{k}')N^{-1}\sum_{A,B} e^{-i\boldsymbol{k}\cdot\boldsymbol{r}_A}\left(-i\frac{\partial e^{+i\boldsymbol{k}\cdot\boldsymbol{r}_B}}{\partial k_y'}\right)\int X^*(\boldsymbol{r}-\boldsymbol{r}_A)\,p_x X(\boldsymbol{r}-\boldsymbol{r}_B)\, d\boldsymbol{r}\\&=-i\omega\int d\boldsymbol{k}'\frac{\partial B_2}{\partial k_y'}\,N^{-1}\sum_{A,B} e^{-i\boldsymbol{k}\cdot\boldsymbol{r}_A+i\boldsymbol{k}'\cdot\boldsymbol{r}_B}\int X^*(\boldsymbol{r}-\boldsymbol{r}_A)\,p_x X(\boldsymbol{r}-\boldsymbol{r}_B)\, d\boldsymbol{r}\\&=-i\omega\, p_x^{12}(\boldsymbol{k})\frac{\partial B_2}{\partial k_y}\,.\end{aligned} \tag{12}$$

The integration by parts with respect to $\boldsymbol{k}'$ gives immediately the third line of the above equation, the surface integrals over the surface of the first Brillouin zone vanishing since all the functions are periodic functions of the reduced wave vector. In Eq. (12) $p_x^{12}(\boldsymbol{k})$ is defined by

$$p_x^{12}(\boldsymbol{k})=\sum_{\rho_{AB}} e^{i\boldsymbol{k}\cdot\boldsymbol{\rho}_{AB}}\int X^*(\boldsymbol{r})\,p_x X(\boldsymbol{r}-\boldsymbol{\rho}_{AB})\, d\boldsymbol{r}\,. \tag{13}$$

As will be shown below, $p_x^{12}(\boldsymbol{k})$ is of the order of $\hbar/a$ in the neighborhood of $\boldsymbol{k}=\boldsymbol{k}^c$, where $\boldsymbol{k}^c$ is a wave vector represented by point C. It will also be seen that the wave function $B_i(\boldsymbol{k})$ becomes wave functions of a harmonic oscillator. Therefore $\partial B_2/\partial k_y$ in (12) is nearly equal to $B_2/\bar{k}_y$, in which $\bar{k}_y$ means the value of k_y averaged with $B_i(\boldsymbol{k})$ and may approximately be given by $\sqrt{neH/\hbar c}$ (n is a quantum number of the harmonic oscillator). Then we shall see that the ratio I_1'/I_1'' will be very small compared with unity at least for small n. As a result of the above considerations we obtain

$$I_1 = I_1'' = -i\omega p_x^{12}(\boldsymbol{k})\frac{\partial B_2}{\partial k_y}\,. \tag{14}$$

To estimate the integral I_2 we substitute $y^2 = y_B^2 + 2y_B(y-y_B) + (y-y_B)^2$ in its integrand. Then I_2 will be given as a sum of three terms:

$$I_2 = I_2' + I_2'' + I_2''' \,,$$

where

$$I_2' = \iint d\boldsymbol{k}'d\boldsymbol{r}\, B_2(\boldsymbol{k}')\varphi_1^*(\boldsymbol{k})\left(\frac{m}{2}\omega^2 y_B^2\right)\varphi_2(\boldsymbol{k}')\,,$$

$$I_2'' = \iint d\boldsymbol{k}'d\boldsymbol{r}\, B_2(\boldsymbol{k}')\varphi_1^*(\boldsymbol{k})\left\{\frac{m}{2}\omega^2 2y_B(y-y_B)\right\}\varphi_2(\boldsymbol{k}')\,,$$

$$I_2''' = \iint d\boldsymbol{k}'d\boldsymbol{r}\, B_2(\boldsymbol{k}')\varphi_1^*(\boldsymbol{k})\left\{\frac{m}{2}\omega^2(y-y_B)^2\right\}\varphi_2(\boldsymbol{k}')\,.$$

Integral I_2' can be evaluated in the similar manner to I_1'' and the order of its magnitude may be given by

$$I_2' \simeq m\omega^2\frac{\partial^2 B_2}{\partial k_y^2} \simeq \omega\frac{eH}{c}\frac{B_2}{\bar{k}_y^2} \simeq \omega\hbar B_2\,.$$

Then we have

$$I_2'/I_1 \simeq a\bar{k}_y \ll 1\,.$$

Similarly it can be found that I_2'' and I_2''' are much smaller than I_2'. In this way we obtain the following equation to a good approximation:

$$\iint d\boldsymbol{k}'d\boldsymbol{r}\, B_2(\boldsymbol{k}')\,\varphi_1^*(\boldsymbol{k})\mathscr{H}\varphi_2(\boldsymbol{k}') = H_0^{12}(\boldsymbol{k})B_2(\boldsymbol{k}) - i\omega p_x^{12}(\boldsymbol{k})\frac{\partial B_2}{\partial k_y}\,. \tag{15}$$

Similarly we have

$$\iint d\boldsymbol{k}'d\boldsymbol{r}\, B_1(\boldsymbol{k}')\varphi_1^*(\boldsymbol{k})\mathscr{H}\varphi_1(\boldsymbol{k}') = H_0^{11}(\boldsymbol{k})B_1(\boldsymbol{k})\,, \tag{16}$$

where

$$H_0^{11}(\boldsymbol{k}) = \sum_{\rho_{AB'}} e^{i\boldsymbol{k}\cdot\boldsymbol{\rho}_{AB'}}\int X^*(\boldsymbol{r})\mathscr{H}_0 X(\boldsymbol{r}-\boldsymbol{\rho}_{AA'})\,d\boldsymbol{r}\,. \tag{17}$$

On the right hand side of (16) only $\mathscr{H}_0$ is retained since the diagonal element of the momentum is negligible compared with the nondiagonal element:

$$\int\varphi_1^*(\boldsymbol{k})\,p_x\,\varphi_1(\boldsymbol{k})\,d\boldsymbol{r} \ll \int\varphi_1^*(\boldsymbol{k})\,p_x\,\varphi_2(\boldsymbol{k})\,d\boldsymbol{r}\,.$$

Now we return to the problem concerning Eq. (8), in which we assumed Ψ as a linear combination of the atomic $2p_z$ functions. The contribution of higher states j, for instance, to the state 1 or 2 can be estimated by the perturbation method. The important matrix element which connects the states 1 and j may be $i\omega p_x^{1j}\partial/\partial k_y$. By the diagonalization we have the following term in our Hamiltonian;

$$\omega^2\frac{|p_x^{1j}|^2}{\Delta E_{1j}}\frac{\partial^2}{\partial k_y^2} \simeq m\omega^2\frac{\partial^2}{\partial k_y^2}\,,$$

which is of the same order of magnitude as I_2' which we neglected.

As a result of the above discussions we obtain the following differential equations for $B_1(\boldsymbol{k})$ and $B_2(\boldsymbol{k})$:

$$\left.\begin{aligned} &\mathrm{H}_0^{11}(\boldsymbol{k})\,B_1(\boldsymbol{k})+\left\{\mathrm{H}_0^{12}(\boldsymbol{k})-i\omega\, p_x^{12}(\boldsymbol{k})\frac{\partial}{\partial k_y}\right\}B_2(\boldsymbol{k})=EB_1(\boldsymbol{k})\,, \\ &\left\{\mathrm{H}_0^{21}(\boldsymbol{k})-i\omega\, p_x^{21}(\boldsymbol{k})\frac{\partial}{\partial k_y}\right\}B_1(\boldsymbol{k})+\mathrm{H}_0^{22}(\boldsymbol{k})\,B_2(\boldsymbol{k})=EB_2(\boldsymbol{k})\,, \end{aligned}\right\} \tag{18}$$

where $\mathrm{H}_0^{11}=\mathrm{H}_0^{22}$, $\mathrm{H}_0^{21}=\mathrm{H}_0^{12*}$ and $p_x^{21}=p_x^{12*}$. In order to obtain solutions for the set of equations (18) in the neighborhood of point C, we expand $\mathrm{H}_0^{11}(\boldsymbol{k})$, $\mathrm{H}_0^{12}(\boldsymbol{k})$ and $p_x^{12}(\boldsymbol{k})$ as power series of $k_x-k_x^c$ and $k_y-k_y^c$. Taking the origin of $\boldsymbol{k}$ at $\boldsymbol{k}^c$, we get to order linear in ak_x and ak_y:

$$\left.\begin{aligned} &\mathrm{H}_0^{11}=\mathrm{H}_0^{22}=E_0\,, \\ &\mathrm{H}_0^{12}=\frac{\sqrt{3}}{4}\gamma_0 a(lk_x+mk_y)\,, \\ &p_x^{12}=lp_0\,, \end{aligned}\right\} \tag{19}$$

where

$$\left.\begin{aligned} &l=\sqrt{3}+i\,, \\ &m=1-\sqrt{3}\,i\,, \\ &\gamma_0=-\int X^*(\boldsymbol{r})\mathscr{H}_0X(\boldsymbol{r}-\boldsymbol{\rho}_{AB})\,d\boldsymbol{r}\,, \\ &-\frac{4}{3}ip_0=\int X^*(\boldsymbol{r})\left(-i\hbar\frac{\partial}{\partial x}\right)X(\boldsymbol{r}-\boldsymbol{r}_{AB})\,d\boldsymbol{r}\,, \\ &\boldsymbol{r}_{AB}=(a/\sqrt{3}\,,0)\,. \end{aligned}\right\} \tag{20}$$

Substituting Eqs. (19) into (18), we have

$$\left.\begin{aligned} &\left(lk_x+mk_y-ils\frac{\partial}{\partial k_y}\right)B_2=\lambda B_1\,, \\ &\left(l^*k_x+m^*k_y-il^*s\frac{\partial}{\partial k_y}\right)B_1=\lambda B_2\,, \end{aligned}\right\} \tag{21}$$

where

$$\lambda=\frac{E-E_0}{(\sqrt{3}/4)\gamma_0 a}\,,\qquad \frac{\hbar}{m}p_0=\frac{\sqrt{3}}{4}\gamma_0' a\,,\qquad s=\frac{\gamma_0'}{\gamma_0}\frac{eH}{\hbar c}\,. \tag{22}$$

The set of equations (21) is the fundamental result of our method which determine the exact energy levels for small quantum numbers near the degeneracy point. Eqs. (21) are identical with Eqs. (2.7a) and (2.7b) in McClure's paper[12] if $\gamma_0=\gamma_0'$, which we can prove as below.

Following Kitano[13] we make use of the operator identity in order to verify $\gamma_0=\gamma_0'$;

$$p_x=\frac{mi}{\hbar}[\mathscr{H}_0, x]\,.$$

Adopting the $2p_z$ functions $X(\boldsymbol{r}-\boldsymbol{r}_A)$, $X(\boldsymbol{r}-\boldsymbol{r}_{A'})$,—and $X(\boldsymbol{r}-\boldsymbol{r}_B)$, $X(\boldsymbol{r}-\boldsymbol{r}_{B'})$,—as the bases, we calculate the matrix element of the above equation as follows:

$$\begin{aligned} p_{xAB}&=\frac{mi}{\hbar}(\mathscr{H}_{0AA}x_{AB}-\gamma_0 x_{BB}-x_{AB}\mathscr{H}_{0BB}+x_{AA}\gamma_0) \\ &=-\frac{mi}{\hbar}\gamma_0(x_{BB}-x_{AA}) \\ &=-\frac{mi}{\hbar}\frac{\gamma_0 a}{\sqrt{3}}\,. \end{aligned}$$

From (20) and (22) we have

$$p_{xAB} = -\frac{4}{3} i p_0 = -\frac{mi}{\hbar} \frac{\gamma_0' a}{\sqrt{3}} ,$$

and therefore

$$\gamma_0 = \gamma_0' .$$

Because the system of the $2p_z$ functions is not complete, our proof is an approximate one, but seems reasonable within the scope of our theory. As we are interested in wave functions which are localized in the Brillouin zone, we may replace the periodic boundary conditions for $B_i(\boldsymbol{k})$ by the requirement that they vanish for large values of $\boldsymbol{k}$. Then the solutions $B_1(\boldsymbol{k})$ and $B_2(\boldsymbol{k})$ for the set of the equations (21) are given by wave functions for the harmonic oscillator and the energy $\mathcal{E} = E - E_0$ becomes with $\gamma_0' = \gamma_0$

$$\mathcal{E} = E - E_0 = \pm \sqrt{\alpha n} , \tag{23}$$

$$\alpha = \tfrac{3}{2} \gamma_0^2 a^2 s , \tag{24}$$

where n takes all the positive integers. Putting $H=0$ in (21), we get the energy levels which Wallace has given:

$$\mathcal{E}(H=0) = \pm \sqrt{\tfrac{3}{4} \gamma_0^2 a^2 (k_x^2 + k_y^2)} . \tag{25}$$

In this section we obtained the same result as McClure's, but analyzed the approximations used by him precisely in view of the tight binding method. On the basis of this two-dimensional model McClure studied the diamagnetism of graphite. He noted that $n=0$ levels are responsible for the most part of the large diamagnetism and that a good agreement with the observed value of the normal susceptibility can be obtained.

§ 3. Method of Tight Binding for Graphite

Graphite lattice is built up of hexagonal layers, whose relation to each other is illustrated in Fig. 3. Dotted lines indicate one layer and the full lines the one 3.37A above it. The points A, B, C and D represent the four atoms of a unit cell. The first Brillouin zone for graphite is a hexagonal pill-box of height $4\pi/c_L$, as is indicated in Fig. 4, where c_L is the spacing between identical layers, 3.37×2=6.74A. The degenerate points are on the six vertical edges of the zone (H–H).

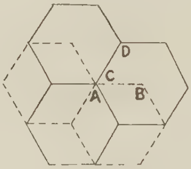

Fig. 3.

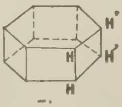

Fig. 4.

As in the case of a single layer we shall define $\varphi_i(\boldsymbol{k})$ in the form:

$$\varphi_i(\boldsymbol{k}) = \sum_{\nu} \exp[i\boldsymbol{k} \cdot \boldsymbol{r}_i^{\nu}] X(\boldsymbol{r} - \boldsymbol{r}_i^{\nu}), \tag{26}$$

where $i=1, 2, 3, 4$ correspond to atoms of the types A, B, C, D, respectively, and ν enumerates the different atoms of a given type in the crystal.

Assuming

$$\Psi = \sum_{i=1}^{4} \int B_i(\boldsymbol{k}') \varphi_i(\boldsymbol{k}') \, d\boldsymbol{k}' , \tag{27}$$

we shall proceed exactly in the same way as in the case of the hexagonal layer. If we suppose that the integrals connecting (A, D), (B, C) and (B, D) are zero, we obtain the following equations with the same approximation as that in section 2:

$$\left.\begin{aligned}
&\mathrm{H}_0^{11} B_1 + \left(\mathrm{H}_0^{12} - i\omega p_x^{12} \frac{\partial}{\partial k_y}\right) B_2 + \gamma_1 \Gamma B_3 && = E B_1 , \\
&\left(\mathrm{H}_0^{21} - i\omega p_x^{21} \frac{\partial}{\partial k_y}\right) B_1 + \mathrm{H}_0^{22} B_2 && = E B_2 , \\
&\gamma_1 \Gamma B_1 \qquad + \mathrm{H}_0^{33} B_3 + \left(\mathrm{H}_0^{34} - i\omega p_x^{34} \frac{\partial}{\partial k_y}\right) B_4 && = E B_3 , \\
&\qquad \left(\mathrm{H}_0^{43} - i\omega p_x^{43} \frac{\partial}{\partial k_y}\right) B_3 + \mathrm{H}_0^{44} B_4 && = E B_4 ,
\end{aligned}\right\} \tag{28}$$

where

$$\gamma_1 = \int X^*(\boldsymbol{r}) \mathscr{H}_0 X(\boldsymbol{r} - \boldsymbol{\rho}_{Ac})\, d\boldsymbol{r} \ ,$$

$$\Gamma = 2 \cos \frac{c_L}{2} k_z \ ,$$

and H_0^{ij} and p_x^{ij} have the same meanings as Eqs. (11), (13) and (17).

In the absence of a magnetic field, we can find that $B_3 = \pm B_1$, where the choice of the sign is immaterial. Therefore we choose $B_3 = -B_1$ in (28); then the upper two equations will become equivalent to the lower two. It will be shown in the next section that this choice does not give any limitation to the result.

Since we are interested in the solutions near the zone edge, we can expand H_0^{ij} and p_x^{ij} with regard to k_x and k_y. Then we can rewrite the upper two equations of (28) as follows:

$$\left.\begin{aligned} \frac{\sqrt{3}}{2} \gamma_0 a \left(l k_x + m k_y - i l s \frac{\partial}{\partial k_y} \right) B_2 &= (E - E_0 + \gamma_1 \Gamma) B_1 \ , \\ \frac{\sqrt{3}}{2} \gamma_0 a \left(l^* k_x + m^* k_y - i l^* s \frac{\partial}{\partial k_y} \right) B_1 &= (E - E_0) B_2 \ , \end{aligned}\right\} \tag{29}$$

which correspond to (21) in the case of the single layer. Substituting $H=0$ in (29), we find the energy levels which agree with Wallace's result:

$$E - E_0 = -\tfrac{1}{2}\gamma_1\Gamma \pm \sqrt{\tfrac{1}{4}\gamma_1^2\Gamma^2 + \tfrac{3}{4}\gamma_0^2 a^2 (k_x^2 + k_y^2)} \ . \tag{30}$$

As in the preceding section, the energy $E - E_0$ in (29), may be found to be

$$E - E_0 = -\tfrac{1}{2}\gamma_1\Gamma \pm \sqrt{\tfrac{1}{4}\gamma_1^2\Gamma^2 + \alpha n} \ . \tag{31}$$

for $n \geq 1$. For $n=0$, B_2 is interpreted to be zero and therefore we have

$$E - E_0 = -\gamma_1 \Gamma \ , \qquad (n=0) \ . \tag{32}$$

The lack of symmetry between B_1 and B_2 is due to our choice of gauge for the vector potential. The solution for the H′–H′ edge is symmetric in the opposite sense to (29), and for this case we have

$$E - E_0 = 0$$

for $n=0$. γ_0 in this section takes a different value from that for a single layer since the lattice fields are not identical, but for simplicity we do not use different notations. The results (31) and (32) is similar to (23) in the two-dimensional case with the difference that the zero point energy is missing in (23).

McClure has concluded on the basis of the two-dimensional model that $n=0$ levels play the dominant role for the diamagnetism. This is explained schematically in Fig. 5, which shows the level density g versus $E - E_0$ curve in a hexagonal layer. When $H=0$, there is no state having $E = E_0$, while $n=0$ levels are induced by the magnetic field. Hence in the magnetic field the electrons, which occupy the states of the valence and the conduction bands having the energy near $E = E_0$, assemble on this $n=0$ levels. This circumstance is indicated by arrows in Fig. 5. Consequently the average energy of the electrons is raised by the magnetic field provided that the number of electrons below E_0 is larger than that above it; this results from the thermal agitation of the Fermi distribution. The smaller the level density becomes, the larger this effect will be. As a result the Fermi energy will become so large as capable of explaining the observed periodicity of the de Haas-van Alphen effect. In the three-dimensional case the situation is not so simple. Unless we compute the susceptibility using the energy levels (31) and (32), we cannot compare our theory with the calculation based on the Peierls formula (1).

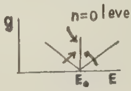

Fig. 5.

§ 4. Extension of Luttinger-Kohn Theory

In the preceding section we have calculated the energy levels of the conduction electrons in the magnetic field, which are correct in the neighborhood of the edge of the Brillouin zone. But the calculation depends so much on the tight binding approximation that it seems difficult to improve it more precisely.

In this section, therefore, we shall try to extend the method of Luttinger and Kohn in the form which will be suitable for the band structure of graphite. For this purpose we shall define the functions ϕ_{nk} as our bases:

$$\begin{aligned}\phi_{nk}&=\exp(i\boldsymbol{k}\cdot\boldsymbol{r})\,u_{nk_x{}^0k_y{}^0k_z}\\&=\exp(i(k_x-k_x{}^0)x+i(k_y-k_y{}^0)y)\psi_{nk_x{}^0k_y{}^0k_z}\,,\end{aligned}\tag{33}$$

where $k_x{}^0$ and $k_y{}^0$ are the values of k_x and k_y at the zone edge.

$$\psi_{nk_x{}^0k_y{}^0k_z}=\exp(ik_x{}^0x+ik_y{}^0+ik_zz)u_{nk_x{}^0k_y{}^0k_z}$$

is the Bloch function on this edge and satisfies

$$\mathscr{H}_0\psi_{nk_x{}^0k_y{}^0k_z}=E_n(k_x{}^0k_y{}^0k_z)\,\psi_{nk_x{}^0k_y{}^0k_z}\,. \tag{34}$$

It is apparent that functions ϕ_{nk} form an orthonormal system.

For simplicity we use u_{nk_z}, ψ_{nk_z} and $E_n(k_z)$ for $u_{nk_x{}^0k_y{}^0k_z}$, $\psi_{nk_x{}^0k_y{}^0k_z}$ and $E_n(k_x{}^0k_y{}^0k_z)$. Then the matrix elements of our Hamiltonian can easily be calculated:

$$\begin{aligned}(n\boldsymbol{k}|\mathscr{H}_0|n'\boldsymbol{k}')=\delta_{nn'}\delta(\boldsymbol{k}'-\boldsymbol{k})&\left[\frac{\hbar'}{2m}\{(k_x'-k_x{}^0)^2+(k_y'-k_y{}^0)^2\}+E_n(k_z)\right]\\&+\delta(\boldsymbol{k}'-\boldsymbol{k})\frac{\hbar}{m}\{(k_x'-k_x{}^0)\,p_x{}^{nn'}+(k_y'-k_y{}^0)\,p_y{}^{nn'}\}\,.\end{aligned}\tag{35}$$

$$(n\boldsymbol{k}|-\omega y p_x|n'\boldsymbol{k}')=i\omega\frac{\partial\delta(\boldsymbol{k}'-\boldsymbol{k})}{\partial k_y'}\{\hbar(k_x'-k_x{}^0)\delta_{nn'}+p_x{}^{nn'}\}\,, \tag{36}$$

$$\left(n\boldsymbol{k}\left|\frac{m}{2}\,\omega^2y^2\right|n'\boldsymbol{k}'\right)=-\frac{m}{2}\,\omega^2\frac{\partial^2(\boldsymbol{k}'-\boldsymbol{k})}{\partial k_y'^2}\,, \tag{37}$$

where

$$p_{x,y}^{nn'}=\int\psi_{nk_z}^*(-i\hbar\nabla_{x,y})\psi_{n'k_z}\,d\boldsymbol{r}\,. \tag{38}$$

With the assumption

$$\Psi=\sum_n\int d\boldsymbol{k}\,B_n(\boldsymbol{k})\,\phi_{nk}\,, \tag{39}$$

we have the set of differential equations for $B_n(\boldsymbol{k})$ from (35), (36) and (37), as before:

$$\begin{aligned}&\left[\frac{\hbar^2}{2m}\{(k_x-k_x{}^0)^2+(k_y-k_y{}^0))\}+E_n(k_z)\right]B_n(\boldsymbol{k})\\&\qquad+\frac{\hbar}{m}\sum_{n'}\{(k_x-k_x{}^0)\,p_x{}^{nn'}+(k_y-k_y{}^0)\,p_y{}^{nn'}\}B_{n'}(\boldsymbol{k})\\&\qquad-i\omega\sum_{n'}\{\hbar(k_x-k_x{}^0)\delta_{nn'}+p_x{}^{nn'}\}\frac{\partial B_{n'}}{\partial k_y}-\frac{m}{2}\,\omega^2\frac{\partial^2B_n}{\partial k_y{}^2}=EB_n(\boldsymbol{k})\,.\end{aligned}\tag{40}$$

In order to solve (40), we must simplify it by making use of the result of § 2. Putting $k_x{}^0=k_y{}^0=0$ and neglecting terms which can be thought to be small we have

$$\sum_{n'}\left\{\frac{\hbar}{m}(k_xp_x{}^{nn'}+k_yp_y{}^{nn'})-i\omega\,p_x{}^{nn'}\frac{\partial}{\partial k_y}\right\}B_{n'}(\boldsymbol{k})=\{E-E_n(k_z)\}B_n(\boldsymbol{k})\,, \tag{41}$$

where n and n' means the four bands which are near each other energetically at the zone edge, higher bands being negligible because their effects may only change the mass in (40) to the effective mass.

Putting $\omega=0$, Eqs. (41) become the ordinary secular equation which determines the energy band structure. According to the result of the tight binding method, this secular equation is reduced to the two-dimensional one if we neglect the energy integrals connecting (A, D), (B, C) and (B, D) as in § 3.[14] In this case the matrix elements of the momentum was already calculated by McClure[14]:

$$p_x^{12}=-ip_0\ ,\qquad p_y^{12}=p_0\ ,\qquad p_x^{11}=p_x^{22}=p_y^{11}=p_y^{22}=0\ , \tag{42}$$

where p_0 is a constant of the order of the magnitude $\hbar/a$ and plays the same role as γ_0. Therefore with the same approximations we can write from (41) as follows:

$$\left.\begin{aligned}\{E-E_1(k_z)\}B_1(\boldsymbol{k})&=\frac{\hbar}{m}p_0\left(-ik_x+k_y-s\frac{\partial}{\partial k_y}\right)B_2(\boldsymbol{k})\ ,\\ \{E-E_2(k_z)\}B_2(\boldsymbol{k})&=\frac{\hbar}{m}p_0\left(ik_x+k_y+s\frac{\partial}{\partial k_y}\right)B_1(\boldsymbol{k})\ .\end{aligned}\right\} \tag{43}$$

Provided that $E_1(k_z)=E_0-\gamma_1\Gamma$, $E_2=E_0$, the above equations become identical with (29).

§5. Remarks on the Diamagnetism of Graphite

The diamagnetic susceptibility of graphite shows a remarkable anisotropy[15]. $\chi_\perp$ is nearly equal to the diamagnetic susceptibility of diamond and is independent of temperature, but $\chi_\parallel$ is large and varies with temperature ($\parallel$ or $\perp$ means that the direction of the magnetic field is parallel or perpendicular to the *c* axis). It is expected that the behavior of $\chi_\parallel$ is caused by the π electrons. The temperature dependence of $\chi_\parallel$ can be evaluated correctly because we have calculated the energy levels near the Fermi surface, while we can say nothing about the magnitude of $\chi_\parallel$ to which all electrons may contribute. In connection with the latter we may point out that the k-dependence of u_k or the band structure is neglected in the Peierls formula (1).

Hove[10] studied the temperature variation of $\chi_\parallel$ in detail using the Peierls formula (1) with the Wallace model (30). He found that γ_1 had to be equal to 0.5 ev in order to obtain the agreement with the experiment. This value is five times as large as that estimated by Coulson[6]. We must study the variation of the susceptibility with temperature using the energy levels (31) and compare the result with Hove's calculation. But this program is left in future on account of laborious numerical computation.

The author wishes to thank Dr. F. Nakano and Mr. S. Mase for their valuable discussions, Prof. Ariyama and Dr. S. Nakajima for their helpful advice and encouragement during the course of this work.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 5, MAY, 1959

The Thermoelectric, Galvanomagnetic and Thermomagnetic Effects of Monovalent Metals, IV. Effect of the Non-equilibrium Distribution of the Phonons

By Mikio TSUJI

General Education Department, Kyushu University, Fukuoka

(Received January 8, 1959)

The effects of the non-equilibrium distribution of the phonons on the electrical and thermal conductivities, thermoelectric power, and transverse galvano- and thermomagnetic effects of metals are calculated. It is shown that Onsager's reciprocal relation holds, actually, in the case of the non-equilibrium distribution of the phonons with presence of a magnetic field. For the spherical band model, the effect on the Ettingshausen-Nernst coefficient is not so large as appeared in literatures. For an anisotropic band model, the phonon drag terms appear in the Ettingshausen, Ettingshausen-Nernst and Righi-Leduc coefficients.

§ 1. Introduction

In the previous papers of this series¹⁾ (I, II and III), we have calculated the thermoelectric power and the transverse galvano- and thermomagnetic effects of the monovalent metals, by assuming the equilibrium distribution of the phonons. In I, it has been shown that the positive signs of the thermoelectric powers and the negative signs of the Ettingshausen and Ettingshausen-Nernst coefficients of the noble metals at high temperatures are interpreted qualitatively by assuming a simple model of the spherical energy band of the conduction electrons. In II and III, the calculations have been generalized to the case of low temperatures and to the anisotropic energy band, and we have derived the relations between the coefficients which hold irrespective of the scatting mechanism. Now the distribution of the phonons deviates, actually, from its equilibrium value, and the effects of this non-equilibrium phonons on the thermoelectric powers of metals²⁾ and semiconductors³⁾ below room temperature are, in fact, not necessarily small.

Assuming the quasi-free electron model, Hanna and Sondheimer⁴⁾ solved the simultaneous Boltzmann equations for the distribution functions of the electrons and the phonons by a method of successive approximations and obtained a set of interpolation formulae. A more rigorous solution was obtained by the author in another paper⁵⁾, in which the distribution function of the phonons was eliminated at first, and then the resultant equation was solved by using a variation principle. An identical method was adopted by Bailyn⁶⁾ independently*. In these articles so far mentioned, only the cases of no magnetic field have been treated. Recently, Parrott⁷⁾, Appel⁸⁾ and V. L. Gurevich (son of L. E. Gurevich) and Obraztsov⁹⁾ have calculated the effect of the non-equilibrium distribution of the phonons on the Ettingshausen-Nernst effect of the semi-conductors. The measurement of the effect has also been done by Herring *et al*¹⁰⁾. However, the effect for metals has not yet been calculated in detail except for a simple considerations of L. E. Gurevich¹¹⁾ who initially calculated the "phonon drag effect" on the thermoelectric power and also suggested the effect on the Ettingshausen-Nornst coefficient. Recently, Paul¹²⁾ has calculated the effects of the non-equilibrium distribution of the phonons on the thermal conductivity and the thermomagnetic effects of metals. However, unfortunately, there are many important errors in his article, and especially his conclusion on the Ettingshausen-Nernst effect is qualitatively invalid.

In this article, we consider the effect of the non-equilibrium distribution of the phonons on the transverse galvano- and thermo- magnetic effects of the monovalent metals, and give the corrections due to this effect for the results obtained in I, II and III. At first, in § 2, we show formally that the general reciprocal relations of Onsager hold for any conductor in a magnetic field, even if we consider the non-equilibrium distribution of the phonons. This fact has been shown by Sondheimer[13] for a special case of no magnetic field. The discussion given in § 2 holds not only for the monovalent metals but also for any conductors. In § 3 we write down the Boltzmann equations for a metal strip which has the spherical energy band and is placed in a transverse magnetic field. At first, we eliminate the distribution function of the phonons from the simultaneous Boltzmann equations, and then we solve the resultant equation by a variational method used in III. From the solution, we obtain the electrical and thermal conductivities, the thermoelectric power, and the Hall, Ettingshausen, Ettingshausen-Nernst and Righi-Leduc coefficients. We discuss, in § 4, the results obtained in § 3 and derive certain relations between the coefficients which hold irrespective of the scattering mechanism. It is shown that the "phonon drag" effect appears in the thermoelectric power, but it does not appear in the galvanomagnetic and thermomagnetic effects. However, the corrections due to the lattice thermal conductivity appear in the latter quantities. The effects for an anisotropic media are considered in § 5 and § 6. In § 5 we show that the phonon drag term of the thermoelectric power of a metal having cubic anisotropy is of the same order of magnitude as that of a metal having spherical energy band. In the presence of a magnetic field, however, the non-equilibrium distribution of the phonons give the phonon drag terms to the Ettingshausen, Ettingshausen-Nernst and Righi-Leduc coefficients of anisotropic metals if the departures from the spherical band are significant. These phonon drag terms disappear in the isotropic metals. These facts are shown in § 6.

---

* I am very grateful to Dr. Bailyn for sending me a copy of his manuscript before publication.

§ 2. Onsager's Reciprocal Relations

Assuming the equilibrium distribution of the phonons, Meixner[14] and Kohler[15] have shown that Onsager's reciprocal relations actually hold in the presence of a magnetic field. For the case of no magnetic field, Sondheimer[13] has shown that the reciprocal relations hold even if we take into account the departure from the equilibrium distribution of the phonons. In this section, we show that the relations also hold for the case where a magnetic field exists in a conductor and the distribution of the phonons deviates from equilibrium value. The proof is easily performed by using a method similar to that used by Kohle[15] in the case of the equilibrium distribution of the phonons. We put the distributions of the electrons and the phonons in the form

$$f(\boldsymbol{k})=f_0(E_{\boldsymbol{k}})-\Phi(\boldsymbol{k})\frac{\partial f_0}{\partial E}\,, \tag{1}$$

and

$$N(\boldsymbol{q})=N_0(h\nu_q)-\frac{\Psi(\boldsymbol{q})}{\kappa T}\frac{\partial N_0}{\partial z}\,, \tag{2}$$

respectively, where f_0 and N_0 are the equilibrium distributions, $\boldsymbol{k}$ and $\boldsymbol{q}$ are the wave numbers of an electron and of a phonon, ν_q is the frequency of the phonon, and $z=h\nu_q/\kappa T$. We assume that there are an electric field $\boldsymbol{F}$, a magnetic field $\boldsymbol{H}$ and a temperature gradient ∇T in any directions. Then we may write the Boltzmann equations schematically in the forms

$$\{L_1+M(\boldsymbol{H})\}\Phi(\boldsymbol{k})+L_2\Psi(\boldsymbol{q})$$
$$=\left(e\boldsymbol{F}-T\nabla\frac{E-\zeta}{T}\right)\cdot\boldsymbol{v}\frac{\partial f_0}{\partial E}\,, \tag{3}$$

$$L_3\Phi(\boldsymbol{k})+L_4\Psi(\boldsymbol{q})=-\boldsymbol{u}\cdot\nabla T\frac{\partial N_0}{\partial T}\,, \tag{4}$$

where $\boldsymbol{v}$ and $\boldsymbol{u}$ are the group velocities of an electron and a phonon respectively and ζ is the Fermi level. The definitions of the linear operators L_1, L_2, L_3 and L_4 are given in the article of Sondheimer[13] and they satisfy the symmetry relations

$$\int F(\boldsymbol{k})L_1(G)d\boldsymbol{k}=\int G(\boldsymbol{k})L_1(F)d\boldsymbol{k}\,, \tag{5}$$

$$2\int F(\boldsymbol{k})L_2(G)d\boldsymbol{k}=\int G(\boldsymbol{q})L_3(F)d\boldsymbol{q}\,, \tag{6}$$

$$\int F(\boldsymbol{q})L_4(G)d\boldsymbol{q}=\int G(\boldsymbol{q})L_4(F)d\boldsymbol{q}\,, \tag{7}$$

where F and G are arbitrary functions of $\boldsymbol{k}$ or $\boldsymbol{q}$. $M(\boldsymbol{H})$ is an operator which gives the effect of the Lorentz force due to the magnetic field and is defined by

$$M(\boldsymbol{H})\equiv\frac{e}{\hbar c}\frac{\partial f_0}{\partial E}\nabla_k E\cdot\boldsymbol{H}\times\nabla_k\,. \tag{8}$$

$M(\boldsymbol{H})$ satisfies the relation[14),15)]

$$\int F(\boldsymbol{k})M(\boldsymbol{H})G(\boldsymbol{k})d\boldsymbol{k}=\int G(\boldsymbol{k})M(-\boldsymbol{H})F(\boldsymbol{k})d\boldsymbol{k}\,. \tag{9}$$

Now if we put

$$\varPhi(\boldsymbol{k})=\left(e\boldsymbol{F}+T\nabla\frac{\zeta}{T}\right)\cdot\boldsymbol{\phi}+\frac{1}{T}\nabla T\cdot\boldsymbol{\psi}\ , \tag{10}$$

$$\varPsi(\boldsymbol{q})=\left(e\boldsymbol{F}+T\nabla\frac{\zeta}{T}\right)\cdot\boldsymbol{\mu}+\frac{1}{T}\nabla T\cdot\boldsymbol{\nu}\ , \tag{11}$$

the Boltzmann equations may be written in the forms

$$v_i\frac{\partial f_0}{\partial E}=\{L_1+M(\boldsymbol{H})\}\phi_i+L_2(\mu_i)\ , \tag{12}$$

$$v_iE\frac{\partial f_0}{\partial E}=\{L_1+M(\boldsymbol{H})\}\psi_i+L_2(\nu_i)\ , \tag{13}$$

$$0=L_3(\phi_i)+L_4(\mu_i)\ , \tag{14}$$

$$-u_iT\frac{\partial N_0}{\partial T}=L_3(\psi_i)+L_4(\nu_i)\ , \tag{15}$$

where the suffices $i=1,\ 2,\ 3$ denote the x, y, z components respectively. The electric and heat current densities are given by

$$\left.\begin{aligned} J_i&=\sum_j\left\{S_{ij}^{(1)}\left(e^2F_j+eT\frac{\partial}{\partial x_j}\frac{\zeta}{T}\right)+S_{ij}^{(2)}\frac{e}{T}\frac{\partial T}{\partial x_j}\right\}\ ,\\ w_i&=\sum_j\left\{S_{ij}^{(3)}\left(-eF_j-T\frac{\partial}{\partial x_j}\frac{\zeta}{T}\right)-S_{ij}^{(4)}\frac{1}{T}\frac{\partial T}{\partial x_j}\right\}\ ,\end{aligned}\right\} \tag{16}$$

respectively, where

$$S_{ij}^{(1)}=\frac{1}{4\pi^3}\int v_i\phi_j\frac{\partial f_0}{\partial E}d\boldsymbol{k}\ , \tag{17}$$

$$S_{ij}^{(2)}=\frac{1}{4\pi^3}\int v_i\psi_j\frac{\partial f_0}{\partial E}d\boldsymbol{k}\ , \tag{18}$$

$$S_{ij}^{(3)}=\frac{1}{4\pi^3}\int v_iE\,\phi_j\frac{\partial f_0}{\partial E}d\boldsymbol{k}-\frac{1}{8\pi^3}\int u_iT\mu_j\frac{\partial N_0}{\partial T}d\boldsymbol{q}\ , \tag{19}$$

$$S_{ij}^{(4)}=\frac{1}{4\pi^3}\int v_iE\,\psi_j\frac{\partial f_0}{\partial E}d\boldsymbol{k}-\frac{1}{8\pi^3}\int u_iT\nu_j\frac{\partial N_0}{\partial T}d\boldsymbol{q}\ . \tag{20}$$

The reciprocal relations are

$$S_{ij}^{(1)}(\boldsymbol{H})=S_{ji}^{(1)}(-\boldsymbol{H})\ , \tag{21}$$

$$S_{ij}^{(4)}(\boldsymbol{H})=S_{ji}^{(4)}(-\boldsymbol{H})\ , \tag{22}$$

$$S_{ij}^{(2)}(\boldsymbol{H})=S_{ji}^{(3)}(-\boldsymbol{H})\ . \tag{23}$$

Here we give the proof of (21). The proof of the remaining relations can be performed in a similar way.

Now we write the solutions of the equations (12) through (15) as ϕ_i^+ and μ_i^+, and the solutions of the equations with the magnetic field reversed in the directions as ϕ_i^- and μ_i^-. Using (12), we have

$$\begin{aligned} 4\pi^3S_{ij}^{(1)}(\boldsymbol{H})&=\int\phi_j^+\{L_1+M(\boldsymbol{H})\}\phi_i^+d\boldsymbol{k}+\int\phi_j^+L_2(\mu_i^+)d\boldsymbol{k}\\ &=\int\phi_j^+\{L_1+M(-\boldsymbol{H})\}\phi_i^-d\boldsymbol{k}+\int\phi_j^+L_2(\mu_i^-)d\boldsymbol{k}\ . \end{aligned} \tag{24}$$

Now using (5), (6), (7), (9) and (14), we have

$$\int\phi_j^+L_1(\phi_i^-)d\boldsymbol{k}=\int\phi_i^-L_1(\phi_j^+)d\boldsymbol{k}\ , \tag{25}$$

$$\int\phi_j^+M(-\boldsymbol{H})\phi_i^-d\boldsymbol{k}=\int\phi_i^-M(\boldsymbol{H})\phi_j^+d\boldsymbol{k}\ , \tag{26}$$

$$\begin{aligned} \int\phi_j^+L_2(\mu_i^-)d\boldsymbol{k}&=\frac{1}{2}\int\mu_i^-L_3(\phi_j^+)d\boldsymbol{q}=-\frac{1}{2}\int\mu_i^-L_4(\mu_j^+)d\boldsymbol{q}\\ &=-\frac{1}{2}\int\mu_j^+L_4(\mu_i^-)d\boldsymbol{q}=\int\phi_j^-L_2\mu_j^+d\boldsymbol{k}\ , \end{aligned} \tag{27}$$

Putting (25), (26) and (27) into (24), we have

$$4\pi^3 S_{ij}^{(1)}(\boldsymbol{H})=\int\phi_i^-\{L_1+M(\boldsymbol{H})\}\phi_j^+dk+\int\phi_j^-L_2(\mu_j^+)dk=4\pi^3 S_{ji}^{(1)}(-\boldsymbol{H})\,.$$

Now certain symmetry relations such as $\sigma(\boldsymbol{H})=\sigma(-\boldsymbol{H})$ (σ=the electrical conductivity) have been derived from (21), (22) and (23) by Meixner[14] and Kohler[15]. Here, it has been proved that these relations also remain valid even if the distribution of the phonons deviates from the equilibrium.

§ 3. Calculation on the Spherical Energy Band Model

In this section we consider only the case of a transverse magnetic field, $\boldsymbol{E}$, and ∇T being in x–y plane and $\boldsymbol{H}$ along z-axis. We assume that the energy of an electron $E(k)$ depends only on $k=|\boldsymbol{k}|$, and assume the Debye model for the phonons. In this case, $\Phi(\boldsymbol{k})$ and $\Psi(\boldsymbol{q})$ can be written in the form

$$\Phi(\boldsymbol{k})=k_xc_x(\eta)+k_yc_y(\eta)\,,\qquad \Psi(\boldsymbol{q})=q_xb_x(z)+q_yb_y(z)\,, \tag{28}$$

where $\eta=(E-\zeta)/\kappa T$. The collision operators can be written also in the form

$$L_1(\Phi)=\hbar^{-1}\{k_x\mathscr{L}_1(c_x)+k_y\mathscr{L}_1(c_y)\}\partial f_0/\partial E\,, \tag{29}$$

$$L_2(\Psi)=\hbar^{-1}\{k_x\mathscr{L}_2(b_x)+k_y\mathscr{L}_2(b_y)\}\partial f_0/\partial E\,, \tag{30}$$

$$L_3(\Phi)=\{q_x\mathscr{L}_3(c_x)+q_y\mathscr{L}_3(c_y)\}\partial N_0/\partial z\,, \tag{31}$$

$$L_4(\Psi)=\{q_x\mathscr{L}_4(b_x)+q_y\mathscr{L}_4(b_y)\}\partial N_0/\partial z\,. \tag{32}$$

The definite forms of $\mathscr{L}_1$, $\mathscr{L}_2$, $\mathscr{L}_3$ and $\mathscr{L}_4$ are given in the reference (5). From the symmetry relations (5), (6) and (7), we easily obtain the relations

$$\int k^4\left(\frac{dE}{dk}\right)^{-1}c(\eta)\mathscr{L}_1\{d(\eta)\}\frac{\partial f_0}{\partial\eta}d\eta=\int k^4\left(\frac{dE}{dk}\right)^{-1}d(\eta)\mathscr{L}_1\{c(\eta)\}\frac{\partial f_0}{\partial\eta}d\eta\,, \tag{33}$$

$$2h^{-1}\int k^4\left(\frac{dE}{dk}\right)^{-1}c(\eta)\mathscr{L}_2\{b(z)\}\frac{\partial f_0}{d\eta}d\eta=q_0^5\left(\frac{T}{\Theta}\right)^5\int z^4b(z)\mathscr{L}_3\{c(\eta)\}\frac{\partial N_0}{\partial z}dz\,, \tag{34}$$

$$\int z^4a(z)\mathscr{L}_4\{b(z)\}\frac{\partial N_0}{\partial z}dz=\int z^4b(z)\mathscr{L}_4\{a(z)\}\frac{\partial N_0}{\partial z}dz\,, \tag{35}$$

where q_0 is the maximum wave number of the phonons, Θ is the Debye characteristic temperature, d and c are arbitrary functions of η, and a and b are arbitrary functions of z.

Now the Boltzmann equations can be writted in the forms

$$\mathscr{L}_1(c_x)+\mathscr{L}_2(b_x)=\left(eF_x-T\frac{\partial}{\partial x}\frac{\zeta}{T}+\frac{E}{T}\frac{\partial T}{\partial x}\right)\frac{1}{k}\frac{dE}{dk}+\frac{eH}{\hbar c}\frac{1}{k}\frac{dE}{dk}c_y\,, \tag{36}$$

$$\mathscr{L}_1(c_y)+\mathscr{L}_2(b_y)=\left(eF_y-T\frac{\partial}{\partial y}\frac{\zeta}{T}+\frac{E}{T}\frac{\partial T}{\partial y}\right)\frac{1}{k}\frac{dE}{dk}-\frac{eH}{\hbar c}\frac{1}{k}\frac{dE}{dk}c_x\,, \tag{37}$$

$$\mathscr{L}_3(c_x)+\mathscr{L}_4(b_x)=\frac{\kappa}{\hbar q_0^2}\left(\frac{\Theta}{T}\right)^2\frac{\partial T}{\partial x}\,, \tag{38}$$

$$\mathscr{L}_3(c_y)+\mathscr{L}_4(b_y)=\frac{\kappa}{\hbar q_0^2}\left(\frac{\Theta}{T}\right)^2\frac{\partial T}{\partial y}\,. \tag{39}$$

Eliminating b_x and b_y from (36) through (39), we have

$$\mathscr{L}(c_x)=\left(eF_x-T\frac{\partial}{\partial x}\frac{\zeta}{T}+\frac{E}{T}\frac{\partial T}{\partial x}\right)\frac{1}{k}\frac{dE}{dk}+\frac{eH}{\hbar c}\frac{1}{k}\frac{dE}{dk}c_y-\frac{\partial T}{\partial x}\frac{\kappa}{\hbar q_0^2}\left(\frac{\Theta}{T}\right)^2\mathscr{L}_2\mathscr{L}_4^{-1}(1)\,, \tag{40}$$

$$\mathscr{L}(c_y)=\left(eF_y-T\frac{\partial}{\partial y}\frac{\zeta}{T}+\frac{E}{T}\frac{\partial T}{\partial y}\right)\frac{1}{k}\frac{dE}{dk}-\frac{eH}{\hbar c}\frac{1}{k}\frac{dE}{dk}c_x-\frac{\partial T}{\partial y}\frac{\kappa}{\hbar q_0^2}\left(\frac{\Theta}{T}\right)^2\mathscr{L}_2\mathscr{L}_4^{-1}(1)\,, \tag{41}$$

where

$$\mathscr{L}\equiv\mathscr{L}_1-\mathscr{L}_2\mathscr{L}_4^{-1}\mathscr{L}_3\,. \tag{42}$$

In (42), $\mathscr{L}_4^{-1}$ denotes the inverse operator of $\mathscr{L}_4$ and have the same symmetry as the original operator $\mathscr{L}_4$.

The last terms of the right sides of (40) and (41) give the effect of the deviation of the the phonon distribution produced by the thermal gradient, and these termes enter in the equation in the forms of "drift" terms. The "reaction" of the effect of the deviation of the electron distribution from equilibrium on the phonon distribution is included in the operator $\mathscr{L}$ as the second term of the right side of (42). This "reaction" has an effect that makes the rate of change of the electron distribution due to collision smaller than the case without the deviation of the distribution of the phonons.

Now we can show that the operator $\mathscr{L}$ has also the same symmetric character as $\mathscr{L}_1$. Bailyn[6] has proved this for a special case in which the term $\mathscr{L}_4(b)$ can be written down by using a relaxation time. Here we give a more general proof by using the relations (33), (34) and (35). For arbitrary functions $c(\eta)$ and $d(\eta)$ we have, by using (34),

$$\int k^4\left(\frac{dE}{dk}\right)^{-1}c(\eta)\mathscr{L}_2\mathscr{L}_4^{-1}\mathscr{L}_3\{d(\eta)\}\frac{\partial f_0}{\partial\eta}d\eta=q_0^5\left(\frac{T}{\Theta}\right)^5\int z^4[\mathscr{L}_4^{-1}\mathscr{L}_3\{d(\eta)\}]\mathscr{L}_3\{c(\eta)\}\frac{\partial N_0}{\partial z}dz\,. \tag{43}$$

Now from (35), we have

$$\int z^4a(z)\mathscr{L}_4^{-1}\{b(z)\}\frac{\partial N_0}{\partial z}dz=\int z^4b(z)\mathscr{L}_4^{-1}\{a(z)\}\frac{\partial N_0}{\partial z}dz\,. \tag{44}$$

Using (44), we can rewrite the right side of (43) as

$$q_0^5\left(\frac{T}{\Theta}\right)^5\int z^4[\mathscr{L}_4^{-1}\mathscr{L}_3\{c(\eta)\}]\mathscr{L}_3\{d(\eta)\}\frac{\partial N_0}{\partial z}dz\,.$$

Therefore, using again (34), we have

$$\int k^4\left(\frac{dE}{dk}\right)^{-1}c(\eta)\mathscr{L}_2\mathscr{L}_4^{-1}\mathscr{L}_3\{d(\eta)\}\frac{\partial f_0}{\partial\eta}d\eta=\int k^4\left(\frac{dE}{dk}\right)^{-1}d(\eta)\mathscr{L}_2\mathscr{L}_4^{-1}\mathscr{L}_3\{c(\eta)\}\frac{\partial f_0}{\partial\eta}d\eta\,. \tag{45}$$

Thus it has been shown that $\mathscr{L}_2\mathscr{L}_4^{-1}\mathscr{L}_3$ and so $\mathscr{L}$ satisfy the same symmetry relation as $\mathscr{L}_1$. More generaly we can prove easily that $L_2L_4^{-1}L_3$ satisfies the same symmetry relation as L_1.

Now, considering that (40) and (41) have the forms similar to the equations derived with the assumption of the equilibrium phonon distribution, we can solve these equations by using the varation principle used in III. Since the procedure is almost the same as in III, we write below only the outline of the procedure. If we put the solutions of (40) and (41) in the forms

$$c_x=c_{x,0}+c_{x,1}\eta\,,\qquad c_y=c_{y,0}+c_{y,1}\eta\,, \tag{46}$$

the coefficients of the right sides of (46) can be determined by the following equations

$$\left.\begin{aligned}&\sum_s c_{x,s}d_{rs}-\sum_s c_{y,s}\gamma_{r+s}-\left(eF_x+T\frac{\partial}{\partial x}\frac{\zeta}{T}\right)\alpha_r^{(1)}-\frac{1}{T}\frac{\partial T}{\partial x}\{\alpha_r^{(2)}+\beta_r^{(2)}\}=0\,,\\&\sum_s c_{y,s}d_{rs}+\sum_s c_{x,s}\gamma_{r+s}-\left(eF_y+T\frac{\partial}{\partial y}\frac{\zeta}{T}\right)\alpha_r^{(1)}-\frac{1}{T}\frac{\partial T}{\partial y}\{\alpha_r^{(2)}+\beta_r^{(2)}\}=0\,,\end{aligned}\right\} \tag{47}$$

where

$$d_{rs}=\int_{-\infty}^{\infty} k^4\left(\frac{dE}{dk}\right)^{-1}\eta^r\mathscr{L}(\eta^s)\frac{\partial f_0}{\partial\eta}d\eta\ , \tag{48}$$

$$\gamma_r=\frac{eH}{\hbar c}\int k^3\eta^r\frac{\partial f_0}{\partial\eta}d\eta=\frac{eH}{\hbar c}\alpha_r{}^{(1)}\ , \tag{49}$$

$$\alpha_r{}^{(n)}=\int E^{n-1}k^3\eta^r\frac{\partial f_0}{\partial\eta}d\eta\ , \tag{50}$$

$$\beta_r{}^{(n)}=-(n-1)\frac{\kappa T}{\hbar q_0{}^2}\left(\frac{\Theta}{T}\right)^2\int k^4\left(\frac{dE}{dk}\right)^{-1}\eta^r\frac{\partial f_0}{\partial\eta}\mathscr{L}_2\mathscr{L}_4{}^{-1}(1)d\eta\ . \tag{51}$$

Putting the solution (46) into (38) and (39), we have the solutions b_x and b_y as

$$\left.\begin{aligned} b_x&=-\mathscr{L}_4{}^{-1}\mathscr{L}_3(c_x)+\frac{\kappa}{\hbar q_0{}^2}\left(\frac{\Theta}{T}\right)^2\frac{\partial T}{\partial x}\mathscr{L}_4{}^{-1}(1)\ ,\\ b_y&=-\mathscr{L}_4{}^{-1}\mathscr{L}_3(c_y)+\frac{\kappa}{\hbar q_0{}^2}\left(\frac{\Theta}{T}\right)^2\frac{\partial T}{\partial y}\mathscr{L}_4{}^{-1}(1)\ .\end{aligned}\right\} \tag{52}$$

The electric and heat current densities are calculated by using the solution (46) and (52) and the results can be written in the same form as (37) in III, with the coefficients K_{mn}'s shown below. Using the notations of (31) in III, we have

$$\left.\begin{aligned}
K_{11}&=\frac{1}{3\pi^2\hbar}(c_0{}^{(1)}\alpha_0{}^{(1)}+c_1{}^{(1)}\alpha_1{}^{(1)})\ ,\\
K_{12}&=\frac{1}{3\pi^2\hbar}(c_0{}^{(2)}\alpha_0{}^{(1)}+c_1{}^{(2)}\alpha_1{}^{(1)})\ ,\\
K_{13}&=-\frac{1}{3\pi^2\hbar}(\bar{c}_0{}^{(1)}\alpha_0{}^{(1)}+\bar{c}_1{}^{(1)}\alpha_1{}^{(1)})\ ,\\
K_{14}&=-\frac{1}{3\pi^2\hbar}(\bar{c}_0{}^{(2)}\alpha_0{}^{(1)}+{}_1\bar{c}^{(2)}\alpha_1{}^{(1)})\ ,\\
K_{21}&=\frac{1}{3\pi^2\hbar}\{c_0{}^{(1)}(\alpha_0{}^{(2)}+\beta_0{}^{(2)})+c_1{}^{(1)}\alpha_1{}^{(2)}\}\ ,\\
K_{22}&=\frac{1}{3\pi^2\hbar}\{c_0{}^{(2)}(\alpha_0{}^{(2)}+\beta_0{}^{(2)})+c_1{}^{(2)}\alpha_1{}^{(2)}+\mathcal{E}\}\ ,\\
K_{23}&=-\frac{1}{3\pi^2\hbar}\{\bar{c}_0{}^{(1)}(\alpha_0{}^{(2)}+\beta_0{}^{(2)})+\bar{c}_1{}^{(1)}\alpha_1{}^{(2)}\}\ ,\\
K_{24}&=-\frac{1}{3\pi^2\hbar}\{\bar{c}_0{}^{(2)}(\alpha_0{}^{(2)}+\beta_0{}^{(2)})+\bar{c}_1{}^{(2)}\alpha_1{}^{(2)}\}\ ,
\end{aligned}\right\} \tag{53}$$

where

$$\frac{1}{3\pi^2\hbar}\mathcal{E}\equiv\frac{(\kappa T)^2q_0}{6\pi^2\hbar}\frac{T}{\Theta}\int z^4\frac{\partial N_0}{\partial z}\mathscr{L}_4{}^{-1}(1)dz\ , \tag{54}$$

and $c_r{}^{(n)}$ and $\bar{c}_r{}^{(n)}$ are given by (32) through (36) in III, by replacing $\alpha_r{}^{(2)}$ by $\alpha_r{}^{(2)}+\beta_r{}^{(2)}$. In the calculation of the phonon parts of K_{2m}'s we used the symmetry relations (34) and (35). From (53) it is easily shown that the following relations hold,

$$K_{21}=K_{12}\ ,\qquad K_{23}=K_{14}\ . \tag{55}$$

In the calculations of K_{mn}'s given by (53), we retain only up to the linear terms of H and the second order terms of $\kappa T/\zeta$. Here we note that $c_1{}^{(n)}$, $\bar{c}_1{}^{(n)}$ and $\alpha_1{}^{(n)}$ are of the orders of magnitudes of $(\kappa T/\zeta)^2$ times $c_0{}^{(n)}$, $\bar{c}_0{}^{(n)}$ and $\alpha_0{}^{(n)}$ respectively, and $\beta_0{}^{(2)}$ and $\beta_1{}^{(2)}$ are of the orders of magnitudes of $\kappa T/\zeta$ times $\alpha_0{}^{(2)}$ and $\alpha_1{}^{(2)}$ respectively. The estimations of the orders of magnitudes of $\beta_r{}^{(2)}$ are easily carried out by putting the definite forms of $\mathscr{L}_2$ and

$\mathscr{L}_4$ given below into (51). By using the values of K_{mn}'s, we can calculate all the quantities by the usual way described in I, and we have the following results. (In the following equations, k_0 is the radius of the Fermi sphere and $\alpha=(dE/dk)_{E=\zeta}$.)

(i) Electrical Conductivity

$$\sigma=\frac{e^2k_0^6}{3\pi^2\hbar d_{00}} . \tag{56}$$

(ii) Thermal Conductivity

$$\kappa_T=\kappa_1+\kappa_2 , \tag{57}$$

where

$$\kappa_1=\frac{\pi^2k_0^6\kappa^2T}{27\hbar d_{11}} , \tag{58}$$

$$\kappa_2=\frac{1}{3\pi^2\hbar}\mathcal{E} . \tag{59}$$

(iii) Absolute Thermoelectric Power

$$S=S_1+S_2 , \tag{60}$$

where

$$S_1=-\frac{\kappa}{e}\left\{\frac{\pi^2\kappa T}{\alpha k_0}-\frac{\pi^2d_{01}}{3d_{11}}+\frac{\pi^4\kappa Td_{00}}{3\alpha k_0d_{11}}\right\} , \tag{61}$$

$$S_2=\frac{\beta_0{}^{(2)}}{eTk_0^3} . \tag{62}$$

(iv) Hall Coefficient

$$R_H=-\frac{3\pi^2}{k_0^3ce}=-\frac{1}{nec} . \tag{63}$$

(v) Ettingshausen Coefficient

$$A_E=\frac{3\pi^2\left(\frac{\pi^2\kappa T}{\alpha k_0}d_{00}-d_{01}\right)}{c\kappa k_0^3d_{11}}\left(1+\frac{\kappa_g}{\kappa_e}\right)^{-1} . \tag{64}$$

(vi) Isothermal Ettingshausen-Nernst Coefficient

$$B^i_{EN}=\frac{\pi^4\kappa k_0^3\left(\frac{\pi^2\kappa T}{\alpha k_0}d_{00}-d_{01}\right)}{9\hbar cd_{11}^2} . \tag{65}$$

(vii) Righi-Leduc Coefficient

$$B_{RL}=-\frac{e\pi^2k_0^3}{3\hbar cd_{11}}\left(1+\frac{\kappa_g}{\kappa_e}\right)^{-1} . \tag{66}$$

It is to be noted that each of d_{rs} is defined by (48) and includes two terms; one of them comes from the first term of (42) and the other comes from the second term of (42). The former is identical with d_{rs} defined by (25) in I and the latter represents the effect of the "reaction". The second term of d_{00}, $d_{10}=d_{01}$ and d_{11} are identical with $\hbar$ times β_0, $\beta_1=\gamma_0$ and γ_1 defined in (35) and (36) in the reference (5). Now the second terms of d_{00} and d_{01} are of the same orders of magnitudes of the first terms of them respectively and become important at low temperatures for pure metals. The second term of d_{11} is of the order of magnitude of $(\kappa T/\zeta)^2$ times the first term, and so is negligible always.

Now the definite forms of $\mathscr{L}_1$, $\mathscr{L}_2$, $\mathscr{L}_3$ and $\mathscr{L}_4$ are given by the formulae[5]

$$\mathscr{L}_1(c)=-\frac{1}{\Lambda}\left(\frac{T}{\Theta}\right)^3\left(\frac{dE}{dk}\right)^{-1}\int_{-\theta/T}^{\theta/T}\left\{1+\left(\frac{1}{\alpha k_0}-\frac{\beta}{\alpha^2}\right)\kappa Tz\right\}$$
$$\cdot\left[c(\eta)-c(\eta+z)\left\{1+\frac{\kappa Tz}{kdE/dk}-\frac{q_0^2}{2k^2}\left(\frac{T}{\Theta}\right)^2 z^2\right\}\right]\frac{e^\eta+1}{e^{\eta+z}+1}\frac{z^2dz}{|1-e^{-z}|}-\frac{\hbar}{\tau_i}, \tag{67}$$

$$\mathscr{L}_2(b)=-\frac{1}{\Lambda}\left(\frac{T}{\Theta}\right)^3\left(\frac{dE}{dk}\right)^{-1}\int_{-\theta/T}^{\theta/T} b(|z|)\left\{1+\left(\frac{1}{\alpha k_0}-\frac{\beta}{\alpha^2}\right)\kappa Tz\right\}$$
$$\cdot\left\{\frac{\kappa Tz}{kdE/dk}-\frac{q_0^2}{2k^2}\left(\frac{T}{\Theta}\right)^2 z^2\right\}\frac{e^\eta+1}{e^{\eta+z}+1}\frac{z^2dz}{|1-e^{-z}|}, \tag{68}$$

$$\mathscr{L}_3(c)=\frac{2\Delta}{3\pi h\Lambda q_0^2}\left(\frac{\Theta}{T}\right)^2\frac{1-e^{-z}}{z^2}\left\{1+\left(\frac{1}{\alpha k_0}-\frac{\beta}{\alpha^2}\right)\kappa Tz\right\}$$
$$\cdot\int_{-\infty}^{\infty} k^4\left(\frac{dE}{dk}\right)^{-2}c(\eta)\left\{\frac{\dfrac{\kappa Tz}{kdE/dk}+\dfrac{q_0^2}{2k^2}\left(\dfrac{T}{\Theta}\right)^2 z^2}{(e^{-\eta}+1)(e^{\eta-z}+1)}-\frac{\dfrac{\kappa Tz}{kdE/dk}-\dfrac{q_0^2}{2k^2}\left(\dfrac{T}{\Theta}\right)^2 z^2}{(e^{-\eta}+1)(e^{\eta}+e^{-z})}\right\}d\eta, \tag{69}$$

$$\mathscr{L}_4(b)=-\frac{2\Delta k_0^2}{3\pi h\Lambda\alpha^2}(z+\Gamma)\left\{1+2\left(\frac{1}{\alpha k_0}-\frac{\beta}{\alpha^2}\right)\kappa T\frac{z^2}{z+\Gamma}\right\}, \tag{70}$$

where $\beta=(d^2E/dk^2)_{E=\zeta}$, Λ is the interaction parameter defined in I, τ_i denotes the relaxation time for the scattering of electrons by the impurity atoms and the lattice defects in the metal, Δ is the volume of the unit cell and Γ is given by

$$\Gamma=\frac{3\pi h\Lambda\alpha^2 u_0}{2\Delta L k_0^2\kappa T}, \tag{71}$$

in which u_0 is the sound velocity and L is the mean free path of the phonons due to the phonon-phonon scattering and phonon-impurity scattering etc. Here we have assumed, for simplicity, that only the longitudinal phonons interact with the electrons. A generalization to the case in which the transverse phonons also interact with the electrons is easy if we compare the results in this article with those given in the reference (5).

Putting (67), (68), (69) and (70) into (48), (51) and (54), we have

$$d_{00}=\frac{k_0^2q_0^2}{\Lambda\alpha^2}\left(\frac{T}{\Theta}\right)^5 J_5+\frac{\hbar k_0^4}{\tau_i\alpha}-\frac{k_0^2q_0^2}{\Lambda\alpha^2}\left(\frac{T}{\Theta}\right)^5 P_6, \tag{72}$$

$$d_{01}=d_{10}=\frac{\kappa Tk_0^4}{\Lambda\alpha^2}\left(\frac{T}{\Theta}\right)^3\left\{\frac{1}{\alpha k_0}+\frac{2\pi^2q_0^2}{3k_0^2}\left(\frac{T}{\Theta}\right)^2\left(\frac{1}{\alpha k_0}-\frac{\beta}{\alpha^2}\right)\right\}J_5+\frac{\hbar\pi^2\kappa Tk_0^4}{3\tau_i\alpha}$$
$$\cdot\left(\frac{4}{\alpha k_0}-\frac{\beta}{\alpha^2}-\frac{1}{\tau_i}\frac{d\tau_i}{dE}\right)-\frac{\kappa Tk_0^4}{\Lambda\alpha^2}\left(\frac{T}{\Theta}\right)^3\left\{\frac{1}{\alpha k_0}+\frac{2\pi^2q_0^2}{3k_0^2}\left(\frac{T}{\Theta}\right)^2\left(\frac{1}{\alpha k_0}-\frac{\beta}{\alpha^2}\right)\right\}P_6, \tag{73}$$

$$d_{11}=\frac{k_0^4}{\Lambda\alpha^2}\left(\frac{T}{\Theta}\right)^3\left\{1+\frac{\pi^2q_0^2}{3k_0^2}\left(\frac{T}{\Theta}\right)^2\right\}J_5+\frac{\pi^2\hbar k_0^4}{3\tau_i\alpha}, \tag{74}$$

$$\beta_0^{(2)}=-\frac{3\pi^2\kappa T}{\Delta}\left(\frac{T}{\Theta}\right)^3 P_5, \tag{75}$$

and

$$\varepsilon=\frac{\kappa^2T^2k_0^4}{q_0^2}\left(\frac{T}{\Theta}\right)P_4, \tag{76}$$

where

$$J_n\equiv\int_0^{\theta/T}\frac{z^ndz}{(e^z-1)(1-e^{-z})}, \tag{77}$$

$$P_n\equiv\int_0^{\theta/T}\frac{1}{z+\Gamma}\frac{z^ndz}{(e^z-1)(1-e^{-z})}. \tag{78}$$

If we put (72), (73) and (74) into (56) through (66), we find

$$\sigma=\frac{\sigma_e}{1-\delta_1}\,, \qquad \rho=\rho_e(1-\delta_1)\,, \tag{79}$$

$$\kappa_T=\kappa_e+\kappa_g\,, \tag{80}$$

$$S=S_e(1+\delta_2)+S_g\,, \tag{81}$$

$$R_H=R_{H,e}\,, \tag{82}$$

$$A_E=A_{E;e}\frac{1-\delta_3}{1+\kappa_g/\kappa_e}\,, \tag{83}$$

$$B^i_{EN}=B^i_{EN,e}(1-\delta_3)\,, \tag{84}$$

$$B_{RL}=\frac{B_{RL,e}}{1+\kappa_g/\kappa_e}\,, \tag{85}$$

where suffices e's denote the values of respective quantities in the case of the equilibrium distribution of the phonons (they have been given in I and III), κ_g is the lattice thermal conductivity in the case of the equilibrium electron distribution, S_g is the thermoelectric power produced by the "phonon drag" and δ_1, δ_2, δ_3 show the effect of the "reaction" term in Eq. (42). δ_1, δ_2, δ_3, S_g and κ_g/κ_e are given by

$$\delta_1=\frac{\Lambda^{-1}q_0{}^2(T/\Theta)^5P_6}{\tau_i{}^{-1}\hbar\alpha k_0{}^2+\Lambda^{-1}q_0{}^2(T/\Theta)^5J_5}\,, \tag{86}$$

$$\delta_2=\frac{\Lambda^{-1}\left(\frac{T}{\Theta}\right)^3\left\{\frac{1}{\alpha k_0}-\frac{\pi^2q_0{}^2}{3k_0{}^2}\left(\frac{T}{\Theta}\right)^2\left(\frac{1}{\alpha k_0}+\frac{2\beta}{\alpha^2}\right)\right\}P_6}{\frac{\pi^2\hbar\alpha}{3\tau_i}\left(\frac{2}{\alpha k_0}+\frac{\beta}{\alpha^2}+\frac{1}{\tau_i}\,\frac{d\tau_i}{dE}\right)+\frac{1}{\Lambda}\left(\frac{T}{\Theta}\right)^3\left\{\frac{2}{\alpha k_0}+\frac{2\pi^2q_0{}^2}{3k_0{}^2}\left(\frac{T}{\Theta}\right)^2\left(\frac{2}{\alpha k_0}+\frac{\beta}{\alpha^2}\right)\right\}J_5}\,, \tag{87}$$

$$\delta_3=\frac{\frac{1}{\Lambda}\left(\frac{T}{\Theta}\right)^3\left\{\frac{1}{\alpha k_0}-\frac{\pi^2q_0{}^2}{3k_0{}^2}\left(\frac{T}{\Theta}\right)^2\left(\frac{1}{\alpha k_0}+\frac{2\beta}{\alpha^2}\right)\right\}P_6}{\frac{\pi^2\hbar\alpha}{3\tau_i}\left(\frac{1}{\alpha k_0}-\frac{\beta}{\alpha^2}-\frac{1}{\tau_i}\,\frac{d\tau_i}{dE}\right)+\frac{1}{\Lambda}\left(\frac{T}{\Theta}\right)^3\left\{\frac{1}{\alpha k_0}-\frac{\pi^2q_0{}^2}{3k_0{}^2}\left(\frac{T}{\Theta}\right)^2\left(\frac{1}{\alpha k_0}+\frac{2\beta}{\alpha^2}\right)\right\}J_5}\,, \tag{88}$$

$$S_g=-\frac{\kappa}{e}\left(\frac{T}{\Theta}\right)^3P_5\,, \tag{89}$$

$$\frac{\kappa_g}{\kappa_e}=\left[\frac{9\hbar^2}{\tau_i\kappa^2Tk_0{}^2\alpha}+\frac{27\hbar}{\pi^2\Lambda\kappa^2Tk_0{}^2\alpha^2}\left(\frac{T}{\Theta}\right)^3\left\{1+\left(\frac{T}{\Theta}\right)^2\frac{\pi^2q_0{}^2}{3k_0{}^2}\right\}J_5\right]\frac{\Lambda k_0{}^4\alpha^2\kappa^2\Theta}{3\pi^2\hbar q_0{}^2}\left(\frac{T}{\Theta}\right)^2P_4\,, \tag{90}$$

respectively.

§ 4. Discussion

For a special case of the quasi-free electron model, we put $\alpha=\hbar^2k_0/m^*$ and $\beta=\hbar^2/m^*$, m^* being the effective mass, and then (79) and (80) coincide prefectly with the interpolation formulae derived by Hanna and Sondheimer⁴⁾. However, Eq. (81) differs from the result of Hanna and Sondheimer, in the point that the latter does not have the term δ_2S_e. For an ideally pure metal ($\tau_i\to\infty$) and at low temperatures, if we assume that the phonons were scattered only by the electrons, P_6 would tend to J_5 and so $\delta_1\to1$, $\delta_2\to1/2$ and $\delta_3\to1$. However, in reality, in most cases, P_6 is smaller than J_5 and $1/\tau_i$ does not vanish, and so δ_1, δ_2 and δ_3 are considerably smaller than unity. Therefore the effects of the "reaction" can be neglected in many cases*. On the contrary, as pointed out by L. E. Gurevich¹¹⁾ and Hanna and Sondheimer[4], the phonon drag term of the thermoelectric power S_g may become considerably large, at low temperatures.

---

* An Approximation used by Parrott⁷⁾ in the calculation of the Ettingshausen-Nernst effect in the semiconductors is equivalent to the neglect of the "reaction" effect.

Eq. (80) shows that the change of the lattice part of the thermal conductivity due to the non-equilibrium electrons is perfectly cancelled out by the change of the electronic part of the thermal conductivity due to the non-equilibrium phonons. Therefore the calculation of the change of the lattice part of the thermal conductivity by Paul[12] is meaningless and Paul's discussion on the change of the thermomagnetic effects due to the change of the lattice part of the thermal conductivity is also invalid.

Eq. (82) shows that the Hall coefficient is not altered by the phonon drift due to the electric current J_x. This may easily be understood as follows. If $F_y=0$, the magnetic field will produce the Hall current $J_{y,H}$ which is proportional to J_x and H. In reality, as an experimental condition, we put $J_y=0$ and so there appeares F_y which is given by the product of $-J_{y,H}$ and the transverse resistivity ρ_y. Now, the total current is in the x-direction and so ρ_x is modified as shown by (79), but ρ_y remains to be ρ_e. Therefore the Hall constant R_H $(=F_y/HJ_x)$ is not modified by the phonon drift in the x-direction.

The factor $(1+\kappa_g/\kappa_e)^{-1}$ in (83) is explained as follows. The magnetic field H produces a heat current $w_{y,H}$ which is proportional to J_x and H. Experimentally, we put $w_y=0$, and so there appeares a temperature gradient $\partial T/\partial y$ which is proportional to $w_{y,H}$ and inversely proportional to the thermal conductivity $\kappa_T=\kappa_e(1+\kappa_g/\kappa_e)$. Therefore, the Ettingshausen coefficient A_E $(=-(\partial T/\partial y)/HJ_x)$ becomes proportional to $(1+\kappa_g/\kappa_e)^{-1}$.

In the case of the Ettingshausen-Nernst effect, the magnetic field produces an electric current J_y which is proportional to the electronic part of the heat current w_x (i.e., proportional to $\kappa_e\partial T/\partial x$ and not $\kappa_T\partial T/\partial x$), and so $B^i_{EN}(=-F_y/H(\partial T/\partial x))$ does not depend on κ_g. Finally, in the case of the Righi-Leduc effect, the magnetic field produces an electronic heat current $w_{y,H}$ which is proportional to $\kappa_e\partial T/\partial x$. Experimentally, we put $w_y=0$, and so there appear a temperature gradient $\partial T/\partial y$ which is proportional to $w_{y,H}$ and inversely proportional to $\kappa_T=\kappa_e+\kappa_g$. Therefore the Righi-Leduc coefficient B_{RL} $(=(\partial T/\partial y)/H(\partial T/\partial x))$ is proportional to $(1+\kappa_g/\kappa_e)^{-1}$. The factor $(1+\kappa_g/\kappa_e)^{-1}$ appeared in (83) and (85) shows the effect of the fact that the heat current is carried by the phonons as well as by the electrons. We shall call the effect simply "the lattice conductivity effect". The "phonon drag" effect does not appear in (83), (84) and (85) (See § 6). Now for the pure metals, κ_g is usually very smaller than κ_e[16], and so we may conclude that, in the spherical band model, the non-equilibrium distribution of the phonons does not give so large contributions to the transverse galvanomagnetic and thermomagnetic effects as the contribution S_g in the thermoelectric power. This conclusion differs from those of Paul[12] and L. E. Gurevich[11] on the Ettingshausen-Nernst effect. Paul's calculation of A_{EN} $(=B^i_{EN}/\kappa_T)$ starts from a first order approximation

$$eF_y=-\frac{\pi^2}{2}\frac{eH\tau}{mc}\frac{\zeta}{T}\frac{\partial T}{\partial x}, \tag{91}$$

which gives as a first order approximation of B^i_{EN},

$$B^i_{EN}=\frac{\pi^2\tau\zeta}{2mcT}. \tag{92}$$

However, the exact first order approximation is given by

$$B^i_{EN}=\frac{\pi^2\kappa^2T}{3mc}\frac{\partial\tau}{\partial\zeta}=\frac{\pi^2\kappa^2\tau T}{2mc\zeta}, \tag{93}$$

where we put $\tau\propto E^{3/2}$ (high temperature and free electron approximation). Therefore Paul's result on the Ettingshausen-Nernst coefficient is not valid. L. E. Gurevich[11] calculated the electric current $\boldsymbol{J}$ from a Boltzmann equation in which usual drift term was replaced by a phonon drift term (corresponds to the last terms of (40) and (41)), expanded $\boldsymbol{J}$ in a power series of $\boldsymbol{H}$ and derived the "Nernst's current" $\boldsymbol{J}_N$ from the first order term of $\boldsymbol{H}$. In actuality, the experimental condition of the Ettingshausen-Nernst effect is $J_x=J_y=0$, and so the derivation of L. E. Gurevich seems to be invalid.

We have derived, in I and III, certain relations between the coefficients. Here we shall reexamine these relations in the case of the non-equilibrium distribution of the phonons. From (83) and (84) of this paper and (47) of III, we see that Bridgmann's relation

$$\frac{B_{EN}^{i}}{\kappa_T}\equiv A_{EN}^{i}=\frac{A_E}{T}\,, \tag{94}$$

holds also in the case of the non-equilibrium distribution of the phonons. This is a natural consequence of the Onsager relations (21), (22) and (23)[17]. (Paul's results do not satify this relation. See his Eqs. (38) and (43).) From (82), (83), (84) and (85), we see that the relation (48) of III is modified as

$$\frac{R_H B_{EN}^{i}}{A_E B_{RL}}\left(=\frac{R_H \kappa_T}{T B_{RL}}\right)=\frac{\pi^2}{3}\left(\frac{\kappa}{e}\right)^2\left(1+\frac{\kappa_g}{\kappa_e}\right)^2. \tag{95}$$

Further, if we neglect the small corrections δ_2 and δ_3 in (81) and (83), we have

$$\frac{1}{T}\left\{ncA_E\left(1+\frac{\kappa_g}{\kappa_e}\right)+\frac{3e}{\pi^2\kappa^2}S\right\}=-\frac{3}{\alpha k_0}-\frac{3e}{\pi^2\kappa^2 T}S_g\,, \tag{96}$$

which is a corrected formula of (61) of III.

Now for the impure metals or alloys at low temperatures, κ_g may become comparable with κ_e[16], and then the correction due to the "lattice conductivity effect" in A_E and B_{RL} may become important.

The results derived in this section is based on the spherical band model. In the next section, we show that the cubic anisotropy in the band structure does not alter the general situation of the electrical and thermal conductivities and the thermoelectric power. Therefore, Eqs. (79), (80) and (81) may be good approximation for the alkali metals such as sodium and potasium in which the band structures are thought to be fairly spherical. As will be shown in § 6, however, the anisotropy gives the "phonon drag" effects for A_E, B_{EN}^{i} and B_{RL}, and this may become important at low temperatures. Therefore the spherical band model of the metals may be useless for the discussion of the "phonon drag" effects of these quantities.

§ 5. Cubic Anisotropic Band Model without Magnetic Field

In III, we have seen that the transverse galvano- and thermomagnetic effects of an anisotropic crystal having cubic symmetry can be calculated approximately by using the variation principle. Hence, at first, it is thought that the calculation described in the preceding section might be generalized to any cubic anisotropic band by replacing the function (28) by the function (15) of III. However, in reality, as shown in the following section, the departure of the distribution of the phonons from the equilibrium gives new contributions (phonon drag terms) to the Ettingshausen, Ettingshausen-Nernst and Righi-Leduc coefficients, which appear only in anisotropic media. Of course these new terms have not appeared in the calculation in § 3. Moreover, if we generalize the calculation in § 3 simply by replacing the function (28) by the function (15) of III, we can not obtain the new terms. This is due to the fact that our method used in III is useless for the calculation of the quantities such as magnetoresistance to which the anisotropy is essentially important, namely the quantities which vanish for isotropic media.

Therefore, in this section we shall limit our calculation only to the case with no magnetic field. This is a simple generalization of the calculations in the reference (5), and so we write only the final results. Let the electric field F and the temperature gradient be in the x-direction. The Boltzmann equations can be written in the forms

$$L_1(\Phi_k)+L_2(\Psi_q)=\frac{1}{\hbar}\left(eF-T\frac{\partial}{\partial x}\,\frac{E-\zeta}{T}\right)\frac{\partial E}{\partial k_x}\,\frac{\partial f_0}{\partial E}\,, \tag{97}$$

$$L_3(\Phi_k)+L_4(\Psi_q)=-u_x\frac{\partial T}{\partial x}\frac{\partial N_0}{\partial T}\,. \tag{98}$$

Eliminating Ψ_q from (97) and (98), we have

$$L(\Phi_k)=\frac{1}{\hbar}\left(eF-T\frac{\partial}{\partial x}\frac{E-\zeta}{T}\right)\frac{\partial E}{\partial k_x}\frac{\partial f_0}{\partial E}+\frac{\partial T}{\partial x}L_2L_4^{-1}\left(u_x\frac{\partial N_0}{\partial T}\right), \tag{99}$$

where

$$L\equiv L_1-L_2L_4^{-1}L_3\,, \tag{100}$$

and L satisfies the symmetry relation (5). The second term of the right side of (100) represents the "reaction" and the second term of the right side of (99) represents the "phonon drag". As an approximate trial function, we put

$$\Phi_k=\frac{\partial E}{\partial k_x}(c_0+c_1\eta)\,. \tag{101}$$

After a calculation similar to that in § 3, we find

$$\sigma=\frac{e^2(\alpha_0^{(1)})^2}{4\pi^3\hbar d_{00}}\,, \tag{102}$$

$$\kappa_T=\kappa_e+\kappa_g\,, \tag{103}$$

$$\kappa_e=\frac{\{\alpha_1^{(1)}\alpha_0^{(2)}-\alpha_0^{(1)}\alpha_1^{(2)}\}^2}{4\pi^3\hbar T(\alpha_0^{(1)})^2 d_{11}}\,, \tag{104}$$

$$\kappa_g=\frac{\mathcal{E}}{4\pi^3\hbar T}\,, \tag{105}$$

$$S=S_e+S_g\,, \tag{106}$$

$$S_e=-\frac{\kappa}{e}\left\{\frac{\alpha_1^{(1)}}{\alpha_0^{(1)}}-\frac{\alpha_2^{(1)}d_{01}}{\alpha_0^{(1)}d_{11}}+\frac{\alpha_1^{(1)}\alpha_2^{(1)}d_{00}}{(\alpha_0^{(1)})^2 d_{11}}\right\}, \tag{107}$$

$$S_g=-\frac{1}{eT}\frac{\beta_0^{(2)}}{\alpha_0^{(1)}}\,, \tag{108}$$

where

$$\alpha_r^{(n)}=\int\left(\frac{\partial E}{\partial k_x}\right)^2E^{n-1}\eta^r\frac{\partial f_0}{\partial E}dk\,, \tag{109}$$

$$d_{rs}=\hbar\int\frac{\partial E}{\partial k_x}\eta^r L\left(\frac{\partial E}{\partial k_x}\eta^s\right)dk\,, \tag{110}$$

$$\mathcal{E}=-\frac{(\kappa\Theta)^2}{2\hbar q_0^4}\left(\frac{\Theta}{T}\right)^2\int q_x L_4^{-1}\left(q_x\frac{\partial N_0}{\partial z}\right)\frac{\partial N_0}{\partial z}dq\,, \tag{111}$$

$$\beta_0^{(2)}=-\frac{\kappa T}{q_0^2}\left(\frac{\Theta}{T}\right)^2\int\frac{\partial E}{\partial k_x}L_2L_4^{-1}\left(q_x\frac{\partial N_0}{\partial z}\right)dk\,. \tag{112}$$

Eq. (104) is identical with Eq. (22) of II, and if we neglect the small effect of the "reaction", σ and S_e given by (102) and (107) become identical with (21) and (23) of II, respectively. Eq. (108) gives the "phonon drag effect" on the thermoelectric power.

It is shown, in the following section, that Eqs. (102) through (108) give the exact results, if the collision operator L is represented by a relaxation time depending only on the electronic energy E_k. Further, in the case of the spherical energy band, these equations reduce to those derived in § 3. There appeares no essentially new term by the introduction of the cubic anisotropy.

§6. Special Case with Magnetic Field

In this section, we treat only a special case in which the collision operator L is represented by a relaxation time which depends only on the energy of the electron E_k. Assuming the equilibrium distribution of the phonons, we have calculated the transverse galvanomagnetic and thermomagnetic effects for the metals having the energy dependent relaxation time (§5 of III). We show below that, if we take into account the departure of the distribution of the phonons from equilibrium, new terms which vanish in the case of the spherical band, appear in the Ettingshausen, Ettingshausen-Nernst and Righi-Leduc coefficients. Now the Boltzmann equations (3) and (4) can be rewritten in the forms

$$L_1(\varPhi_k)+L_2(\varPsi_k)=\frac{1}{\hbar}\left(eF_x+T\frac{\partial}{\partial x}\frac{\zeta}{T}+\frac{E}{T}\frac{\partial T}{\partial x}\right)\frac{\partial E}{\partial k_x}\frac{\partial f_0}{\partial E}+\frac{1}{\hbar}\left(eF_y+T\frac{\partial}{\partial y}\frac{\zeta}{T}+\frac{E}{T}\frac{\partial T}{\partial y}\right)\frac{\partial E}{\partial k_y}\frac{\partial f_0}{\partial E}+\frac{eH}{\hbar^2 c}\frac{\partial f_0}{\partial E}\varOmega_3\varPhi_k\,, \tag{113}$$

$$L_3(\varPhi_k)+L_4(\varPsi_q)=-u_x\frac{\partial T}{\partial x}\frac{\partial N_0}{\partial T}-u_y\frac{\partial T}{\partial y}\frac{\partial N_0}{\partial T}\,, \tag{114}$$

where

$$\varOmega_3=\frac{\partial E}{\partial k_x}\frac{\partial}{\partial k_y}-\frac{\partial E}{\partial k_y}\frac{\partial}{\partial k_x}\,. \tag{115}$$

Eliminating $\varPsi(\boldsymbol{q})$ from (113) and (114), we have

$$L(\varPhi_k)=\frac{1}{\hbar}\left(eF_x+T\frac{\partial}{\partial x}\frac{\zeta}{T}+\frac{E}{T}\frac{\partial T}{\partial x}\right)\frac{\partial E}{\partial k_x}\frac{\partial f_0}{\partial E}+\frac{1}{\hbar}\left(eF_y+T\frac{\partial}{\partial y}\frac{\zeta}{T}+\frac{E}{T}\frac{\partial T}{\partial y}\right)\frac{\partial E}{\partial k_y}\frac{\partial f_0}{\partial E}+\frac{eH}{\hbar^2 c}\frac{\partial f_0}{\partial E}\varOmega_3\varPhi_k+\frac{\partial T}{\partial x}L_2L_4^{-1}\left(u_x\frac{\partial N_0}{\partial T}\right)+\frac{\partial T}{\partial y}L_2L_4^{-1}\left(u_y\frac{\partial N_0}{\partial T}\right)\,. \tag{116}$$

where L is given by (100).

Now we shall consider a special case in which $L(\varPhi)$ is given by

$$L(\varPhi)=-\frac{1}{\tau}\frac{\partial f_0}{\partial E}\varPhi\,, \tag{117}$$

where we assume that the relaxation time τ depends only on the energy of the electron E_k. By the method of the successive approximations, we can obtain the solution of (116) in a power series of H. Here we need to calculate only up to the first order term of H. From the solution $\varPhi_k$, we easily obtain the contribution of the electrons to K_{mn}. In the calculation, we use the fact that, for a cubic crystal, K_{11}, K_{22}, $K_{12}=K_{21}$ are the even functions of H and K_{13}, K_{21}, $K_{11}=K_{23}$ are the odd functions of H. This can be proved easily, by using the relations (21), (22) and (23). Putting the solution $\varPhi_k$ into (114), we have $\varPsi_k$. Then we can calculate the phonon contribution to K_{2n}, by using the formula of the lattice heat current

$$\boldsymbol{w}=\frac{1}{8\pi^3}\int \boldsymbol{u}T\varPsi_q\frac{\partial N_0}{\partial T}d\boldsymbol{q}\,. \tag{118}$$

The final results are

$$K_{11}=-\frac{1}{4\pi^3\hbar^2}\int\left(\frac{\partial E}{\partial k_x}\right)^2\tau\frac{\partial f_0}{\partial E}d\boldsymbol{k}\,, \tag{119}$$

$$K_{12}=K_{21}=-\frac{1}{4\pi^3\hbar^2}\int\left(\frac{\partial E}{\partial k_x}\right)^2 E\tau\frac{\partial f_0}{\partial E}d\boldsymbol{k}-\frac{T}{4\pi^3\hbar}\int\left(\frac{\partial E}{\partial k_x}\right)\tau L_2L_4^{-1}\left(u_x\frac{\partial N_0}{\partial T}\right)d\boldsymbol{k}\,, \tag{120}$$

$$K_{13}=-\frac{eH}{4\pi^3\hbar^4 c}\int\left(\frac{\partial E}{\partial k_x}\right)\tau\varOmega_3\left(\tau\frac{\partial E}{\partial k_y}\right)\frac{\partial f_0}{\partial E}d\boldsymbol{k}\,, \tag{121}$$

$$K_{14}=K_{23}=-\frac{eH}{4\pi^3\hbar^4c}\int\frac{\partial E}{\partial k_x}\tau\Omega_3\left(\tau E\frac{\partial E}{\partial k_y}\right)\frac{\partial f_0}{\partial E}d\boldsymbol{k}$$
$$-\frac{TeH}{4\pi^3\hbar^3c}\int\frac{\partial E}{\partial k_x}\tau\Omega_3\left\{\tau L_2L_4^{-1}\left(u_y\frac{\partial N_0}{\partial T}\right)\right\}d\boldsymbol{k}\,, \tag{122}$$

$$K_{22}=-\frac{1}{4\pi^3\hbar^2}\int\left(\frac{\partial E}{\partial k_x}\right)^2E^2\tau\frac{\partial f_0}{\partial E}d\boldsymbol{k}-\frac{T}{2\pi^3\hbar}\int\frac{\partial E}{\partial k_x}E\tau L_2L_4^{-1}\left(u_x\frac{\partial N_0}{\partial T}\right)d\boldsymbol{q}$$
$$+\frac{T^2}{8\pi^3}\int u_xL_4^{-1}\left(u_x\frac{\partial N_0}{\partial T}\right)\frac{\partial N_0}{\partial T}d\boldsymbol{q}\,, \tag{123}$$

$$K_{24}=-\frac{eH}{4\pi^3\hbar^4c}\int\frac{\partial E}{\partial k_x}E\tau\Omega_3\left(\tau E\frac{\partial E}{\partial k_y}\right)\frac{\partial f_0}{\partial E}d\boldsymbol{k}$$
$$-\frac{TeH}{2\pi^3\hbar^3c}\int\frac{\partial E}{\partial k_x}E\tau\Omega_3\left\{\tau L_2L_4^{-1}\left(u_y\frac{\partial N_0}{\partial T}\right)\right\}d\boldsymbol{k}\,. \tag{124}$$

The second terms of K_{12} and K_{14} are the phonon drag terms of the electric current. Using (119) through (124), we can calculate all the quantities required. The results for σ, κ_e and S are identical with (102) through (108) if we replace only the operator L by $-(1/\tau)\partial f_0/\partial E$. This fact guarantees that the procedure used in § 4 is an useful approximation. For the galvano- and thermomagnetic coefficients, we have

$$R_H=-\frac{4\pi^3}{ec}\frac{f_5}{f_1^2}\,, \tag{125}$$

$$A_E=\frac{4\pi^2T}{c}\frac{\left[f_5\left(\frac{1}{\tau}\frac{d\tau}{dE}-\frac{1}{f_1}\frac{\partial f_1}{\partial E}+\frac{1}{f_5}\frac{\partial f_5}{\partial E}\right)-\frac{3}{\pi^2\kappa^2T^2f_1}(f_1\xi_0^{(2)}-f_5\beta_0^{(2)})\right]}{f_1^2\left(1+\frac{\kappa_g}{\kappa_e}\right)}\,, \tag{126}$$

$$B_{EN}^{i}=\frac{\pi^2\kappa^2T\tau}{3\hbar^2cf_1}\left[f_5\left(\frac{1}{\tau}\frac{d\tau}{dE}-\frac{1}{f_1}\frac{\partial f_1}{\partial E}+\frac{1}{f_5}\frac{\partial f_5}{\partial E}\right)-\frac{3}{\pi^2\kappa^2T^2f_1}(f_1\xi_0^{(2)}-f_5\beta_0^{(2)})\right]\,, \tag{127}$$

$$B_{RL}=-\frac{e\tau}{\hbar^2c}\frac{\left[f_5-\frac{6\zeta}{\pi^2\kappa^2T^2f_1}(f_1\xi_0^{(2)}-f_5\beta_0^{(2)})\right]}{f_1\left(1+\frac{\kappa_g}{\kappa_e}\right)}\,, \tag{128}$$

where f_1 and f_5 are given by (29) and (28) of III, and

$$\beta_0^{(2)}=-T\hbar\int\frac{\partial E/\partial k_x}{|\mathrm{grad}_{\boldsymbol{k}}E|}L_2\left\{L_4^{-1}\left(u_x\frac{\partial N_0}{\partial T}\right)\right\}\left(\frac{\partial f_0}{\partial E}\right)^{-1}dS\,, \tag{129}$$

$$\xi_0^{(2)}=-T\hbar\int\frac{1}{|\mathrm{grad}_{\boldsymbol{k}}E|}\Omega_3\left(\frac{\partial E}{\partial k_y}\right)L_2\left\{L_4^{-1}\left(u_x\frac{\partial N_0}{\partial T}\right)\right\}\left(\frac{\partial f_0}{\partial E}\right)^{-1}dS\,. \tag{130}$$

where the integrations are carried over the Fermi surface. (Note that L_2 has a factor $\partial f_0/\partial E$ and (129) is identical with (112).) The second terms of the numerators of (126), (127) and (128) give the phonon drag effects. If we neglect these phonon drag terms, κ_g/κ_e in (126) and (128) and the "reaction term" in $1/\tau$, (125) through (128) become identical with (40), (52), (53) and (54) in III. Now for the spherical band model we can show easily that

$$f_1\xi_0^{(2)}-f_5\beta_0^{(2)}=0\,, \tag{131}$$

and if we replace $\mathscr{L}$ in § 3 by $-\hbar/\tau$, we see that the results obtained in § 3 are identical with those obtained in this section. Therefore the procedures used in § 3 are justified to be approximately valid for the spherical band model. Eq. (131) shows that the phonon drag effects do not appear in the transverse galvano- and thermomagnetic effects of the isotropic metals. In the case of the spherical band model, we have

$$\frac{\beta_0^{(2)}}{f_1}=-\kappa T\left(\frac{T}{\Theta}\right)^3P_5\,. \tag{132}$$

Therefore, if the second terms of the numerators of (126), (127) and (128) do not cancell out for a cubic anisotropic band, the ratios of the second terms to the first terms are of the order of magnitude of

$$\sim \frac{\zeta}{\kappa\Theta}\left(\frac{T}{\Theta}\right)^2 P_5 . \tag{133}$$

From the definition of P_n, we see that P_5 is always smaller than J_4. However, if the phonons are scattered predominantly by the electrons, P_5 becomes to be of the same order of magnitude as J_4 and so, at low temperatures, (133) becomes $\sim\zeta/\kappa T$. Therefore, there is a possibility that for a cubic anisotropic metal, the non-equilibrium distribution of the phonons gives fairly large contributions to the Ettingshausen, Ettingshausen-Nernst and Righi-Leduc effects, at low temperatures. This may be detected experimentally for the pure noble metals at low temperatures.

As a matter of course, (126) and (127) satisfy the Bridgmann relation (94). The relations (95) and (96), however, do not hold for the anisotropic media in which the cancelation (131) does not hold.

The cancellation of (131) is based on the Fermi statistics. Exactly speaking, the left side of (131) is of the order of $(\kappa T/\zeta)^2$ times $f_1\zeta_0^{(2)}$ or $f_5\beta_0^{(2)}$, for highly degenerate Fermi gas. For the non-degenerate semiconductors, owing to the Boltzmann statistics, the phonon drag terms do not vanish, even if the band structures are spherical, and so the phonon drag effects do appear in the Ettingshausen-Nernst coefficient *etc.* of the semi-conductors[7),8),9)]. If the band structure of the semiconductor is anisotropic, however, the phonon drag effects become larger than those of the isotropic semiconductor. The significan of the anisotropy in the cubic semiconductor has been pointed out by Herring *et al.*[1)]

Unfortunately, the measurements of the Ettingshausen, Ettingshausen-Nernst and Righi-Leduc coefficients of the monovalent metals at low temperatures have never been worked out, and so we can not, at present, compare our results with experiment.

Added Note. After communication to the editors, I became aware of the paper of G. E. Tauber (Canad. J. Phys. **36** (1958) 1308), in which he formulated a generalized variational principle by taking into account the phonon distribution functions and the external magnetic field. His formulation is a generalization of that of Dorn (Z. Naturforsch. **12a** (1957) 739) in the case of the presence of the magnetic field. We discussed the relation between our method and Dorn's one in ealier paper[5)]. The discussion would also hold for the relation between the Tauber's method and the method described in this paper.

Theoretical Treatment of the Movement of 180° Domain in $BaTiO_3$ Single Crystal

By Ryuji ABE

Faculty of Science, Nagoya University, Nagoya, Japan

(Received January 8, 1959)

A theoretical treatment was proposed for the movement of wedge-shaped 180° domains in $BaTiO_3$ single crystal. It was proved that the experimental relations found by Merz can be explained satisfactorily by considering this new mechanism of the domain motion. Further a few quantitative examinations were made and it was ascertained that there is no clear quantitative inconsistency between the theoretical relations and Merz's experimental relations.

§ 1. Introduction

A few years ago Merz observed 180° domains of $BaTiO_3$ single crystal by his original means, and with his cooperator[1] he succeeded in creating single crystals composed of only 180° domains. Using these crystals he studied their dynamic characteristics[2] by electrical means and found that there are simple relations between applied field and maximum of the induced current. To explain these relations, he assumed that at high fields the maximum of the current is determined by the growth process of nuclei while at low fields the maximum is determined mainly by the nucleation process of these nuclei. Then he proved that if the shape of a nucleus is a long flat dagger, the latter relation can be explained.

This experimental result and his explanation are very interesting because they are useful to study the properties of 180° wall. His explanation, however, is not satisfactory, because it contains a few questionable points. Furthermore no detailed explanation is given for the simple relation found at high fields. Therefore to explain these relations satisfactorily a more precise investigation on the movement of 180° domain should be made.

In the present paper a new treatment of the movement of 180° domain will be proposed, after Merz's explanation is examined. Then it will be proved that Merz's experimental relations can be explained saisfactorily by using this new treatment.

§ 2. Examination of Merz's Explanation

To fascilitate the later explanation, a brief review of Merz's experimental result and his explanation will be given at first. He applied square pulses to crystals and observed the induced current by cathode ray tube (Fig. 1). Then he plotted maximum of the current *versus* applied field (Fig. 2) and found from such figures that the current changes linearly with field at high fields, while it changes proportionally to $\exp(-(1/E))$ at low fields.

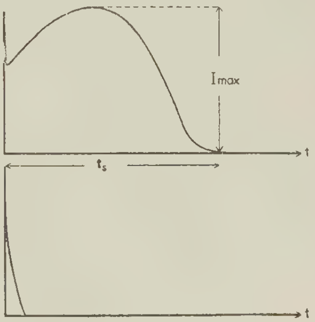

Fig. 1. Switching current *versus* time (after Merz).
Upper: when a field against the polarization is applied.
Lower: when a field for the polarization is applied.

To explain the former relation he assumed simply that the wall velocity changes linearly with the change of applied field, while to explain the latter relation he assumed that the maximum of the current is proportional to the nucleation rate of the new domain with antiparallel polarization and that the shape of the domain is a long flat dagger with a length l (in the direction of field) and a cross dimension $t \times w$ ($l \gg w > t$). The free energy of the new domain is then given by

$$\Delta F = -2EP_s lwt + \sigma_{W'}(wl + tl) + \sigma_{W''}wt \quad (1)$$

where P_S is the spontaneous polarization, $\sigma_{W'}$ is the wall energy/cm² of the side walls and $\sigma_{W''}$ is the wall energy/cm² of the front wall. The effects of the depolarizing field are neglected here because the new domain is very long and thin. Then assuming further that the nucleation rate is proportional to

$$\exp(-(\Delta F^*/kT))$$

and a width of the domain w is constant during the nucleation process, it can be obtained that

$$i_{\max} \propto \exp\left(-\frac{\Delta F^*}{kT}\right) = \exp\left(-\frac{w}{2}\frac{\sigma_{W'}\sigma_{W''}}{kTEP_S}\right) \tag{2}$$

where ΔF^* is the maximum of the free energy.

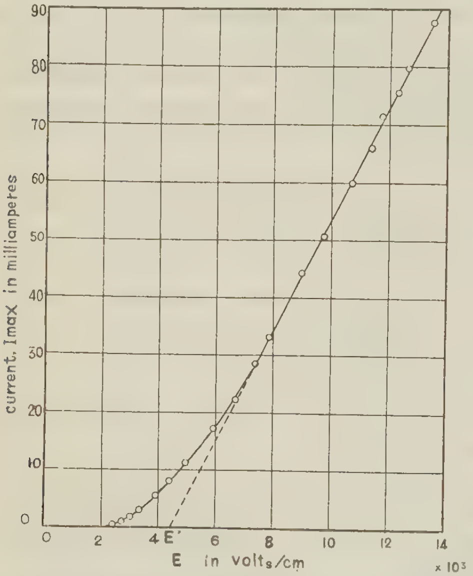

Fig. 2. Switching current *versus* applied field (after Merz).

Merz's explanation, however, contains a few questionable points. The first point is that Merz assumes that the free energy of a nucleus changes continuously with the change of its volume. Certainly this assumption is correct for the very large nucleus of which free energy can be considered to change continuously against the discontinuous change of the radius or the length by an unit lattice spacing. For the BaTiO$_3$ crystal, however, such a large nucleus can not appear within a few seconds, because the free energy of the nucleus is much higher than kT. This can be seen as follows: suppose that the nucleus is a long prolate spheroid with the radius r and the length l. The free energy of the nucleus is given by

$$\Delta F = -\frac{4}{3}\pi P_S E r^2 l + 4\pi\sigma_W r l + \frac{d}{2}\frac{4}{3}\pi\frac{r^4}{e}P_S^2 \dagger \tag{3}$$

where $d=4\pi(\log(l/r)-1)$. This free energy becomes maximum at $r=r^*$ and the maximum value is given by

$$\frac{4}{3}\pi P_S(d\sigma_W)^{1/2}(r^*)^{5/2} .$$

Since this maximum free energy must be of the order of kT in order that the new domain can be nucleated within a few seconds, the radius of the domain should be restricted to be

$$r^* \lesssim \left(\frac{3}{4\pi}\frac{kT}{P_S(d\sigma_W)^{1/2}}\right)^{5/2} . \tag{4}$$

Putting that $P_S=7.8\times10^4$ esu, $kT=4\times10^{-14}$ esu, $\sigma_W=1.40$ esu (according to Kinase and Takahasi's result4)) and $d=16\pi$, this condition becomes

$$r^* \lesssim 1\times10^{-9}\ \text{cm} .$$

This result indicates that Merz's assumption is not appropriate for the BaTiO$_3$ crystal. The second point is that Merz neglects the energy due to the depolarizing field. Certainly this neglection is correct for the nucleus of which length is much longer than the cross diameters. For such long nucleus, however,

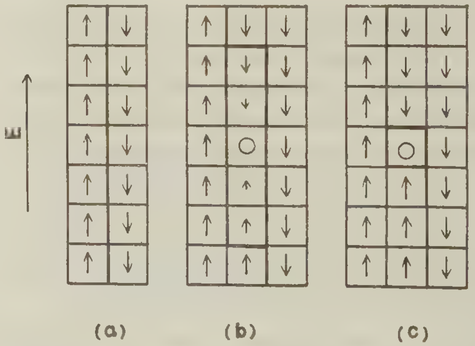

Fig. 3. Side wall and Front wall of 180° domain.
(a) 180° wall.
(b) Front wall with the thickness of 5 lattice spacings.
(c) Front wall with the thickness of one lattice spacing.

[†] The depolarizing energy is underestimated by the factor of $1/\varepsilon$ by Landauer3), because he assumes that the crystal is a linear dielectric, where ε is the dielectric constant of the crystal.

the wall energy of the front wall (the last term in Eq. (1)) may be also much smaller than the energy of the side walls (the second term in Eq. (1)). In fact it can be proved for a long prolate spheroid that the former is much smaller than the latter whenever the depolarizing energy is much small than the wall energy of the front wall.† Thus Merz's explanation by the dagger model may be also inappropriate to explain the relation $I_{\max}\propto e^{-(1/E)}$. The third points is that Merz uses two different mechanisms i.e. both nucleation and growth in explainning his experimental relations. Namely he explains the relation $I_{\max}\propto e^{-(1/E)}$ at low fields by the nucleation of new domains, while he explains the relation $I_{\max}\propto(E-E')$ at high fields by the growth of the nucleated domains. His explanation, however, seems to be rather artificial. As stated before, Merz assumes that at high fields the wall velocity of every nucleus is proportional to $(E-E')$. If this relation should be also kept at low fields, no growth of nuclei would occur by applying a field lower than the critical field E'. It will be easily seen that little current could be induced by applying the field, because, as proved above, by nucleation little current can be induced within a few seconds. This fact suggests that the observed relation at low fields should be also explained by considering the growth of 180° domains.

§ 3. Theoretical Treatment of the Movement of 180° Domain

Recently it has been proved by Kinase and Takahasi⁴⁾ that the 180° wall in the $BaTiO_3$ crystal has no thickness (Fig. 3(a)). On the other hand the front wall in the wedge-shape domain may have some thickness (Fig. 3(b)), because near the front wall the dipolar field acting on each Ti ion is quite different from the field near the 180° wall. The detailed study on the front wall is yet in progress by Kinase⁵⁾, and some informations were kindly given me by his private communication. Following discussions, accordingly, will be made by using these informations.

It has been proved by Kinase and Takahasi that Ti ion at the boundary of 180° wall can shifts its position to another stable position only when the applied field acting on the Ti ion satisfies the condition

$$3.246E\cdot e_{\mathrm{eff}}\geq\frac{\partial U^{i}}{\partial x}\qquad(5)$$

where e_{eff} is the effective charge of the Ti ion and $\partial U^{i}/\partial x$ is the gradient of the potential at the inflection point. The coefficient of E is determined by considering the modification of applied field in the crystal. The critical field satisfying this condition is evaluated to be 5.79×10^{6} volts/cm. This field is much higher than the field usually used in experiments ($\lesssim10^{4}$ volts/cm), hence the shift of Ti ion at the 180° boundary can not be caused only by the application of an outer field. Well then how high is the critical field for the front wall? In Fig. 4 the potentials in and near the front wall are shown schematically, assuming that the thickness of the front wall is 4 lattice spacings according to Kinase. Since the polarization should be continued fairly smoothly in the front wall,†† it will be correct to the rough approximation to

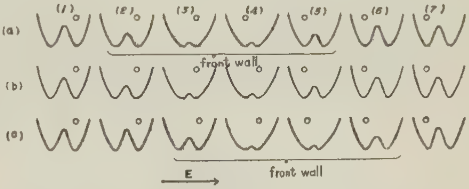

Fig. 4. Movement of front wall.
(a) When the field is abscent. (b) and (c) After applying the critical field. ○ Position of Ti ion.

---

† For a long prolate spheroid the free energy can be written approximately to be

$$\Delta F=4\pi\sigma_{W'}rl+2\pi r^{2}\sigma_{W''}+\frac{d}{2}\frac{4}{3}\pi\frac{r^{4}}{l}P_{S}^{2}\,.$$

In order that the depolarizing energy can be neglected in comparison with the wall energy of the front wall, the length should be limited to be

$$l\gg\frac{d}{3\sigma_{W''}}r^{2}P_{S}^{2}\,.$$

Then putting that $\sigma_{W'}=1.40$ esu⁴⁾, $\sigma_{W''}=80$ esu⁵⁾ and $d=16\pi$, it results in

$$\frac{\text{energy of the front wall}}{\text{energy of the side wall}}\ll7\times10^{-8}r^{-1}\,.$$

It will be seen from this relation that the energy of the front wall is negligible for real domains, because the right hand side of this relation is only of the order of unity even when $r=4\times10^{-8}$ cm.

†† This is caused by the fact that the dipoles, which are in head-to-tail relation, interact strongly with each other as proved by Kinase and Takahasi¹⁾.

assume that the polarization in the front wall changes linearly from lattice to lattice. Then the dipole moments in the front wall are given by $e_{\text{eff}}x' = \frac{1}{5}e_{\text{eff}}x_S$ for cells (3) and (4) and by $e_{\text{eff}}x'' = \frac{3}{5}e_{\text{eff}}x_S$ for cells (2) and (5) (Fig. 4(a)), where $e_{\text{eff}}x_S$ is the dipole moment in a cell that does not belong to the front wall and x', x'' and x_S are the displacements of each Ti ion from the center of each cell. According to Kinase and Takahasi, this displacement can be written in general to be

$$x = \sqrt{\frac{(-a'-a)}{2b}} \tag{6}$$

where a' is a negative constant relating with the dipole interaction, while a and b are positive constants relating with the van der Waal's and overlap interactions. Then using the relation

$$\frac{\partial U^i}{\partial x} = \frac{8}{3\sqrt{3}} x^3 b \tag{7}$$

and considering that b for the cell (4) is larger by about 10% than b for the normal cell e.g. cell (1),[†] the critical field for the Ti ion in cell (4) becomes

$$E^{(4)} \sim 5 \times 10^4 \text{ volts/cm}$$

which is still higher than the field usually applied in experiments. In Fig. 4(b) and Fig. 4(c) the displacements of Ti ions by applying this critical field are shown in dividing the process into two steps. It will be seen from Fig. 4(c) that a new front wall has been formed in cells (3), (4), (5) and (6). This fact indicates that the front wall can shift its position by applying this field and so the critical field for the Ti ion in cell (4) can be identified with the critical field for the front wall itself. Further this fact suggests that at ordinary fields the front wall can not move at all without the effects of thermal vibration of Ti ion. Therefore in treating the movement of the front wall the effects of thermal vibration should be introduced precisely into calculation. In Fig. 5 and Fig. 6 the movements of a part of the front wall are shown schematically. It will be seen from Fig. 6 that the wall should have the high energy state on the way of proceeding by one lattice spacing in the direction of applied field. This fact implies that the front wall will move most rapidly as a whole when a certain volume of the wall reverses its polarization simultaneously in a single vibration of Ti ion. To consider the intermediate high energy state, let us denote the increase of the energy of front wall from the normal state by σ^* per unit area. Further let us assume that the domain grows by the successive formation of small steps in the front wall such as the shaded part in Fig. 5. For brevity call the part "local wall". Then the changes of free energy of the local wall in the intermediate state, ΔF^M, and in the final state, ΔF^F, are given respectively by

$$\Delta F^M = -EP_S\Delta V + \frac{\sigma^*}{u}\Delta F \tag{8}$$

and by

$$\Delta F^F = -2EP_S\Delta V + \sigma_W\Delta S \tag{9}$$

where ΔV and ΔS denote the increases of

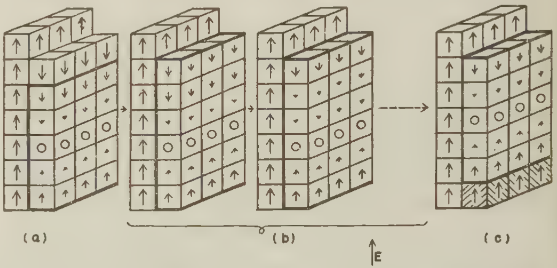

Fig. 6. Movement of local wall.
It is assumed here that the thickness of the front wall is 5 lattice spacings in making the movement clear. (a) Initial state. (b) Intermediate states. (c) Final state.

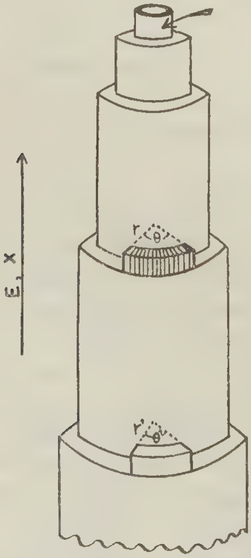

Fig. 5. Spike-shaped 180° domain.

[†] These can be easily proved using Kinase and Takahasi's result.

volume and surface of the domain respectively, u is the unit lattice spacing and σ_W is the wall energy/cm² of 180° wall. The probability by which the local wall proceeds by one unit lattice spacing in the direction of applied field is then given approximately by

$$p=\nu\left(\exp\left(-\frac{((\sigma^*/u)-EP_S)}{kT}\right)\Delta V-\exp\left(-\frac{\{((\sigma^*/u)+EP_S)\Delta V-\sigma_W\Delta S\}}{kT}\right)\right) \tag{10}$$

where ν is the frequency of the thermal vibration of Ti ion. The free energy ΔF^M must be of the order of kT in observing the wall motion within a few minutes. Further at an ordinary field both $EP_S\Delta V$ and $\sigma_W\Delta S$ are much smaller than $(\sigma^*/u)\Delta V$. Then Eq. (10) can be expanded, resulting in

$$p=\frac{\nu}{kT}(2EP_S\Delta V-\sigma_W\Delta S)\exp\left(-\frac{\sigma^*\cdot\Delta V}{kT\cdot u}\right) \tag{11}$$

where the smaller terms are neglected. The current induced by this wall motion is then given by

$$i_{\text{local}}=\frac{2P_S}{d_0}p\Delta V\,, \tag{12}$$

where d_0 is the thickness of the crystal. Neglecting the curvature of the local wall[†] and putting that $\Delta V=su^2$ and $\Delta S=2u^2$, above relation becomes

$$i_{\text{local}}=\frac{4P_S\nu u^4 s}{d_0kT}(sEP_S-\sigma_W)\exp\left(-\frac{\sigma^* su}{kT}\right). \tag{13}$$

This equation represents the relation between the applied field and the current caused by the movement of a local wall with the width s. It will be easily seen that this current becomes maximum when

$$s=s^*=\frac{2A+BC+\sqrt{4A^2+B^2C^2}}{2AC}\qquad\left(s>\frac{\sigma_W}{EP_S}\right), \tag{14}$$

where

$$A=\frac{4EP_S^2\nu u^4}{d_0kT}\,,\qquad B=\frac{4P_S\nu u^4\sigma_W}{d_0kT}$$

and

$$C=\frac{\sigma^* u}{kT}\,,$$

and the maximum current is given by

$$i^*_{\text{local}}=\frac{4P_S\nu u^4 s^*}{d_0kT}(s^*EP_S-\sigma_W)\exp\left(-\frac{\sigma^* s^* u}{kT}\right), \tag{13′}$$

In case of either $2A\gg BC$ (which is satisfied when applied field is fairly high) or $2A\ll BC$ (which is satisfied when applied field is low) this relation can be simplified to be

$$i^*_{\text{local}}=\frac{16P_S^2\nu u^2kT}{d_0(\sigma^*)^2}\left(E-\frac{\sigma_W\sigma^* u}{2kTP_S}\right)e^{-2} \tag{15}$$

or

$$i^*_{\text{local}}=\frac{4P_S\nu u^3\sigma_W}{d_0\sigma^*}\exp\left(-\frac{\sigma_W\sigma^* u}{kTEP_S}\right). \tag{16}$$

respectively. These dependences of the local current on applied field are analogous to the dependences of the observed maximum current on applied field. Therefore if the total maximum current[††] can be represented in terms of this local current, Merz's experimental relations will be explained favorably using above relations. Although this is not satisfied in general, it can be proved as shown in Appendix that in case of either $2A\gg BC$ or $2A\ll BC$ the total maximum current can be represented by the forms similar to the maximum local current. Later in § 5 this consideration will be used.

For the BaTiO₃ crystal, however, the depolarizing field may have severe effects on the movement of whole wall. Further, at the top of wedge-shaped domain the behaviors of the local walls may be different. Therefore in trying to explain Merz's relations it should be further tried to clarify how large these effects are. These examinations will be given in the following sections.

§ 4. Formation of New Steps

It will be seen in Fig. 5 that the top of a spike-shaped domain is formed by a small cylindrical step, indicated by arrow in the figure. This step can be newly formed in the way similar to the growth of a local wall in the lower steps. The new step, however, can not be formed so fast as other local walls, because as seen in Fig. 7 at the final state the whole side wall of the new step should be added and so the transition probability for the new step becomes smaller than the probability for the local wall of the same dimension. In the following, accordingly, some examination will be done for the movement of the new step. Suppose that the new step is a disk with the radius r and the height n.

[†] If the local wall is assumed to be an arc with the radius r and the angle θ (Fig. 5), above relations $\Delta V=su$ and $\Delta S=2u^2$ should be replaced by $\Delta V=r\theta u^2$ and $\Delta S=2u^2+\theta u^2$ respectively. This difference, however, will be negligible for a fairly large r.

[††] Some confusion may be caused by the use of the term "maximum". "Maximum" in the maximum local current means that the current becomes maximum when a local wall has a certain valume s^*u^2. On the other hand "maximum" in the total maximum current means that the current becomes maximum in the process of the switching of all domains. Accordingly, there is no direct connection between the two terms.

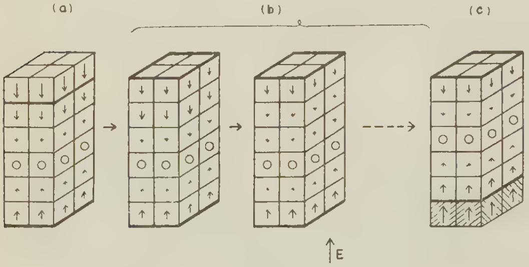

Fig. 7. Movement of step.
It is assumed here that the thickness of the front wall is 5 lattice spacings in making the movement clear. (a) Initial state. (b) Intermediate states. (c) Final state.

The probability by which the new step is formed per unit time is given analogously to Eq. (11) by

$$p=\frac{2\pi r u\nu}{kT}(rEP_S-\sigma_W)\exp\left(-\frac{\pi\sigma^* r^2}{kT}\right). \qquad (11')$$

This probability becomes maximum for a certain radius $r=r^*$ which satisfies the equation

$$r^3-\frac{B'}{A'}r^2-\frac{1}{C'}r+\frac{B'}{2AC'}=0$$

where

$$A'=\frac{2\pi u\nu EP_S}{kT}, \qquad B'=\frac{2\pi u\nu\sigma_W}{kT}$$

and

$$C'=\frac{\pi\sigma^*}{kT},$$

and the maximum probability is given by

$$p_{\max}=\frac{2\pi r^*\nu u}{kT}(r^*EP_S-\sigma_W)\exp\left(-\frac{\pi\sigma^*(r^*)^2}{kT}\right)$$
$$\left(r^*>\frac{B'}{A'}\right). \qquad (17)$$

In case of $r^*\gg(B'/A')$ (which is satisfied when the applied field is fairly high) this probability reduces approximately to be

$$p_{\max}=\frac{2\nu uP_S}{\sigma^*}\left(E-\frac{\sqrt{\pi\sigma^*}\,\sigma_W}{\sqrt{kT}\,P_S}\right)e^{-1}, \qquad (18)$$

while in case of $r^*\simeq(B'/A')$ (which is satisfied when the applied field is low) it reduces approximately to be

$$p_{\max}=\frac{2u\nu EP_S}{\sigma^*}\exp\left(-\frac{\pi\sigma_W{}^2\sigma^*}{E^2P_S{}^2kT}\right). \qquad (19)$$

These probabilities correspond respectively to the maximum probabilities for the local wall

$$p_{\max}=\frac{2u\nu P_S}{\sigma^*}\left(E-\frac{\sigma_W\sigma^* u}{kTP_S}\right)e^{-1} \qquad (20)$$

and

$$p_{\max}=\frac{2u\nu EP_S}{\sigma^*}\exp\left(-\frac{\sigma_W\sigma^* u}{EP_SkT}\right). \qquad (21)$$

It will be easily seen from these relations that at high fields the probability for the new step is not so different from the probability for the local wall, while at low fields the former becomes much smaller than the latter. The slower motion of the step at low fields, however, will little affect on the movement of the whole front wall, owing to the effects of dipolarizing field as discussed in the following section. Accordingly, we will neglect at all the particular motion of the step in the latter calculation.

§ 5. Effects of Depolarizing Field

In the previous sections the effects of the depolarizing field on the wall motion have been neglected thoroughly. This effects, however, may be quite large for the $BaTiO_3$ crystal in which the very large spontaneous polarization is caused. For example it can be seen as follows: suppose that the domain has a shape of a long prolate spheroid with the radius r and the length l. When the field is abscent, the free energy of the domain is given by[†]

$$\Delta F=4\pi\sigma_W rl+\frac{2}{3}\pi d\frac{r^4}{l}P_S{}^2. \qquad (22)$$

This energy becomes minimum at a certain length

[†] The present expression of depolarizing energy is correct when the thickness of the crystal is much larger than the length of the domain. If the length becomes comparable with the thickness, the effects of depolarizing field will be much changed.

$$l=l_{\min}=\left(\frac{d}{6}r^3\frac{P_S{}^2}{\sigma_W}\right)^{1/2}$$

for a certain radius r. Assuming that $d=16\pi$, $P_S=7.8\times10^4$ esu and $\sigma_W=1.40$ esu, the length becomes about 2×10^{-1} cm, 6×10^{-3} cm and 2×10^{-4} cm for $r=10^{-4}$ cm, 10^{-5} cm and 10^{-6} cm respectively. Since in the minimum the depolarizing energy of the domain is of the same order as the wall energy, in case of Merz's 180° domains, which have the length of about 10^{-3} cm and the radius of about 10^{-4} cm, the depolarizing energy will be much higher than the wall energy. This seems to mean that for the observed domain the movement of the front wall should be determined mainly by the effects of depolarizing field. On the contrary the switching current observed in experiments is sensitively dependent on applied field and so the movement of the front wall may be determined rather by the strength of applied field. Why does this discrepancy appear ? How can this inconsistency be resolved ?

One way to answer this question is to consider that the actual depolarizing field is much weaker than the depolarizing field expected from the calculation. In fact this may be realized for a standing or very slowly moving domain, because the depolarizing change on the front wall will be neutralized gradually by the floating charge. For a rapidly moving domain, however, such neutralization is not expected at all, because the $BaTiO_3$, crystal is not a good conductor, but may be only a little conductive. Accordingly, in explaining Merz's experimental result this seems to be inappropriate. The other way to answer the question is to consider again the proposal in § 3 that the front wall of a domain should have a high energy state on the way of each proceeding by one lattice spacing. This assumption indicates that the whole front wall can not shift its position simultaneously even when large amount of decrease of the depolarizing energy will be caused and further suggests that the effects of applying field may be predominant in the movement of the whole front wall in spite of the large effects of depolarizing field, if the movement of each local wall would be little affected by the depolarizing field. Although it is very difficult to treat this problem precisely, the effects of applying field on the real domain can be introduced into calculation as follows: in Fig. 8 a part of a real domain is shown two-dimensionally. The dotted line in this figure represents the surface of the ideal ellipsoid having an uniform depolarizing field. It will be seen from this figure that the real domain wall can not fit at all with the ideal surface. This fact implies that for a number of Ti ions in the front wall the two possible states of polarization may be nearly equally probable, because the departure of a small part of the wall from the ideal surface may cause the increase of depolarizing energy. In other words the whole domain wall may be deformed a little by the application of an outer field, in spite of the large effects of depolarizing field. In addition, it is known that an uniform deformation of the whole front wall may cause the gradual decrease of depolarizing energy. Therefore if a certain uniform deformation of the front wall is attained by the application of an outer field, the whole front wall will continue to proceed in the direction of applied field in decreasing the total free energy of the domain. The features of the movement are shown schematically in Fig. 9.

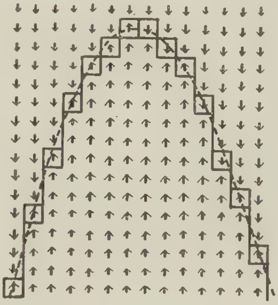

Fig. 8. A part of a domain.
The dotted line indicates the ideal surface of the domain.

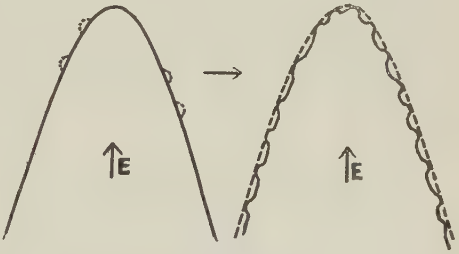

Fig. 9. Movement of the domain caused by the local shift. The dotted lines indicate the shifts of wall with the lapse of time.

To consider this movement, let us assume now that (1) when a certain number of the local walls, which have the two possible stable states, have shifted their positions in the direction favorable to the applied field—accurately speaking when the shifted front area of the original wall reaches a certain magnitude—the whole front wall can proceed to form a new front surface which fits nearly to a new ideal ellipsoid, (2) the shifts of these local walls are not affected at all by the effects of the depolarizing field and (3) owing to the change of depolarizing field the other local walls which have only one stable state at first also can shift their positions very rapidly according to the shifts of the easily movable local walls. Then the transition time necessary for the whole front wall to shift its position by the least distance is given by

$$\Delta t=\frac{n}{p^*} \tag{22}$$

where p^* is the transition probability of the local wall and n is the number of times of the transition when the shifted front area becomes a certain critical area, S_0. Here it is assumed that all the local walls have the constant front area of s^*u. Since n can be written to be

$$n=\frac{S_0}{ms^*u}$$

the transition time becomes

$$\Delta t=\frac{S_0}{ms^*up^*} \tag{23}$$

where m is the number of the local walls which can shift simultaneously. Thus the effects of the depolarizing field can be introduced into calculation to the rough approximation. In the following section Merz's experimental relations will be explained using this relation.

§ 6. Explanation of Merz's Experimental Result

Before trying to explain Merz's experimental relations we will study how a wedge-shaped domain grow or decay. In Fig. 10 the process is shown two dimensionally. It will be seen from this figure that there are three stages of movement of every domain i.e. the first stage of the growth of each domain, the second stage of the apparent sidewise motion of each wall and the third stage of the decay of remanent domain. It should be noticed here that the remanent domain may have a fairly complicated shape at first, because real three-dimensional domains may be arranged in a more complicated way. Among these three stages some different movements of the wall may be appeared. For example at the first stage a new step should be formed successively to continue the growth, while at the third stage a step which is already existing may immediately disappear by the movement of the other local walls. As supposed by the discussion in the previous section such differences will be little important on the movement of the whole front wall. Accordingly, we will neglect them at all now. Then from Eq. (23) the current induced by the movement of a domain can be written to be

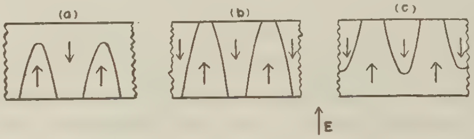

Fig. 10. Growth and decay of 2-dimensional domains.
(a) 1st stage. (b) 2nd stage. (c) 3rd stage.

$$i_{\text{domain}}=\frac{2P_S}{d_0}\frac{\Delta V_{\text{domain}}}{\Delta t}$$

where ΔV_{domain} is the volume change caused by the displacement of the domain. This can be reduced using the relation

$$s^*up^*=\frac{d_0}{2P_S}\,i^*_{\text{local}}$$

to be

$$i_{\text{domain}}=\frac{m\Delta V_{\text{domain}}}{S_0u}\,i^*_{\text{local}}\,, \tag{24}$$

Then summing this current over all domains in the crystal, the total current becomes

$$I=\sum_{i=1}^{N}\frac{m^i\Delta V^i_{\text{domain}}}{S_0{}^iu}\cdot i^*_{\text{local}}\,. \tag{25}$$

It will be seen from this equation that the total current is proportional to the maximum local current at any instant and it becomes when the term $\sum(m^i\Delta V^i_{\text{domain}}/S_0{}^iu)$ is maximum. To the first approximation let us assume that all the domains have a same dimension and takes a similar behavior with the lapse of time. Then the total maximum current is given by

$$I_{\max}=\frac{N^*m^*\varDelta V^*_{\mathrm{domain}}}{S_0^*}\cdot i^*_{\mathrm{local}} \tag{26}$$

where N^*, m^*, S_0^* and $\varDelta V^*_{\mathrm{domain}}$ represent respectively N, m, S_0 and $\varDelta V_{\mathrm{domain}}$ in the maximum current. Substituting Eqs. (15) or (16) into Eq. (26), this becomes

$$I_{\max}=\frac{16N^*m^*\varDelta V^*_{\mathrm{domain}}}{S_0^*}\cdot\frac{P_S^2\nu ukT}{d_0(\sigma^*)^2}\left(E=\frac{\sigma_W\sigma^*u}{2kTP_S}\right)e^{-2} \tag{27}$$

at fairly high fields or

$$I_{\max}=\frac{4N^*m^*\varDelta V^*_{\mathrm{domain}}}{S_0^*}\cdot\frac{P_S\nu u^2\sigma_W}{d_0\sigma^*}\exp\left(-\frac{\sigma_W\sigma^*u}{kTEP_S}\right) \tag{28}$$

at low fields. It will be seen from these relations that Merz's experimental relations can be explained satisfactorily, considering that N^*, m^*, S_0^* and $\varDelta V^*_{\mathrm{domain}}$ will be little dependent on the strength of applied field.

The relations between applied field and switching time can be also obtained from Eq. (23). That is, from Eq. (23) the switching time can be written to be

$$t_S=\int_0^{t_S}dt=\frac{2P_Su}{i^*_{\mathrm{local}}\cdot d_0}\sum_t\frac{S_0^t}{m^t}\,. \tag{29}$$

To the first approximation let us assume that (S_0^t/m^t) is not changed at all through the switching process and it is equal to (S^{0*}/m^*). Then the switching time can be written approximately to be

$$t_S=\frac{d_0}{u}\cdot\frac{2P_Su}{i^*_{\mathrm{local}}\cdot d_0}\frac{S_0^*}{m^*}=\frac{2P_SS_0^*}{m^*i^*_{\mathrm{local}}}\,. \tag{29'}$$

Then using the previous result, the reciprocal of the switching time is given by

$$\frac{1}{t_S}=\frac{8m^*P_S\nu u^2kT}{S_0^*d_0(\sigma^*)^2}\left(E-\frac{\sigma_W\sigma^*u}{2kTP_S}\right)e^{-2} \tag{30}$$

at fairly high fields and by

$$\frac{1}{t_S}=\frac{2m^*\nu u^3\sigma_W}{S_0^*d_0\sigma^*}\exp\left(-\frac{\sigma_W\sigma^*u}{kTEP_S}\right) \tag{31}$$

at low fields. It will be seen from these relations that Merz's experimental relations⁶⁾ (Fig. 11) can be explained satisfactorily, considering that m^* and S_0^* are little dependent on the strength of applied field.

§ 7. Discussions

To construct the preceeding theory it has been assumed that a front wall must pass across a certain potential barrier to move by an unit lattice spacing in the direction of appried field. This assumption is essentially important to determine whether the theory is appropriate to explain Merz's result or not. One way to judge this assumption is to examine the theoretical relations quantitatively. If a clear quantitative inconsistency appears in them, the present model should be abandoned. Below a few quantitative examinations will be given.

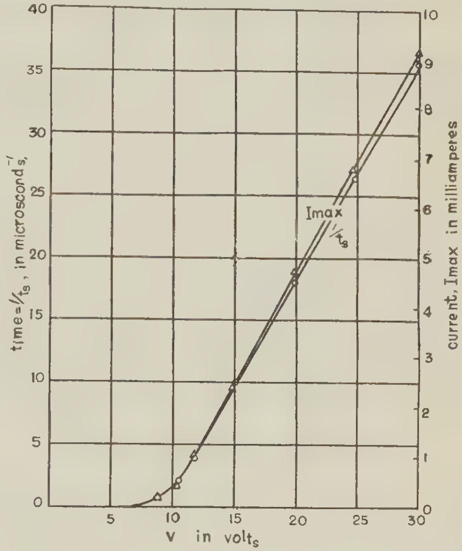

Fig. 11. Switching current and reciprocal switching time *versus* applied field (after Merz).

(1) We will determine at first the value of σ^* in comparison with Merz's experimental result. Using the data that $E'=14.3$ esu† at 23°C and $P_S=7.8\times10^4$ esu and putting that $kT=4\times10^{-14}$ esu and $\sigma_W=1.40$ esu it can be obtained that

---

† This value was determined from Merz's figure (Fig. 2).

†† If the thickness of the wall is n lattice spacings, the wall can proceed by one lattice spacing in the direction of applied field by passing through the intermediate high energy state which corresponds to the state of wall with $(n+1)$ lattice spacing. According to Kinase⁵⁾ the thickness of the front wall is about 4 lattice spacing and the wall energy is about 80 erg/cm². Using these values and assuming as done by Merz²⁾ that the anisotropy energy of wall is proportional to the number of lattice in the wall, while the dipole interaction energy of wall is proportional to the reciprocal of the number, it can be obtained that

$$\sigma^*\simeq2\ \mathrm{erg/cm^2}\,.$$

$$\sigma^*=1.6\ \mathrm{erg/cm^2}\ .$$

This value will be plausible, considering that by another calculation†† the value of σ^* is given to be about 2 erg/cm².

(2) The restriction for the thermal frequency of Ti ion can be deduced from Eq. (30) in comparison with Merz's experimental result. Namely, using the data that $t_S=0.4\times10^{-6}$ sec at $E=40$ esu and $d_0=5\times10^{-3}$ cm, it can be obtained that

$$\frac{S_0^*}{m^*\nu}=4.3\times10^{-27}\ \mathrm{cm^2\ sec}\ . \qquad (32)$$

Using the relations that $n=(S_0^*/m^*s^*u)\geqq1$ and $s^*u=(2kT/\sigma^*)$† the restriction reduces to be

$$\nu\geqq1.2\times10^{13}\ \mathrm{sec^{-1}}\ .$$

This result indicates that the magnitude of ν will be plausible if n is of the order of one.

(3) The term $N^*\Delta V^*_{\mathrm{domain}}/u$ can be determined from Eq. (27) in comparison with Merz's experimental result; using Eq. (32) and the result that $I_{\max}=75\times10^{-3}$ amperes$=22.5\times10^7$ esu at $E=40$ esu, it can be seen that

$$\frac{N^*\Delta V^*_{\mathrm{domain}}}{u}=5.6\times10^{-4}\ \mathrm{cm^2}\ .$$

Since $\Delta V^*_{\mathrm{domain}}/u$ is of the order of the cross section of the domain, $N^*(\Delta V^*_{\mathrm{domain}}/u)$ will be of the order of the electrode surface. This expectation seems to be satisfied, reminding the fact that the electrode surface of Merz's crystal is about 10^{-4} cm².

Thus above quantitative analysis shows that no apparent inconsistency appears between the present theory and Merz's experimental result.

Finally the author wishes to express his thanks to Dr. S. Marutake and Dr. T. Nakamura for their valuable advices and to Dr. W. Kinase for his kind communications.

Appendix

For the movement of the front wall of which front area is much larger than the area of s^*u, the current can be written approximately to be

$$i_{\mathrm{front}}=\alpha\int_0^\infty i_{\mathrm{local}}(s)\,ds \qquad (1)$$

where α is a certain constant. Using the relations that

$$i_{\mathrm{local}}(s)=f(s)(E-E'(s))\exp\left(-\frac{\sigma^*su}{kT}\right) \qquad (2)$$

and $s_0=(\sigma_W/EP_S)$, the current becomes

$$i_{\mathrm{front}}=\alpha E\int_{\sigma_W/EP_S}^\infty f(s)\exp\left(-\frac{\sigma^*su}{kT}\right)ds$$
$$-\alpha\int_{\sigma_W/EP_S}^\infty f(s)E'(s)\exp\left(-\frac{\sigma^*su}{kT}\right)ds\ . \qquad (3)$$

For the sufficiently large E which satisfies the condition $2A\gg BC$ the lower limit of each integral can be replaced approximately by 0. Then it will be easily seen that the current has the same dependence on applied field as i^*_{local}.

For the small E which satisfies the condition $2A\ll BC$ the current becomes maximum when s is nearly equal to σ_W/EP_S and it decreases abruptly with the increase of s. Since both $f(s)$ and $E'(s)$ changes slowly with the change of s in comparison with $\exp(-(\sigma^*su/kT))$, the current can be written approximately to be

$$i_{\mathrm{front}}=\alpha f(s^*)(E-E'(s^*))\int_{s^*}^\infty\exp\left(-\frac{\sigma^*su}{kT}\right)ds \qquad (4)$$

which reduces to be

$$i_{\mathrm{front}}=\frac{4\alpha kTP_S\nu u^2\sigma_W}{d_0(\sigma^*)^2}\exp\left(-\frac{\sigma^*\sigma_Wu}{kTEP_S}\right)\ . \qquad (5)$$

This result indicates that at low fields the current also has the same dependence on applied field as i^*_{local}.

By the way, the total maximum current can be written to be

$$I_{\max}=\alpha_{\max}\int i_{\mathrm{local}}(s)\,ds \qquad (6)$$

if the effects of depolarizing field is neglected thoroughly. Then from above relations it will be seen that in case of $2A\gg BC$ or $2A\ll BC$ the total maximum current has the form similar to Eq. (15) or Eq. (16).

Nuclear Magnetic Resonance in Dilute Copper Alloys at Low Temperatures, I.
Experimental Aspects*

By Tadashi SUGAWARA

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received January 8, 1959)

The nuclear magnetic resonance of Cu^{63} in dilute copper alloys has been studied in order to make clear the origin of their anomalous magnetic, electric and thermal behaviors observed at low temperatures. The specimens were the dilute solid solutions of Ti, Cr, Mn, Fe, Co, Ni, Zn and Sn in Cu. From the temperature dependence of the observed line width, it was concluded that Ti, Ni, and Zn behave as non-magnetic ions while the others do as paramagnetic ions. Sn in Cu-alloy showed temperature dependent paramagnetism in spite of its temperature independent paramagnetism in the metal. The solute contribution to the widths in Cu–Cr, Cu–Mn, Cu–Fe and Cu–Co in weak field showed a Curie-Weiss behavior. The Weiss temperatures obtained indicated increasing ferromagnetic interaction with increasing solute concentration. The width in Cu–Mn was proportional to the magnetic field except at very low temperatures, while those in Cu–Cr and Cu–Fe showed anomalous field dependence at temperatures below 20°K. The Knight shift in these paramagnetic alloys was larger than that in pure Cu, but the deviation was very small at high temperatures. At very low temperatures the spin-lattice relaxation times in Cu–Cr, Cu–Mn and Cu–Fe became shorter than those in pure Cu and in non-magnetic alloys such as Cu–Zn.

§ 1. Introduction

Recently the low temperature property of the dilute alloys of iron group elements in noble metals has received considerable attention by experimental and theoretical physicists. Particularly the magnetic, electric, and thermal properties of Cu–Mn system have been studied in detail1)-5). The alloy is paramagnetic at high temperatures and becomes antiferromagnetic as the temperature is lowered. The electron spin resonance at high temperatures shows a single absorption line with $g \simeq 2.00$, suggesting the existence of of Mn^{2+} or Mn^{0}. Below the Néel temperature the resonance shows some characteristics of the antiferromagnetic resonance. The line width of Cu^{63} nuclear resonance is broad and temperature-dependent in the paramagnetic state, while the Knight shift is nearly the same as that in pure Cu. A broad peak in the specific heat curve has also been observed near the Néel point6). In addition to these magnetic anomalies, very dilute alloys show resistance maximum and minimum at low temperatures and also anomalous magnetoresistance which depends upon the magnetization of the sample.

Some of these anomalous properties of Cu–Mn have been explained theoretically in terms of the *s–d* exchange interaction7)-9). However, there remain many problems to be solved such as the resistance maximum and minimum and the mechanism of spin ordering in Cu–Mn. In addition, no satisfactory explanation has been made of the fact that the other alloys of transition elements show different magnetic and electric behaviors as compared with Cu–Mn10),11). For instance, only a minimum has been observed in the resistance *vs.* temperature curve in dilute Cu–Fe12) which is paramagnetic like Cu–Mn12),13). For the better understanding of the nature of the dilute alloys, a detailed experimental study concerning the electronic structure of them seems to be required. The present work was undertaken for this purpose.

The electron spin resonance of the solute ion and the nuclear spin resonance of the solvent nuclei provide powerful means for the present purpose. The former has an advantage over the latter as it gives a direct information on the electronic state of the solute ion and the magnetic interaction effects. However, its application to the present problem seems to be limited because of the fact that no resonance has been observed in alloys other than Cu–Mn and other Mn alloys2). The nuclear spin resonance gives informations on the state of the localized unpaired spin through the line broadening and the charge density of the *s*-electrons through the Knight shift. In this work, the Cu^{63} resonance was studied in dilute copper alloys containing iron group metals such as Ti, Cr, Mn, Fe, Co and Ni, and from the result it was intended to draw a conclusion about the electronic structure of these alloys. Cu–Zn and Cu–Sn, each containing nonmagnetic element as the solute, were also studied for comparison. The resonance behavior of Cu–Sn attracted much interest as it shows a resistance minimum14) and an anomalous magnetic behavior at low temperature15).

---

* A preliminary report of this work has been published previously. T. Sugawara: J. Phys. Soc. Japan **12** (1957) 309.

In this paper (Part I) only the experimental result is described, and theoretical considerations of the result as well as of the electronic structure of the dilute alloys will be published in a subsequent paper (Part II).

§ 2. The Apparatus

A block diagram of the experimental arrangement is shown in Fig. 1. An electromagnet of the Bitter type provided magnetic fields up to 10^4 oersted in a 40 mm air gap. The pole faces were 165 mm in diameter and the inhomogeneity of the field across the sample of about 1 cm^3 was less than 0.1 oersted at 5000 oersted. The field was modulated at 50 cps from a low frequency oscillator. The resonance signal was detected with a marginal oscillator of the Pound-Knight-Watkins type. The derivative of the absorption line was displayed on a recorder by sweeping the magnetic field at a constant frequency or by sweeping the frequency of the oscillator at a constant field. The sample coil were wound with silver wire. Special care was taken to avoid mixing of the external Cu signal with that from the sample.

A metal cryostat was used throughout this work. The temperatures of liquid hydrogen and helium range were determined by measuring the vapor pressure of the bath liquid or the resistance of a carbon resistor placed near the sample.

	0.20		Cu		0.005

§ 3. Preparation of Samples

The compositions of the alloys studied are collected in Table I. The concentration of the solute and impurities was determined by chemical analysis.

The alloy was prepared by melting electrolytic copper of about 99.99% purity and the mother alloy containing solute metal of about 10% in an induction furnace *in vacuo*. The melt was held at 1200°C for about 30 minutes and then casted into a cold ingot case. The ingot was cold-worked into a rod of about 11 mm indiameter and pickled in a 50% solution of nitric acid to a diameter of 8 mm to remove surface contamination. The ingot was sealed in a quartz tube under vacuum and annealed at about 950°C for 30 hours. The effect of annealing period upon the homogeneity of the alloy was tested by comparing the Cu^{63} resonance in two Cu–Mn samples of the same concentration annealed for 20 hours and 100 hours respectively. A period of 30 hours proved to be sufficient as the widths were the same within the experimental error. The annealed sample was quenched into water to avoid precipitation. This procedure was necessary for obtaining a good solid solution as the solubility of Fe, Co, Cr, and Ti in Cu are rather small at room temperature[16]. Finally the rod was pickled in a nitric acid solution and then powdered.

For magnetic resonance work on conductors the grain size of the sample should be smaller than the skin depth[17]-[19], given by

$$\delta=(\rho\times10^9/\mu f)^{1/2}(2\pi)^{-1}\,, \qquad (1)$$

where ρ is the specific resistance in Ω-cm, μ is the permiability, and f is the frequency in cps. δ's of pure Cu at 4.2°K and of 0.03% Cu–Mn at the temperature of resistance maximum are 1.5 micron and 6 micron respectively for the frequency of 10 Mc/sec. Therefore, the mean diameter of the sample should be smaller than 1 micron for pure copper and also smaller than 5 micron for most of the alloys. Preparation of such a fine powder was not easy. After trying various methods a rather teadous but primitive method, in which the alloy was rubbed with a finely grained oil stone in liquid paraffine, was proved to be satisfactory. Very fine powders were separated from the product by use of the difference of the falling velocity in benzene. The yield of powders less than 2 micron in

diameter was about a few per cent of the coarse powder. Finally about 0.5 gr of fine powders thus obtained was suspended in molten paraffine and mold into a thin walled glass tube.

§ 4. Line Width and its Field Dependence

The derivatives of Cu^{63} absorption line in the sample were measured at various magnetic fields and temperatures. The separation ΔH_1 between points of extreme deflection and the separation ΔH_2 between points where the deflection had fallen to half of the peak value of the derivative curve were both used as measures of the line width. In this work, the latter was used frequently as it was more sensitive to the effect of the solute than the former. The observed ΔH_2 of Cu^{63} in various samples are shown in Figs. 2 through 7.

In most of the alloys of transition metals the line width increased as the temperature was decreased or the field was increased. The effect, among the alloys of the same concentration, was largest for Cr and Mn and was not observed for Ni and Ti. Non-transition metal alloys showed, in general, no excess broadening as compared with pure Cu. However, Cu–Sn be haved like Cu–Mn alloy though the broadening was smaller.

The shape of the broad line, observed at

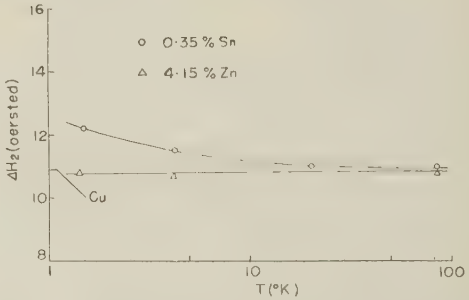

Fig. 7. Line width ΔH_2 *versus* temperature in Cu–Sn and Cu–Zn at 7350 oersted.

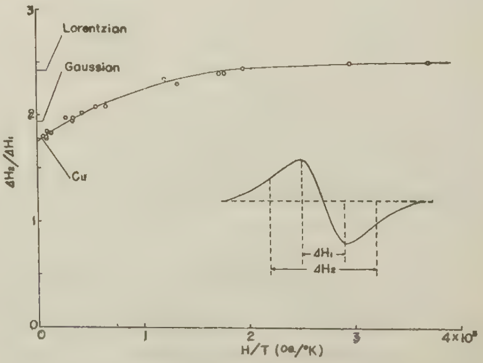

Fig. 8. Ratio $\Delta H_2/\Delta H_1$ in 0.026% Cu–Mn.

low temperatures, was nearly Lorentzian in shape and became nearly Gaussian as the temperature was increased. As an example of this change the ratio $\Delta H_2/\Delta H_1$ of Cu^{63} resonance in Cu–Mn has been plotted against H/T in Fig. 8. The ratio is 1.94 for a Gaussian line and 2.40 for a Lorentzian line.

Broadening of the line width is expected when the solute atoms or ions have a localized 3d state with unpaired spins. The effect of the solute spins is simply to give a local field at a nucleus due to its dipolar and indirect exchange coupling with Cu nuclear spins, as the relaxation time of the 3d spin is considered to be short compared with the nuclear spin-spin relaxation time of Cu. The local field at a nucleus is given by[7),9)]

$$H_{\mathrm{loc},i}=-\langle S_Z\rangle\left(\frac{3n}{N}\right)^2\frac{2\pi}{E_f}\frac{AJ_{sd}}{g_N\mu_N}\Sigma_kF(2k_mr_{ik})$$
$$-g\mu_B\langle S_z\rangle\Sigma_kr_{ik}{}^{-3}(1-3\gamma_{ik}{}^2)\ , \qquad (2)$$

where $\langle S_z\rangle$ is the average of the z component of the 3d spin, N is the total number of atoms, n is the total number of conduction electrons, E_F is the Fermi energy of Cu, A is the hyperfine interaction constant, J_{sd} is the s–d exchange constant and γ_{ik} is the direction cosine of the radius vector r_{ik} between the kth solute atom and the ith nucleus under consideration with respect to the external field direction (z-axis), and F is a complex function of the maximum wave vector k_m and r_{ik}. This local field will have different values for different Cu sites and, therefore, the distribution of them will give a line broadening mechanism of inhomogeneous type[23)]. The spectrum of this local field for a system of randomly diluted spins becomes in general Lorentzian as was shown by Kittel and Abrahams[20)] and by Behringer[9)]. In fact, such broadening of the line width in Cu–Mn was originally observed by Owen et al and has been discussed theoretically by Behringer[9)]. The spin-spin interaction between Cu nuclei will give the broadening of the component line of the local field spectrum. Then the total line shape will be expressed by

$$I(H)=\int_{-\infty}^{+\infty}g(H-H_0)\,p(H_0)\,dH_0\ , \qquad (3)$$

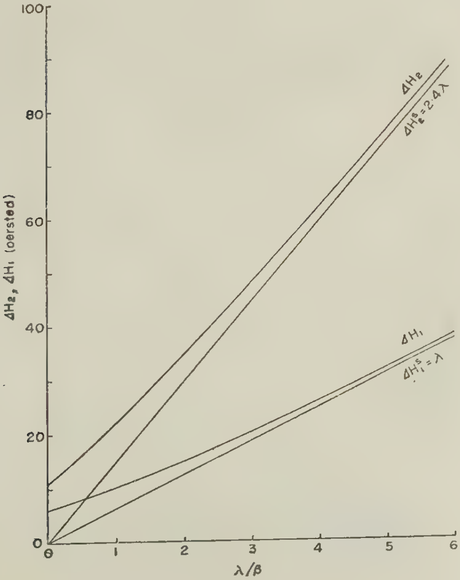

Fig. 9. Calculated line width, ΔH_2 and ΔH_1, for paramagnetic alloys. The straight line shows the contribution of the solute to the width.

b) 0065% Cr.

Fig. 10. Field dependence of $\Delta H_2{}^s$, the contribution of the solute to ΔH_2, in Cu–Cr.

where $g(H)$ is the shape function for pure Cu and $p(H_0)$ is the intensity distribution function of the local field given by Eq. (2).

Informations about the magnetic behavior of the solute have been derived from the line width data by the following procedure. Assuming a cut-off Lorentzian shape for $p(H_0)$* and the line shape of pure Cu for $g(H)$, the derivative of $I(H)$ has been calculated for various values of a parameter λ/β, where λ is the width of $p(H_0)$ and β is that of $g(H)$. The theoretical line widths which should correspond to the measured width ΔH_1 and ΔH_2 respectively, have been plotted in Fig. 9 as functions of λ/β. The line widths of $p(H_0)$, ΔH_1^s and ΔH_2^s, which are just the solute contributions to the width ΔH_1 and ΔH_2, have been plotted in the same figure using the relation

$$\Delta H_1^s = \lambda\,, \qquad \Delta H_2^s = 2.40\lambda\,.$$

From the figure ΔH_2^s (or ΔH_1^s) corresponding to the observed line width ΔH_2 (or ΔH_1) has been obtained easily. In Figs. 10, 11 and 12 ΔH_2^s's for Cu–Cr, Cu–Mn, and Cu–Fe at various temperatures have been plotted as functions of the field strength.

For a cut-off Lorentzian, λ is given by

$$\lambda = \frac{\pi}{\alpha\sqrt{3}}\langle \Delta H^2 \rangle\,, \qquad (4)$$

where α is the cut-off frequency large compared with λ and $\langle \Delta H^2 \rangle$ is the second moment given by

$$\langle \Delta H^2 \rangle = \Sigma_i (H_{\mathrm{loc},i})^2\,. \qquad (5)$$

The cut-off frequency α can be regarded as the frequency corresponding to the maximum value of the local field given by Eq. (2).

b) 0.11% Fe.

Fig. 12. Field dependence of ΔH_2^s, the contribution of the solute to ΔH_2, in Cu–Fe.

---

* This assumption has been justified experimentally as is seen from Fig. 8. See also Ref. 9).

Combining Eqs. (4) and (5) and using the summation method of Kittel and Abrahams[20], one obtains an expression for ΔH_2^s,

$$\Delta H_2^s = 2.40 \frac{\pi}{\alpha\sqrt{3}} f \Sigma'(H_{\text{loc}})^2$$
$$= 4.35 \frac{f}{\gamma (H_{\text{loc}})_{\max}} \Sigma'(H_{\text{loc}})^2 \qquad (6)$$

where Σ' means the sum over the whole lattice points, and f is the fractional concentration of the solute. Eq. (6) shows that ΔH_2^s (and also ΔH_1^s) should be proportional to $\langle S_z \rangle$ and consequently should have the same temperature and field dependence as the magnetization of the alloy. In fact that field dependence of ΔH_2^s in Cu–Mn was in agreement with the magnetization curves reported by Schmidt and Jacobs[4]. However, Cu–Cr and also Cu–Fe showed anomalous field dependences as seen in Figs. 10 and 12. The deviation from the linear relation at 7000 oersted was maximum at about 5°K in 0.040% Cu–Fe and at about 15°K in 0,11% Cu–Fe.

From the foregoing it is concluded that $\Delta H_2^s/H$ should be proportional to the susceptibility of the alloy. Fig. 13 is a plott of the reciprocal of $\Delta H_2^s/H$, obtained from the slope of the low field part of the ΔH_2^s curve, as a function of temperature. As is seen from the figure, the Curie-Weiss law,

$$\Delta H_2^s/H = C_2^s/(T-\Theta) \qquad (7)$$

holds fairly well in Cu–Cr, Cu–Mn and Cu–Fe. Deviations from the Curie-Weiss law occur only at very low temperatures in Cu–Cr and in Cu–Mn, but at temperatures below 20°K in Cu–Fe. In Table II, Θ and C_2^s for various alloys are collected and compared with Θ obtained from the susceptibility data found in the literatures.

The foregoing analysis of the line width is based upon a phenomenological theory of the line broadening and therefore requires more rigorous theoretical foundation. This will be made in Part II of this paper in conjunction with the electronic state of the solute and the *s–d* exchange interaction in dilute alloys.

§ 5. The Knight Shift

The Knight shift was obtained by measuring the difference between the resonance field of the alloy and of the reference sample at a same frequency. As the reference a small amount of CuBr was sealed in the sample tube, so that the resonance field could be compared at the same temperature. The measurements were carried out mostly at a frequency of about 8.3 Mc but sometimes at lower frequencies. Temperature dependence of the shift of Cu^{63} resonance in various alloys is illustrated in Fig. 14. Alloys containing non-magnetic or weakly magnetic solutes show nearly the the same shift as compared with pure Cu. On the other hand, Cu–Cr, Cu–Mn and Cu–Fe, which are paramagnetic, show slightly larger shift than pure Cu in contradiction to the previous results on Cu–Mn by Owen *et al*2) and by van der Lugt *et al.*22)

When the dimension of a metallic specimen is not small compared with the skin depth, the absorption signal contains the real and imaginary components, i.e.

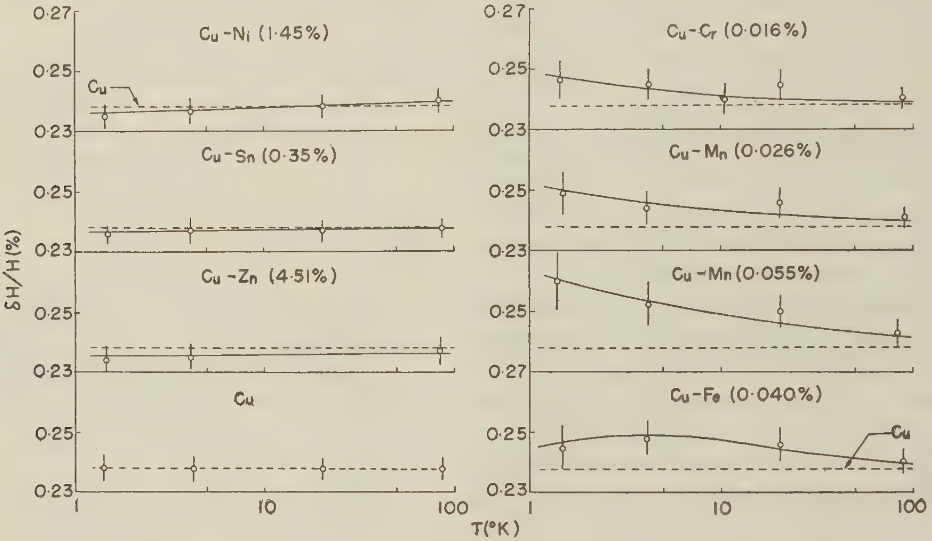

Fig. 14. Knight shifts of Cu^{63} in dilute alloys and in pure copper.

$$dI/dH=a(d\chi'/dH)+b(d\chi''/dH)\,, \qquad (8)$$

where χ' and χ'' are the real and imaginary parts of the nuclear susceptibility. Consequently the signal is asymmetric and the apparent Knight shift measured at the point of zero derivative becomes smaller thanthe true Knight shift18). The grain size of samples used in this work was smaller than the skin depth, so the effect was considere dto be negligible as compared with the experimental error.

The line shift δH of the host nucleus in paramagnetic alloys can be expressed by the sum of two components of different origin, one due to the hyperfine interaction of the nucleus with conduction electrons and the other due to the interaction of the nuclear spin with the localized spins as discussed before Therefore, it follows that

$$\delta H=(\delta H)_\sigma+(\delta H)_S\,. \qquad (9)$$

The first term is proportional to the conduction electron magnetization and, if a uniform polarization of the conduction electron spin due to *s–d* exchange exists, it will depend upon the magnetization of the solute spin1). According to Yoshida7), however, the polarization is localized in the vicinity of the solute atom and, therefore, the shift should not differ from that for the solvent metal. Similarly the variation of the shift due to a change in the electron charge density upon alloying has been shown negligible as the extra charge is also highly localized23). The second term contains the first order shift due to the z-component of the solute spin and the second order shift due to the perpendicular component. The first order shift is equal to the first moment of the local field given by Eq. (2), in which the dipolar contribution vanishes for a powdered sample and the indirect exchange contribution gives a small negative value⁷⁾. The second order effect, which produces a paramagnetic shift, is negligible in dilute alloys.

The above consideration gives no satisfactory explanation of the observed temperature dependent shift in the alloys with Cr, Mn and Fe. Therefore the extra shift must be attributed to the uniform polarization of s-electrons due to s–d exchange in contrast with the theory⁷⁾. It is also interesting to note that the shift in Cu–Ni have the same value as that of pure Cu. The alloy shows fairly large increase of the temperature independent paramagnetism with increasing Ni concentration²⁴⁾. The present data will be useful for understanding the anomalous magnetic behavior of the system Cu–Ni.

§ 6. The Spin-Lattice Relaxation Time

The saturation curve method was used for the determination of the nuclear spin-lattice relaxation time T_1 of Cu^{63} nucleus. The experiments were carried out mostly at a frequency of about 8.3 Mc. Determination of T_1 from the saturation curve of the paramagnetic alloys was made as follows. As has been mentioned in the previous section, the line broadening in these alloys is of inhomogeneous type. The saturation behavior of the derivative of the inhomogeneously broadened line can be expressed by²⁵⁾

$$dI(H, H_1)/dH$$
$$=\frac{d}{dH}\int_{-\infty}^{+\infty} p(H_0)\frac{g(H-H_0)}{1+\frac{1}{4}\pi\gamma^2H_1^2T_1g(H-H_0)}\,dH_0 \tag{10}$$

where $p(H_0)$ and $g(H-H_0)$ have the same meanings as in Eq. (3) respectively, and H_1 is the radio frequency magnetic field at the sample. Eq. (10) is varid only when the homogeneous saturation occurs over the narrow interval limitted by the width of the component line $g(H)$. It is not certain whether this condition is realized in the paramagnetic alloys or not. Therefore Eq. (10) has been assumed tentatively,* and the line shape function of pure Cu has been taken for $g(H)$ as a limiting case. Using Eq. (8) theoretical saturation curves have been constructed for various values of the parameter λ/β as has been done in § 4. The curve for the case $\lambda=0$ has been made to coincide with the observed saturation curve in pure Cu. T_1 has been calculated by fitting the observed saturation data with the theoretical curve having the same λ/β or $\Delta H_1^s/\beta$. Values of T_1 thus obtained have been plotted against temperature in Fig. 15.

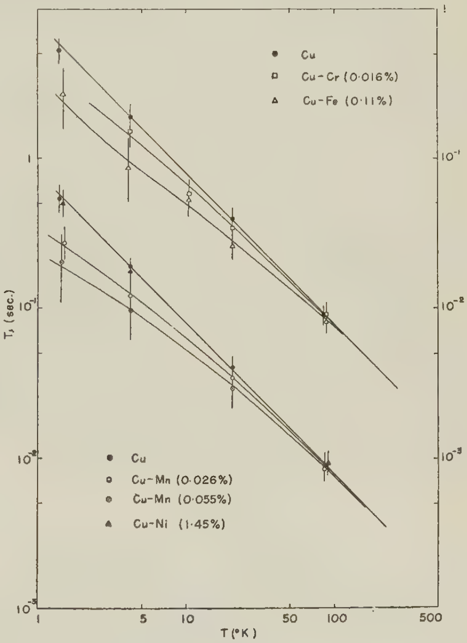

Fig. 15. Spin-lattice relaxation time T_1 of Cu^{63} in dilute alloys and in pure copper.

As is seen from Fig. 15, T_1 in paramagnetic alloys becomes shorter than that in pure Cu when the temperature is lowered. The deviation is large for alloys containing Mn and Cr, in which the line width is also large at low temperatures. In alloys containing non-magnetic solute such as Ni or Zn, T_1 is nearly the same as that of pure Cu. In general, $(1/T_1)$ can be expressed by the sum of transition probabilities of various relaxation mechanisms,

$$1/T_1=(1/T_1)_\sigma+(1/T_1)_S+(1/T_1)_D \tag{11}$$

where $(1/T_1)_\sigma$ is the contribution from the Heitler-Korringa relaxation²⁶⁾, $(1/T_1)_S$ is that due to the interaction of the nuclear spins with the solute spins and $(1/T_1)_D$ is that due to the spin diffusion[27]. It is not possible to derive the contribution of $(1/T_1)_S$ and of $(1/T_1)_D$ separately from the observed data. But the present result shows that $(1/T_1)_S$ or $(1/T_1)_D$ is comparable in magnitude with $(1/T_1)_\sigma$ in paramagnetic alloys such as Cu–Mn. At present the origin of such short T_1 is not clear, though the spin diffusion seems to be responsible in part for this.

---

* However, this assumption was proved to be not a poor approximation from the fact that the theoretical saturation curve agreed with experimental data fairly well and also the whole line shape did not change appreciably with increasing degree of saturation.

The foregoing analysis has been made on the assumption that the homogeneous saturation occurs only over the region determined by the width of pure Cu. If the homogeneous region is more broad than that assumed, T_1 of paramagnetic alloys at low temperatures will become shorter than the value shown in Fig. 15.

Acknowledgements

The author would like to express his thanks to Prof. E. Kanda for his continued interest and encouragement. He is also grateful to Dr. T. Moriya, Mr. Y. Obata, Mr. H. Hasegawa, Dr. Y. Shibuya, Mr. T. Otsuka, and Mr. S. Nagasaki for their helpful suggestions and discussions. This work has been supported in part by the Scientific Research Expenditure from the Ministry of Education.

Theory of Spatially Growing Plasma Waves

By Masao Sumi

Electrical Communication Laboratory,
Musashino-shi, Tokyo

(Received January 26, 1959)

The linearized theory of spatially growing waves in a uniform plasma is investigated in detail. By solving the dispersion relation in this case, characteristics of excited waves are presented. Behaviors of the growth-rate and the phase-velocity of amplified wave are examined in connection with the frequency and various conditions of the medium plasma and the directed beam. It is seen that the theory is in good agreement with some features of experimental results.

§ 1. Introduction

Longitudinal plasma waves which increase with distance have been discussed by many authors. The amplification process in double-stream discovered by Haeff and others[1)] is a simple example of this kind. Two groups of electrons with different velocities interact with each other, as a result of which, under some favorable circumstances, a disturbance located at some point increases in the direction of streams as it propagates. It is found that an amplified wave receives energy from the faster stream and has a phase-velocity which lies almost midway between two velocities in the double-stream. If the plasma consists of electrons with distributed velocities, the simple theory of double stream is not appropriate. This case has also been discussed to some extent in several papers by taking approximate velocity distribution in the thermal plasma. Feinstein and Sen[2)] took the square velocity distribution of thermal electrons and established the region over which the wave is amplified, but they did not give the magnitude of amplification. A dispersion relation equivalent to theirs was also examined by Lampert[3)], who disclosed a part of features of its solution.

The present paper, which solves fundamental equations as a boundary value problem, completes the more detailed investigation for beam excitation of plasma waves in linear approximation, together with our latest work[4)] (abbreviated hereafter as I), in which characteristics of solutions for an initial value problem were examined. The procedure in analysis employed here will follow that adopted in I: the Fourier-Laplace transform of fundamental equations will lead to a dispersion relation, the solution of which will yield characteristics of growing waves in space.

§ 2. Dispersion Relation

Fundamental equations used here are the same as those in part I; namely, the Boltzmann equation and the Poisson equation.

As usual the linearized equations for oscillating components are obtained, neglecting short range collisions, as below

$$\frac{\partial f_1}{\partial t}+\boldsymbol{v}\frac{\partial f_1}{\partial \boldsymbol{x}}-\frac{e}{m}\boldsymbol{E}\frac{\partial f_0}{\partial \boldsymbol{v}}=0\,, \tag{2.1}$$

and

$$\frac{\partial \boldsymbol{E}}{\partial \boldsymbol{x}}=-\frac{e}{\varepsilon_0}\int f_1 d\boldsymbol{v}\,. \tag{2.2}$$

To deal with a boundary-value problem, let the equations above be Fourier-analysed in time and Laplace-transformed in space. In one dimensional case. they become

$$i(\omega-ku)F(u,\,k,\,\omega)+uf(u,\,0,\,\omega)+\frac{e}{m}\mathcal{E}(k,\,\omega)\frac{df_0}{du}=0\,, \tag{2.3}$$

$$ik\mathcal{E}(k,\,\omega)-E(0,\,\omega)=-\frac{e}{\varepsilon_0}\int_{-\infty}^{\infty}F(u,\,k,\,\omega)du\,, \tag{2.4}$$

where $E(u,\,k,\,\omega)$ and $\mathcal{E}(k,\,\omega)$ are the Fourier-Laplace transforms of $f(u,\,z,\,t)$ and $E(z,\,t)$ respectively,

$$\begin{Bmatrix} F(u,\,k,\,\omega) \\ \mathcal{E}(k,\,\omega) \end{Bmatrix}=\frac{1}{2\pi}\int_0^\infty dz\int_{-\infty}^{\infty}dt e^{-i(kz-\omega t)}\begin{Bmatrix} f(u,\,z,\,t) \\ E(z,\,t) \end{Bmatrix}\,. \tag{2.5}$$

While $f(u,\,0,\,\omega)$ and $E(0,\,\omega)$ represent the Fourier components for the boundary value of respective quantity.

From Eqs. (2.3) and (2.4) we obtain the transformed electric field component

$$\mathcal{E}(k,\omega)=\frac{-iE(0,\omega)+\dfrac{e}{\varepsilon_0 k}\displaystyle\int_{-\infty}^{\infty}\frac{uf(u,0,\omega)}{(u-\omega/k)}du}{k\left[1-\dfrac{e^2}{m\varepsilon_0 k^2}\displaystyle\int_{-\infty}^{\infty}\frac{df_0/du}{(u-\omega/k)}du\right]}\,, \tag{2.6}$$

for Im$(k)<0$. The expression which is valid for the whole k plane can be defined by means of analytical continuation of Eq. (2.6). The result is that the path of integration along the real axis of u-plane in Eq. (2.6) has to be replaced by the contour C or C′, according to whether the value of ω is positive or negative, respectively. The contour C, as argued in I, goes from $-\infty$ to $+\infty$ making a downward detour in the lower half u-plane in order to avoid all singularities; and the contour C′ takes the similar path in the upper half-plane.

To find $E(z,t)$, $\mathcal{E}(k,\omega)$ must be transformed inversely to the original coordinates. Then it becomes necessary to get roots of the denominator of $\mathcal{E}(k,\omega)$ which, in turn, are determined by the dispersion relation

$$D(k,\omega)\equiv 1-\frac{e^2}{m\varepsilon_0 k^2}\int_{\mathrm{C\ or\ C'}}\frac{df_0/du}{u-\omega/k}du=0\,. \tag{2.7}$$

Thus the solution of the relation (2.7) for ω real and k complex, such as $k=k_0-i\gamma$, gives characteristics of plasma waves in a boundary value problem.

In our case of beam excitation, it is supposed that the stationary distribution function $f_0(u)$ is composed of one part for uniform plasma and the other for a directed beam; the former has a Maxwellian form and the latter a δ-functional form corresponding to a single velocity. Hence we may write

$$f_0(u)=(n_p/\sqrt{\pi}\,u_T)\exp\left[-(u/u_T)^2\right]+n_b\delta(u-u_b)\,, \tag{2.8}$$

where n_p and n_b are electron densities in the plasma and the beam respectively, and u_T denotes the mean thermal velocity in the plasma: $u_T=(2\kappa T/m)^{1/2}$. With this distribution function, the dispersion relation (2.7) becomes

$$D(k,\omega)=1+\left[2\beta_p^2\{1\pm i\sqrt{\pi}\,\beta e^{-\beta^2}[1\pm\Phi(i\beta)]\}-\frac{\beta_b^2}{(\xi-\beta)^2}\right]=0\,, \tag{2.9}$$

(+sign for $\omega>0$, $-$sign for $\omega<0$)

where $\beta_p=\omega_p/ku_T$, $\beta_b=\omega_b/ku_T$, $\beta=\omega/ku_T$, $\xi=u_b/u_T$, $\omega_p^2=n_pe^2/m\varepsilon_0$, $\omega_b^2=n_be^2/m\varepsilon_0$ and

$$\Phi(x)=\frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}dt\,.$$

If the value of ω/k_0 is positive, k_0 being the real part of complex k, the excited wave propagates in the same direction as that of beam velocity; or it is a forward wave. If it is negative, the wave propagates in the reverse direction, or a backward wave. Accordingly the double signs in Eq. (2.9) can be rewritten as follows

$$D(k,\omega)=1+\left[2\beta_p^2\{1+i\sqrt{\pi}\,\beta e^{-\beta^2}[1+\Phi(i\beta)]\}-\frac{\beta_b^2}{(\xi\mp\beta)^2}\right]=0\,, \tag{2.10}$$

where the minus sign corresponds to forward waves and the plus one to backward waves. Solutions of Eq. (2.10) for Im$(k)\gtreqless 0$ will give features of spatially growing, stationary or decaying waves, respectively. They will be examined in later sections.

§ 3. Characteristics of Growing Waves

On the physical ground it may be inferred that a growing wave will occur in the forward direction and not in the backward, since a forward wave alone couples closely with the beam and receives energy from it. Hence in this section only forward waves will be considered.

Now the dispersion relation for a forward wave will be solved for $Im(k)>0$. We are mainly interested in the case when the electron velocity in the beam is much greater than the mean thermal velocity of electrons in the medium plasma, or $\xi\gg 1$. As an amplified wave has a phase velocity a little below the beam velocity, $|\beta|$ may also be greater than 1. For $|\beta|\gg 1$, $\Phi(i\beta)$ is expanded as a power series in β^{-2}. Thus the dispersion relation (2.10) can be written as

$$1=\frac{\beta_p^2}{\beta^2}\left(1+\frac{3}{2\beta^2}+\frac{15}{4\beta^4}+\cdots\right)+\frac{\beta_b^2}{(\xi-\beta)^2}\,. \tag{3.1}$$

After some manipulations we devide Eq. (3.1) into a real and an imaginary part by putting $k=k_0-i\gamma$ ($\gamma>0$), in order to seek solutions for growing waves. Then we get

$$\left(\frac{\omega}{\omega_p}\right)^2=\left[1+\frac{3}{2\xi^2}\frac{(1-\varepsilon^2)}{(1-\chi)^2}+\frac{15}{4\xi^4}\frac{\{(1-\varepsilon^2)-4\varepsilon^2\}}{(1-\chi)^4}+\cdots\right]+\sigma\frac{(1-\chi^2)(\chi^2-\varepsilon^2)}{(\chi^2+\varepsilon^2)^2}\,. \tag{3.2}$$

$$\frac{3}{2\xi^2}\frac{(\chi^2+\varepsilon^2)^2}{(1-\chi)^4}\left[1+\frac{5}{\xi^2}\frac{(1-\varepsilon^2)}{(1-\chi)^2}+\cdots\right]=\sigma\chi\,, \tag{3.3}$$

where $\sigma=n_b/n_p$, $\varepsilon=\gamma/k_0$ and $\chi=1-(\omega/k_0u_b)$. Solutions of these two equations will give characteristics of growing waves of the form $\exp(\gamma z)\exp[i(k_0z-\omega t)]$; namely, relations between the frequency ω, the growth-rate γ and the phase-velocity of the wave ω/k_0.

Consider first the extreme case of $u_T\rightarrow 0$, or the case without thermal motions in the medium plasma. Then ξ tends to infinity, giving solutions of Eq. (3.3), $\chi=0$ or 1. From the definition $\chi=1$ implies the wave phase velocity $u_w=\omega/k_0=0$. It is indeed a physically trivial solution. For $\chi=0$, $u_w=u_b$; the wave is entirely synchronized with the beam. Hence we can obtain from Eq. (3.2) the growth-rate

$$(\gamma u_b/\omega_p)^2=\sigma/[(\omega_p/\omega)^2-1]\,. \tag{3.4}$$

In the frequency range $0<\omega<\omega_p$, it gives $0<\gamma<\infty$ and ω_p is a sort of resonant frequency. It is this situation that was early discussed by Pierce[1].

In general cases, Eqs. (3.2) must be solved numerically. With two parameters of ξ and σ, Eq. (3.3) gives a function of $\chi(\varepsilon;\,\xi,\,\sigma)$. Inserting it into the right hand side of Eq. (3.2), ω/ω_p is obtained as a function of ε, too. From these both the growth-rate γ and the phase velocity u_w of the wave are traced against a variable ε, by the use of relations such that $\gamma u_b/\omega_p=\varepsilon(\omega/\omega_p)/(1-\chi)$ and $u_w/u_b=1-x$. Then we get finally Figs. 1–4.

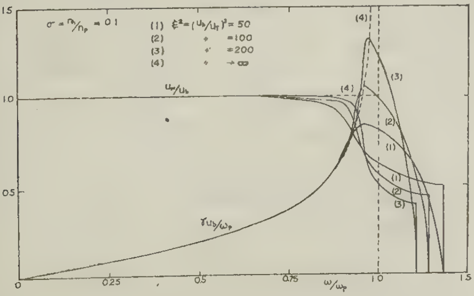

Fig. 1. Characteristics of amplified wave *versus* the frequency, when the mean thermal velocity of electrons in the plasma is varied.

Fig. 1 represents the rate of growth and the phase-velocity of the amplified wave versus the modulating frequency with a parameter ξ, σ being held constant: a typical value 0.1. In the frequency range far below the plasma frequency ω_p, γ increases slowly with ω, but remains small. The wave phase velocity is nearly equal to the beam velocity. As ω approaches ω_p, γ rises sharply and reaches its maximum at a frequency a little below ω_p, beyond which it falls steeply to zero. The phase velocity u_w decreases rapidly near the maximum point of γ, where the energy transfer from the beam to the wave also reaches its maximum proportional to γ. If we suppose u_b to be kept constant and u_T to be varied, the peak value becomes larger with decreasing u_T or increasing ξ, until it tends fo infinity at vanishing u_T as was mentioned in the preceding paragraph. This limiting case for $\xi^2\rightarrow\infty$ is also shown in Fig. 1 by a broken line.

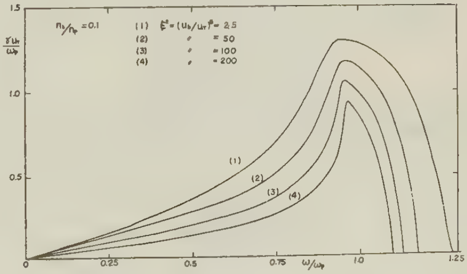

Fig. 2. The growth-rate of amplified wave *versus* the frequency, when the beam velocity is changed.

On the contrary to the above, when u_T holds constant and u_b becomes greater, curves for the rate of growth $\gamma u_T/\omega_p$ are plotted in Fig. 2. As u_b or ξ increases, the magnitude of peak value of γ gets smaller. In the limit of $\xi^2\rightarrow\infty$, the curve for γ is flattened; it implies that the amplification is reduced to infinitecimal. The reason is that the faster is the beam velocity, the shorter becomes the interaction time per unit length, resulting the reduction of growth-rate.

In Fig. 3 the behavior for varying beam density with a definite beam velocity is represented. With increasing density, the peak of the growth-rate curve is more elevated and more apart from the plasma frequency.

Finally Fig. 4 presents several curves of amplification rate, $\gamma u_b/\omega_b$ with a parameter of modulating frequency ω, when the plasma density is varied and the beam is unvaried. Each curve shows an abrupt rise beyond the critical density until it reaches its peak-value at a density such that ω_p is slightly over ω. Beyond the peak, the curve falls off rather gradually. In the next section this feature will be compared with that observed.

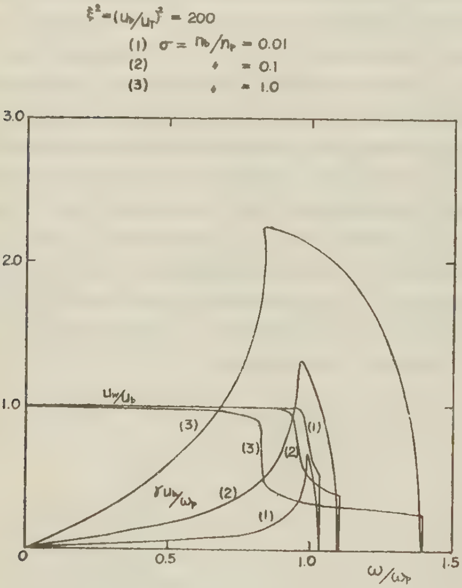

Fig. 3. Wave characteristics for varying beam density with a constant beam velocity.

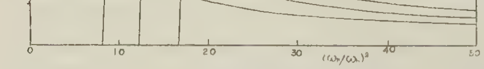

Fig. 4. The rate of amplification for the variation of plasma density, the beam being unaltered.

§4. Comparison with Experimental Results and Discussions

Recently an experiment corresponding to the excitation of spatially growing waves as discussed above has been successfully performed[5]. A fast electron beam, passed through a plasma in gaseous discharges with a definite depth, was modulated near the incident boundary by a microwave signal. Then an output signal was picked up from the modulated beam after leaving the opposite boundary of the plasma. Thus the amplification of the signal was observed; curves for relative output gain versus arc current were obtained at several frequencies. These may be compared with the theory in the following.

An electric field of amplified wave can be written as $E=E_0 \exp(\gamma z)$, so that the output gain expressed by decibels is found to be proportional to γ. On the other hand it is known that the plasma arc current is proportional to the electron density, or to ω_p^2. Consequently, experimental curves in this case should correspond to theoretical curves given in Fig. 4. Indeed it is the case as expected, since the rapid rise on one side of the peak and the gradual fall on the other side can be seen in both groups of curves and besides the shift of each curve with respect to the variation of frequency occurs in a quite similar way. This can be regarded as a satisfactory verification for qualitative agreements between theory and experiment.

The experimental value of output gain, about 8 db per cm for the beam voltage of 400 volts and the modulating frequency of about 3000 Mc/sec, has been obtained*. The theoretical value is now expressed as $8.69\,\gamma$ db. The maximum γ for different values of σ are estimated from Fig. 3; the value of $\gamma_{\max} u_b/\omega$ are about 1.3, 0.7 and 0.3 for $\sigma=0.1$, 0.01 and 0.001, respectively. We see that the calculated gain is much greater than that observed, since it amounts to about 40 db per cm even at $\sigma=0.001$. The reason for this discrepancy has not yet been clarified. If a high gain such as predicted by the theory is realized, it will cause a saturation effect of amplification, although it is beyond the validity of linear theory.

The approximation for $|\beta|\gg 1$ in which the error integral can be expanded as a power series does not hold good as $|\beta|$, or ξ, approaches 1. In the range of $|\beta|\sim 1$, the expansion cannot be applied and a numerical table for the error integral must be used. As seen in Fig. 2, the decrease of u_b or ξ gives rise to a higher peak-value of $\gamma u_T/\omega_p$. However as $|\beta|$ approaches one, it would not be so. It would be inferred that the peak-value begins to reduce and finally to zero somewhere u_b is nearly equal to u_T, although the detailed knowledge of it cannot be obtained unless we have exact solutions for $|\beta|\sim 1$.

---

* This result was reported at the Brooklyn Polytechnic Symposium in April 1958. In this report the calculation for gain similar to that we developed here was carried out independently and its result agrees with a part of ours. The author is indebted to Dr. Boyd for his communication.

So far we have considered only the case for growing waves. Now some remarks will be given concerning stationary or decaying waves. For a stationary or undamped wave, we may suppose both ω and k as real. Hence so is β, and the function $\Phi(i\beta)$ becomes pure imaginary. The imaginary part of Eq. (2.10) can then be written as

$$2\sqrt{\pi}\,\beta_p{}^2\beta e^{-\beta^2}=0\,. \tag{4.1}$$

Thus we get

$$\beta=0 \quad \text{or} \quad \beta\to\infty\,, \tag{4.2}$$

which, for ω non-zero and finite, yields

$$k\to\infty \quad \text{or} \quad k\to 0\,,$$

respectively. We find that the real part of Eq. (2.10) is not satisfied in the former case, whereas in the latter it gives the frequency $\omega=(\omega_p{}^2+\omega_b{}^2)^{1/2}$. It is to be noted that this is the only stationary wave. The wave which seems to exist in the limit of vanishing amplification, $\gamma\to 0$, cannot be realized, since the limit of $\varepsilon\to 0$ should be excluded in the case of amplification. This consequence is, of course, in accord with that derived by Berz6), in which the only stationary wave was that for $k=0$ and $\omega=\omega_p$ in the absence of beam.

For decaying waves, the dispersion relation can be expanded in Taylor's series with respect to γ in the case of smallest damping. Retaining only the first order terms for γ, we obtain a result

$$\frac{\gamma u_b}{\omega}\sim -\sqrt{\pi}\left(\frac{u_w}{u_T}\right)^2\left(\frac{\omega_p}{\omega_b}\right)^2 e^{-(u_w/u_T)^2}\,, \tag{4.3}$$

for $u_w \gg u_b$. The damping described by Eq. (4.3) is seen to behave in a similar way as the Landau damping7), which depends on the continuous velocity distribution of electrons in the plasma. In the limit of $k_0\to 0$, γ tends to zero, corresponding to the stationary wave. It may be concluded, at any rate, that the stationary and decaying waves discussed above would be practically unimportant for the beam excitation of plasma waves.

The spatially growing waves described in the present theory as well as in the double-stream theory have so far been observed only when the beam or beams were artificially modulated by a signal in the injection side. Without such a modulation, it will be impossible to get amplified waves propagating along the beam in a homogeneous plasma. In a usual gaseous discharge where a directed beam exists, it may be possible to get an amplified wave because of the inhomogeneity in the electron density. This phenomenon has recently been discussed by Emeleus et al8). In the case of a homogeneous plasma, on the contrary, it can be expected that plasma waves of a standing-wave form are excited9). The detailed comparison between theory and experiment with respect to it will be developed in the forthcoming paper.

Acknowledgment

The author wishes to express his gratitude to Professors T. Kihara and S. Kojima, and also to Dr. K. Takayama for their valuable remarks and discussions.

High Subsonic Flow with Normal Shock Wave at Nearly Critical Mach Number

By Takeo SAKURAI*

Department of Aeronautical Engineering, Faculty of Engineering, Kyoto University

(Received October 22, 1958)

High subsonic flow past a biconvex circular arc aerofoil with a pair of normal shock waves at nearly critical Mach number is discussed by a very simple approximation procedure. The shock waves are assumed to be the normal shock waves which start from the surface of the aerofoil and stand perpendicularly to the direction of the uniform flow. The locations of the sonic line and the shock waves are treated as unknown parameters to be determined in the course of analysis. The results show that these parameters have real physical meaning only when the Mach number exceeds the usual critical Mach number calculated by means of Prandtl-Glauert approximation. The results also suggest that the curvature of the profile must change discontinuously at its intersection with the shock wave. This fact is also confirmed by applying Lin's exact consideration. Thus, it is concluded that there can exist no high subsonic flow of ideal fluid with normal shock waves starting from the surface past a profile having continuous curvature.

§ 1. Introduction

The study of the high subsonic flow past a profile with shock waves is very important from the practical as well as the academic viewpoints. The analytic solution of the problem is, however, very difficult, because there is no simple fundamental solution for the mixet subsonic and supersonic flow field in the presence of shock waves. A few examples which have hitherto been attacked with success are all based on tedious numerical calculations. Emmons[1)] analysed the flow past a profile with a pair of shock waves originating from the surface by the relaxation method, and obtained the results which seemed to agree well with experiments. His results also suggest that there is a singular point of the flow field on the profile immediately behind the shock wave. The details of the structure of the singularity, however, have not been worked out, because the meshes used by him are too coarse. Recently, Oswatitsch[5)] proposed a method based on an integral equation which is deduced from the basic equations of transonic flow. He solved the integral equation by using a very rough approximation, and obtained the results which agreed qualitatively with experiments. Later on, Gullstrand[2)] and Spreiter[6)] improved his analysis, and obtained the results which seemed to be reliable quantitatively as well as qualitatively. They solved the integral equation assuming a kind of the velocity distribution in the y-direction all over the field, such that the length of the shock wave is infinite. The procedure of the numerical calculations is still very tedious in spite of the above simplifications. Thus, it may be said that their results are indeed useful, but not at all completely satisfactory. Because of these circumstances, it seems worthwhile to reconsider the problem of the high subsonic flow, and to complement the results hitherto obtained.

In this paper, the writer proposes a new simple approximation procedure to treat the high subsonic flow past a profile with shock waves at nearly critical Mach number, and applies this procedure to the flow past a biconvex circular arc aerofoil.

§ 2. Basic Equations

Following Oswatitsch,[4)] the basic equations of the high subsonic flow past a thin aerofoil are represented as follows,

$$(1-u)\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0 \tag{1}$$

---

* This work was done at the Department of Physics, Faculty of Science, University of Tokyo. This is abstracted from the thesis presented in partial fulfilment of the requirements for the degree of the Doctor of Science at the University of Tokyo.

$$\frac{\partial u}{\partial y}-\frac{\partial v}{\partial x}=0 \tag{2}$$

with

$$x=\hat{x}\,, \quad y=\beta_\infty\hat{y}\,, \quad \beta_\infty=\sqrt{1-M_\infty^2} \tag{3}$$

$$u=\frac{\hat{u}-\hat{u}_\infty}{\hat{c}_*-\hat{u}_\infty}\,, \quad v=\frac{1}{\beta_\infty}\frac{\hat{v}}{\hat{c}_*-\hat{u}_\infty} \tag{4}$$

Here $(\hat{x}, \hat{y})$ are the Cartesian coordinates of a point in the plane of fluid motion in which the $\hat{x}$-axis is taken parallel to the direction of the uniform flow. $(\hat{u}, \hat{v})$ are the velocity components and M_∞, $\hat{u}_\infty$ and $\hat{c}_*$ are respectively the Mach number, the magnitude of the velocity and the critical velocity of the uniform flow. Letters with circumflex indicate variables in the physical plane.

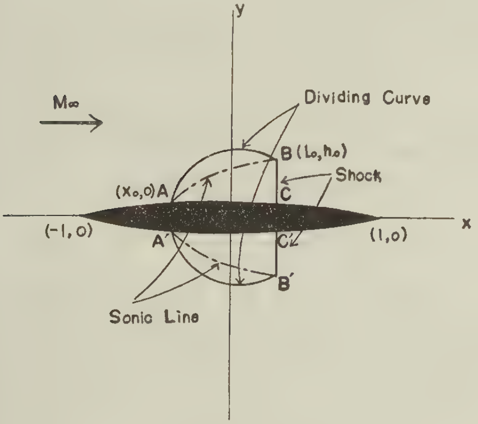

Fig. 1.

Let us divide the flow field into two regions, inner and outer, such that the latter corresponds to the purely subsonic flow while the former to the partly supersonic flow. (Fig. 1). From Eq. (4), it is clear that u is everywhere smaller than 1 in the purely subsonic region. Hence, we can obtain the crudest approximation to Eqs. (1) and (2) in the outer region by neglecting the nonlinear term of Eq. (1). This is, of course, equivalent to the well-known Prandtl-Glauert approximation:

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0 \tag{5}$$

$$\frac{\partial u}{\partial y}-\frac{\partial v}{\partial x}=0 \tag{6}$$

If the Mach number of the uniform flow exceeds the critical value only slightly, it is expected that the partly supersonic region is very small and u is almost equal to 1 in and near the region. Then, to the crudest approximation, we can neglect the first term of Eq. (1) in the inner region. It is equivalent to the Prandtl-Glauert equation at Mach number 1, and the equation is of parabolic type having characteristic curves perpendicular to the x-axis:

$$\frac{\partial v}{\partial y}=0 \tag{7}$$

$$\frac{\partial u}{\partial y}-\frac{\partial v}{\partial x}=0 \tag{8}$$

Boundary conditions are similar to those in the usual thin wing theory:

1) (u, v) is one-valued and finite all over the flow field,

2) $(u, v)\to 0$ as $|x+iy|\to\infty$,

3) $\hat{v}=\hat{u}_\infty \frac{d\hat{y}}{d\hat{x}}\Big|_{\hat{y}=0}$ on the surface of the profile, which lies approximately on $\hat{y}=0$

$$v=\frac{M_\infty^*}{\beta_\infty^2(1-M_\infty^*)}\frac{dy}{dx}\Big|_{y=0} \quad \text{with} \quad M_\infty^*=\frac{\hat{u}_\infty}{\hat{c}_*}\,. \tag{9}$$

§ 3. The Method of Solution

Before proceeding to the discussion of the new method of solution, we must consider the relation which connects the inner and the outer solutions. The boundary curve between the inner and the outer regions is assumed to be composed of the shock wave and some suitable curve (e.g. a circular arc). On the portion of the boundary corresponding to the shock wave, two solutions are related by the shock condition:

$$1-u_i=u_o-1 \tag{10}$$

As will be shown below, the relation on the remaining part of the boundary may be taken simply as

$$u_i=u_o\,, \qquad v_i=v_o \tag{11}$$

where (u_i, v_i) and (u_o, v_o) are respectively the inner and the outer solutions. Indeed, if we could have obtained the exact solutions of the original equations (1) and (2) for the two regions, the above relations would obviously ensure the coincidence of the derivatives of u and v of any arbitrary order on both sides of the boundary curve. In our case, however, different approximate equations have been adopted in the two regions, so that we could not expect the coincidence of the values of derivatives of u and v calculated in the respective regions, even if we adjust the solutions so as to satisfy the relations (11). Such discrepancies are, however, expected to become smaller, if we adopt higher approximations to the original equations (1) and (2). Thus it appears that the above relations (11) are suitable for our purpose.

The procedure of solving the problem is as follows: First, we assume the location of the sonic line which represents the boundary of the supersonic region. We next divide the flow field, as mentioned above, into the inner and the outer regions by a curve which is composed of the shock wave and the other part wholly lying in the purely subsonic region (Fig. 1).

Now, the inner solution is uniquely determined by the boundary condition on the surface of the profile and the location of the sonic line already assumed. Then the connecting relations (11) together with the shock conditions (10) afford the u_o-distribution over the dividing curve. The outer solution is determined uniquely by means of this u_o-distribution and the remaining boundary conditions.

Comparing the solutions thus obtained, on the dividing curve, we find of course $u_i=u_o$ but in general $v_i\neq v_o$. Unknown parameters relating to the location of the sonic line are then adjusted by the requirement $v_i=v_o$ on the dividing curve.

Since the boundary condition (9) is satisfied in our approximation, (u_i, v_i) already coincide with (u_o, v_o) at the connecting point on the profile. There exist, however, discrepancy of the velocity gradient at that point. Such a discrepancy is undesirable, because the velocity gradient is one of the most important quantities from the physical viewpoints. Hence, let us require further that the velocity gradients of both solutions must be equal on the profile though it may appear to be an over-determinate condition in the exact treatment of the original equations (1) and (2).

§ 4. Application to the Flow past a Biconvex Circular Arc Aerofoil

Let us consider the flow past a biconvex circular arc aerofoil. The shock wave is assumed to be normal to the x-axis, extending from the point B to B′ (Fig. 1). The shape of the sonic line is assumed to be parabola passing points A, B(A′, B′) with its axis of symmetry on the line $x=l_0$:

$$y=\pm h_0\left\{1-\left(\frac{x-l_0}{x_0-l_0}\right)^2\right\}$$

+: upper half plane
−: lower half plane (12)

The dividing curve is assumed to be a circle passing points BA(A′)B′:

$$\left\{x-\frac{l_0^2-x_0^2+h_0^2}{2(l_0-x_0)}\right\}^2+y^2=\left\{\frac{(l_0-x_0)^2+h_0^2}{2(l_0-x_0)}\right\}^2 \tag{13}$$

From the assumed shape of the sonic line and the boundary condition on the profile the inner solution is obtained immediately:

$$\left.\begin{aligned} u_i&=1+2\nu\left[h_0\left\{1-\left(\frac{x-l_0}{x_0-l_0}\right)^2\right\}-y\right]\\ v_i&=-2\nu x\end{aligned}\right\} \tag{14}$$

where

$$\nu=\frac{tM_\infty^*}{\beta_\infty(1-M_\infty^*)}$$

and t is the thickness ratio of the profile. Here the boundary condition (9) for the circular arc aerofoil is expressed as follows;

$$v=-2\nu x \tag{15}$$

In order to obtain the outer solution, let us decompose the solution as follows:

$$w_o=u_o-iv_o=w_o^{(1)}+w_o^{(2)} \tag{16}$$

$$w_o^{(1)}=\frac{2\nu}{\pi}\left(2+z\log\frac{z-1}{z+1}\right),\qquad z=x+iy \tag{17}$$

$w_o^{(1)}$ is nothing but the usual Prandtl-Glauert solution. $w_o^{(2)}$ represents the distortion of the outer solution imposed by the existence of the shock wave, and must satisfy the following boundary conditions:

(A) $w_o^{(1)}$ is one-valued and continuous throughout the outer region,

(B) $w_o^{(2)}\to 0$ as $|z|\to\infty$,

(C) $v_o^{(2)}=0$ on the surface of the profile,

(D) on the dividing curve the following conditions must be satisfied:

(a) on the shock wave:

$$u_o^{(2)}=1-\frac{4\nu}{\pi}(1-l_0^2)+2\nu(2y-h_0) \tag{18}$$

(b) on the dividing circle:

$$u_o^{(2)}=1-\frac{4\nu}{\pi}(1-x^2+y^2)+2\nu h_0\left\{1-\left(\frac{x-l_0}{x_0-l_0}\right)^2\right\} \tag{19}$$

In these expressions, we have assumed that the Mach number of the uniform flow is nearly critical, that is, $x_0, l_0, h_0\ll 1$, and retain only the terms of the lowest order of these quantities. Also, inspecting these conditions, we find that

$$l_0 \sim x_0\,, \qquad h_0 \sim x_0^2 \tag{20}$$

provided that x_0, h_0, l_0 contributed simultaneously to the value of $u_o^{(2)}$ on the dividing curve. From the above relations (20) we can show that the shape of the sonic line of our solution is similar to that of the continuous solution $w_o^{(1)}$. Thus, the above relation seems to be plausible from the physical viewpoint, for it is expected that the shape of the sonic line does not change suddenly even if a shock wave appears. We assume, therefore, the above relation (20), and take the lowest order of x_0.

Further, since $l_0 \ll 1$, the trace of the shock wave can be safely replaced by the circular arc BB′, so that the problem reduces to a very simple form, that is, to obtaining a harmonic function, the value of which is given over a small circle and which becomes 0 at ∞. The condition on the profile is satisfied automatically by the symmetry of the solution.

The point (x, y) on the dividing circle is represented, by the assumption (20), as follows,

$$\left.\begin{aligned} x &= \frac{l_0+x_0}{2} + \frac{l_0-x_0}{2}\cos\theta \\ y &= \frac{l_0-x_0}{2}\sin\theta \end{aligned}\right\} \tag{21}$$

where $0 \leq \theta \leq 2\pi$. Inserting (21) into Eqs. (18) and (19), these conditions are rewritten as follows:

on the unit circle of the ζ-plane,

$$u_o^{(2)} = u_o^{(2),1} + u_o^{(2),2} \tag{22}$$

$$\begin{aligned} u_o^{(2),1} = 1 &- \frac{4\nu}{\pi} + \frac{\nu}{\pi}(l_0+x_0)^2 + \frac{5}{4}\nu h_0 \\ &+ \left\{\frac{2\nu}{\pi}(l_0^2-x_0^2) + \nu h_0\right\}\cos\theta \\ &+ \left\{\frac{\nu}{\pi}(l_0-x_0)^2 - \frac{\nu h_0}{4}\right\}\sin 2\theta \\ &\qquad 0 \leq \theta \leq 2\pi \end{aligned} \tag{23}$$

$$u_o^{(2),2} = \begin{cases} -4\nu h_0 + 4\nu h_0 \dfrac{\theta}{\theta_0} & 0 \leq \theta \leq \theta_0 \\ 0 & \theta_0 \leq \theta \leq 2\pi - \theta_0 \\ -4\nu h_0 + 4\nu h_0 \dfrac{2\pi-\theta}{\theta_0} & 2\pi - \theta_0 \leq \theta \leq 2\pi \end{cases} \tag{24}$$

where

$$\zeta = \left(z - \frac{l_0+x_0}{2}\right) \bigg/ \left(\frac{l_0-x_0}{2}\right) \tag{25}$$

the analytic function $w_o^{(2)}$ which satisfies the above conditions is easily obtained by the formula in the theory of functions:[7)]

$$\begin{aligned} w_o^{(2)} = 1 &- \frac{4\nu}{\pi} + \frac{\nu}{\pi}(l_0+x_0)^2 + \frac{5}{4}\nu h_0 \\ &+ \left\{\frac{2\nu}{\pi}(l_0^2-x_0^2) + \nu h_0\right\}\frac{1}{\zeta} \\ &+ \left\{\frac{\nu}{\pi}(l_0-x_0)^2 - \frac{\nu h_0}{4}\right\}\frac{1}{\zeta^2} \\ &+ \frac{2\nu h_0}{\pi}\int_0^{\theta_0}\left(-1+\frac{\theta}{\theta_0}\right)\frac{\zeta e^{i\theta}+1}{\zeta e^{i\theta}-1}d\theta \\ &+ \frac{2\nu h_0}{\pi}\int_{2\pi-\theta_0}^{2\pi}\left(-1+\frac{2\pi-\theta}{\theta_0}\right)\frac{\zeta e^{i\theta}+1}{\zeta e^{i\theta}-1}d\theta \end{aligned} \tag{26}$$

It is clear that this solution already satisfies the conditions (A), (C) and (D). However, the first term (constant) as well as the integral terms do not vanish in general at ∞, contrary to the condition (B). Because the contributions from the integral terms are $O(x_0^3)$ and may be neglected, the condition (B) then requires the first constant term to vanish, i.e.

$$1 - \frac{4\nu}{\pi} + \frac{\nu}{\pi}(l_0+x_0)^2 + \frac{5}{4}\nu h_0 = 0 \tag{27}$$

On the other hand, from Eqs. (14), (16), (17) and (26), the condition that the velocity gradients of the inner and outer solutions must coincide at $(x_0, 0)$ is represented as follows:

$$\frac{16x_0}{\pi} + \frac{3h_0}{l_0 - x_0} = \frac{4h_0}{x_0 - l_0} \tag{28}$$

Also it is required, as already mentioned, that $v_i = v_o$ on the dividing circle. But, because two conditions (27) and (28) have already been assigned for three parameters x_0, l_0 and h_0, we can satisfy the condition: $v_i = v_o$ at only one point or in the mean on the circle. The latter procedure gives

$$\frac{4}{\pi}(l_0^2 - x_0^2) + h_0 = 0 \tag{29}$$

The same relation would also be obtained by satisfying the condition at the top of the circle ($\theta = \pi/2$). Hence, we shall adopt (29) as the third condition for determining the parameters x_0, l_0 and h_0.

Solving (27), (28) and (29), we obtain the following expressions for x_0, l_0, h_0:

$$\left.\begin{aligned} &x_0=-\frac{7\sqrt{\pi}}{\sqrt{216}}\sqrt{\frac{4\nu/\pi-1}{\nu}}, \qquad l_0=-\frac{3}{7}x_0 \\ &h_0=\frac{160}{216}\frac{4\nu/\pi-1}{\nu} \end{aligned}\right\} \tag{30}$$

§ 5. Results and Discussions

The manner of variation of x_0, l_0 and h_0 with Mach number is shown in Table I, for the case when the thickness ratio of the profile is 0.06.

Table I.

M_∞	x_0	l_0	h_0
0.85	positive	negative	negative
0.8526	−0.0438	0.0188	0.00199
0.853	−0.0772	0.0331	0.00620
0.854	−0.1266	0.0543	0.01666
0.856	−0.1897	0.0813	0.03742
0.86	−0.2745	0.1176	0.07892

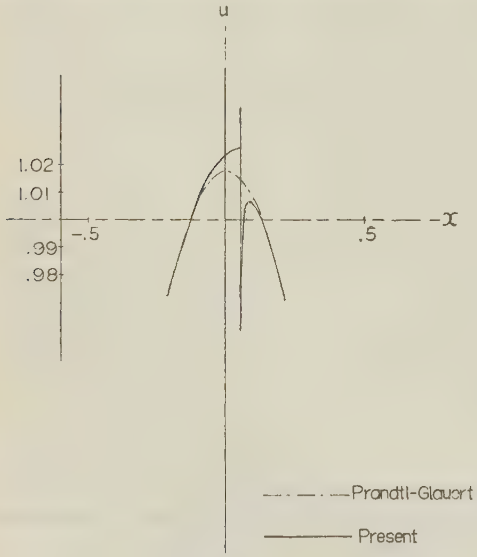

Fig. 2.

When the Mach number of the uniform flow is below the critical value corresponding to Prandtl-Glauert solution (0.8524), all x_0, l_0 and h_0 take values without any physical meaning. But as soon as the Mach number exceeds this critical value, these parameters become significant and their absolute values increase with Mach number. This is a very remarkable feature of our result, which gives a new meaning to the concept of the usual critical Mach number. The rapid change of l_0 near the critical Mach number also agrees qualitatively with Spreiter's results.

Fig. 2 gives the velocity distribution over the profile for the case $t=0.06$, $M_\infty=0.854$, where the neighbourhood of the supersonic region is magnified in order to reveal the fine structure of the distribution. Comparing our result with Spreiter's, we find that in our case the velocity changes very rapidly behind the shock wave and becomes partly supersonic. Especially the velocity gradient becomes infinite, immediately behind the shock wave, suggesting that it is a singular point of the solution. This is due to the fact that we have used the normal shock condition to obtain u_o on the back side of the shock wave. Let us now discuss this point in some detail.

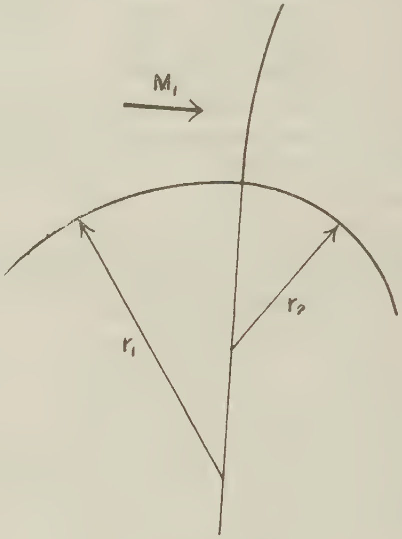

Fig. 3.

From the irrotationality $\partial v_i/\partial x=\partial u_i/\partial y$, $\partial v_o/\partial x=\partial u_o/\partial y$ and the shock condition $1-u_i=u_o-1$, we obtain

$$-(\partial v_i/\partial x)=\partial v_o/\partial x \tag{31}$$

In the thin-wing expansion method, $\partial v/\partial x$ represents the curvature of the profile, so that Eq. (31) represents the fact that there must be a discontinuity of the curvature of the profile through the shock wave. This result is clearly of general nature and can be applied to the case of Spreiter and Gullstrand. Their results seem at first sight to be plausible because of the moderate behaviour of velocity distribution behind the shock wave. However, this is wholly due to their erroneous assumption for the form of the velocity distribution normal to the aerofoil surface immediately after the shock wave. The velocity gradient there must be infinite as in the present case. C. C. Lin[3] discussed in an exact manner the case of the normal shock wave on the curved profile, and deduced the following relation,

$$\frac{2}{\gamma+1}\left\{M_1^2-\frac{\gamma+3}{2}\right\}\cdot\left(-\frac{1}{r_1}\right) - \frac{1}{\gamma+1}\left\{\frac{2}{M_1^2}+(\gamma-1)\right\}\cdot\left(-\frac{1}{r_2}\right)=0 \qquad (32)$$

where M_1 is the Mach number in front of the shock wave, r_1 and r_2 are the radii of curvature of the profile in front and after the shock wave respectively (Fig. 3). In this equation, if we assume $M_1 \simeq 1$, we obtain $r_1 \simeq -r_2$, which is equivalent to the relation (31).

From the above discussions, it is concluded that there can exist no high subsonic flow with shock waves past a profile having continuous curvature. The only exceptional case is that of zero curvature, e.g. the case of flow past a wedge or a diamond profile. The former case has recently been discussed by H. Yoshihara.[8] The existence of approximately normal shock waves observed in experiments seems to be due to the interference of the shock wave and the boundary layer. Full explanation of the phenomenon will be the subject of the future work.

Acknowledgement

Flash X-Ray Radiography for the Density Measurement in a Hypersonic Air Flow

By Fumio TAMAKI
Institute of Industrial Science, University of Tokyo
and KIM, Chul-Soo
Department of Physics, Faculty of Science, University of Tokyo

(Received January 30, 1959)

Soft X-ray radiograph method using a flash X-ray tube was developed as a means of measuring air density in a hypersonic flow in a shock tube. The method was applied to the measurement of the density distribution between a circular cylinder and the detached shock wave at a free-stream Mach number of 5.5 and a free-stream density of about one-tenth of the normal atmosphere. Results suggest that the method is promising for the investigation of hypersonic flow fields, especially for the measurement of narrow regions with steep density gradients, because the effect of refraction can be neglected without error in the wavelength range of X-rays.

§ 1. Introduction

The technique most frequently used for the quantitative measurement of density in a high-speed air flow is the optical interferometry. The method is simple and has sufficient accuracies in most applications to the studies of transonic and supersonic flows in wind tunnels and shock tubes. However, it has certain disadvantages inherent in itself. Due to the refraction of light rays passing through the testing medium, the accuracy decreases when the measurement is made over a long path length in the neighbourhood of a model surface or in the region with a steep density gradient. Furthermore, the sensitivity of the method decreases seriously at low air density.

An alternative method which utilizes the absorption of soft X-rays has been introduced by Arnold.1) In his method, a narrow beam of X-rays normal to the direction of the flow is used, and the intensity of the transmitted X-rays as measured by an ionization chamber furnishes a measure for the integrated gas density across the test section. Considerable improvements in the techniques have been made by Winkler,2) Weltman, Fairweather and Papke,3) and Dimeff, Hallett and Hansen,4) using Geiger-Müller counters and improved X-ray tubes. A general survey of the X-ray techniques has also been made by Winkler.5)

In comparison to the usual optical methods, refraction and diffraction phenomena can be neglected with X-rays because of the small deviation of the index of refraction from unity and the short wavelength. Moreover, the method can be used at fairly low density if the wavelength of the X-rays is sufficiently long. Therefore, the method is considered to be particularly useful for the studies of such phenomena as occur near the body nose or within the boundary layer in a hypersonic, low-density air stream.

As to the technique of obtaining absorption data of a flow field, it is usual to make point-by-point measurements by moving the X-ray tube and the receiver. An alternative way is the so-called radiography, that is to photograph a certain portion of the flow field by the transmitted X-rays and measure the film density by a photodensitometer. This method has been proposed by Weltman, Fairweather and Papke in Ref. 3. Main difficulties in this procedure are that the photographic film is less sensitive to small X-ray intensities than ionization chamber or counter, and the production of strong X-rays of long wavelengths is a very difficult matter. Recently, we have noticed that the radiograph method with a continuously operating X-ray tube has been used successfully by Stine, Wagoner and Lugn6) for the studies of the transonic flow about a sharp leading edge.

In the present work, a technique for the soft X-ray radiography using a flash X-ray tube has been developed and applied to the hypersonic flow in a shock tube. The flash tube is of the type which has been developed by Prof. M. Hirata and Dr. F. Tachibana.[7] Air density of the free stream treated in our experiments is about one-tenth of the normal atmosphere, and the path length is 5.8 cm. In the X-ray range suitable for such measurements, a large portion of the X-rays produced in the flash tube is absorbed in its window material, so that at present a single flash is not sufficient for obtaining sufficient film densities. Accordingly, photographs are taken by repeating two or more times the operations of both the X-ray tube and the shock tube. However, the authors consider that the production of stronger X-rays by a single flash will be possible by improving the design of the X-ray tube and the discharge circuit.

§ 2. Theory of Density Determination by X-Ray Radiography

Theory of density determination by X-ray radiography has been developed by Weltman and others in Ref. 3. Outlines of the theory will be given in the following.

Assume that the X-rays are emitted conically from a point source, and after passing through an absorbing medium, reach a photographic film situated at a distance r from the source. Then the ratio of the intensity I of the X-rays remaining after absorption to the intensity I_0 of the X-rays incident on the absorber is expressed as

$$\frac{I}{I_0}=\frac{cA}{4\pi r^2}e^{-B\rho L} \qquad (1)$$

where B is the total mass absorption coefficient, ρ the density of the absorber, L the path length in the absorber, A the cross-sectional area of the X-ray beam at the distance r, and c a factor which accounts for the absorption before entering and after leaving the absorber.

Sensitivity in density measurement is given by the minimum detectable density change $\Delta\rho$ divided by the density ρ. This ratio can be calculated from Eq. (1) as

$$\frac{\Delta\rho}{\rho}=-\frac{\Delta I}{IB\rho L} \qquad (2)$$

where ΔI is the minimum detectable change in the X-ray intensity.

The characteristic curve of a photographic material, representing the film density as a function of the logarithmic exposure, is a straight line over a considerable portion. The equation of this straight line is expressed as

$$D=\gamma\{\log(I/A)+\log t-\log i\} \qquad (3)$$

where D is the film density, γ the slope of the line, t the exposure time and i the inertia of the film.

Substituting Eq. (1) into Eq. (3), we have

$$\rho=-\frac{D}{0.434\gamma BL}+K \qquad (4)$$

where

$$K=\gamma\left(\log\frac{I_0c}{4\pi r^2}+\log t-\log i\right)\Big/(0.434\gamma BL) \qquad (5)$$

is a constant for a given experimental arrangement and exposure time.

From Eq. (4), the sensitivity in air-density measurement is written as

$$\frac{\Delta\rho}{\rho}=-\frac{\Delta D}{0.434\gamma B\rho L} \qquad (6)$$

where ΔD is the minimum detectable change in film density. This equation shows that a high sensitivity can be obtained when the total mass absorption coefficient is large.

Total mass absorption coefficient is expressed by the empirical relation

$$B=CZ^4\lambda^3+\sigma(Z,\lambda) \qquad (7)$$

The first term accounts for the true absorption and the second term for the scattering. In the first term, C is a constant which changes its value at the critical absorption wavelengths, Z is the atomic number of the absorbing element and λ is the wavelength of the X-rays. As mentioned by Winkler,[5] the above formula represents the value of B for air with fair accuracy up to 5 Å, but gives too large values for longer wavelengths, and the formula of Victoreen,[8]

$$B=(C'\lambda^3-D'\lambda^4)+\sigma(Z,\lambda) \qquad (8)$$

is better for wider range of wavelengths. Here C' and D' are constants which may be calculated from the atomic energy states of the absorbing element.

The scattering term $\sigma(Z,\lambda)$ increases slowly with Z and λ. However, in the wavelength range of soft X-rays, σ is negligible compared with the first term.

In our experiments, X-rays with a continuous spectrum are used. In this case, the effective wavelength is controlled by the operating voltage of the X-ray tube. When the anode voltage is V kilovolts, the shortest wavelength in Ångstrom unit is expressed by the formula

$$\lambda_0 = 12.405/V \qquad (9)$$

and the effective wavelength λ_{eff} is approximately equal to $1.3\lambda_0$, so that we have

$$\lambda_{\text{eff}} \fallingdotseq 16.13/V \qquad (10)$$

It can be concluded from Eqs. (6), (7) and (10) that a high sensitivity in air-density measurement can be realized by operating the X-ray tube at a sufficiently low voltage.

§ 3. Shock Tube and Flash X-Ray Tube

The shock tube used in the experiments is the same type as previously used by the present authors.[9),10)] The schematic diagram of the tube is shown in Fig. 1. The pressure in the high pressure chamber is raised to 12 atms by supplying the air from a reservoir, the low pressure chamber is evacuated to the pressure of 2 mm Hg, and a cellophane diaphragm separating these chambers is ruptured by a steel needle installed in the high pressure chamber. Then the air in the high pressure chamber expands through the divergent nozzle in the low pressure chamber, and a quasi-steady flow of Mach number of 5.5 is obtained at the test section. Duration of the uniform flow is about 1 millisecond, and the density of this flow is $1.0\times10^{-4}\,\text{g/cm}^3$.

The flash X-ray tube is shown in Figs. 1 and 2. Photo. 1 shows its parts disassembled, and Photo. 2 shows the tube attached to the shock tube wall.

Fig. 2. X-ray tube.

The anode A is made of a tungsten rod of 6 mm diameter, its end being sharpened to a 30° total-angle cone. Two ring plates of stainless steel are used as the cathode K and the trigger electrode K′. They are set on each side of an insulator plate P of polyetrafluoroethylene. Inner edges of the electrode plates face each other with a clearance of 0.1 mm, so as to form a ring-shaped spark gap.

The distance between the anode and the plane of the cathode is adjusted to 20 mm. A voltage of 1.65∼2.75 kV is applied to the anode, and about 4 kV is applied to the trigger electrode. Electric circuits are shown in Fig. 3.

A discharge between the trigger electrode and the cathode through the ring-shaped gap is made to occur at a desired instant by the aid of a timing device shown in Fig. 3. This trigger discharge induces the main discharge between the anode and the cathode. With this discharge, soft X-rays of high intensity are emitted from the anode during a very short time interval.

The timing device consists of an auxiliary spark gap S in the trigger discharge circuit and a thyratron circuit for triggering a spark discharge through S. This circuit has an automobile ignition coil in the plate side of the thyratron and a metallic contact element in the grid side. This contact element, utilizing the deformation of a thin aluminium foil by pressure, is attached to the end of a glass tube which is connected to the orifice on the shock tube wall (see Fig. 1), and made to act by the pressure wave propagating through the glass tube.

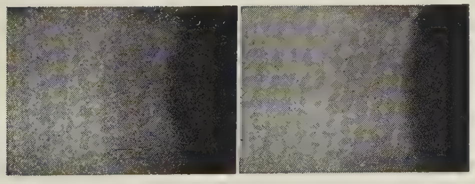

Photo. 3. Radiographs of flow with detached shock wave, taken by: (a) two flashes at $V_a=2.75$ kV; (b) eight flashes at $V_a=1.65$ kV.

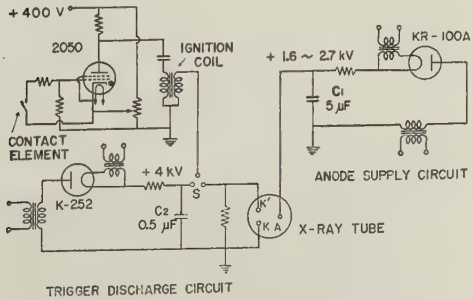

Fig. 3. Electric circuits.

The X-ray tube has a window W of 5 mm diameter, and a thin cellophane of 2 micron thickness is used as a window material. As the discarges in the tube are accompanied with the radiation of visible rays, it is required for the window material to pass only the X-rays and cut off all the visible rays. For this purpose, special black ink "Cello-Colour 7694 Black", made by Toyo Ink Co., is painted on the cellophane. This window permits higher transmission of soft X-rays than other materials, such as beryllium or aluminium foils.

Since the window cannot keep a high vacuum of the tube permanently, it is evacuated continuously to the pressure below 10^{-5} mm Hg by using a rotary and an oil diffusion pump. The latter is seen in the right part of Photo. 2.

§ 4. Experiments and Results

We attempted to apply the above-mentioned apparatus to the measurement of the hypersonic flow past a circular cylinder, in particular, to the measurement of the density distribution between the detached shock and the nose of the cylinder.

In order to determine the wavelength suitable for our purpose and to obtain the relation betweent the air density in the test section and the photographic density of the film exposed to the X-rays transmitted through the test section, low pressure chamber of the shock tube was evacuated to various values of pressure between 20 and 450 mm Hg, and for each case, the film held on the shock tube wall was exposed to the X-rays emitted from the flash tube.

The effective wavelength of the X-rays was varied by varying the anode voltage V_a. Trigger electrode voltage V_t, capacitances C_1 and C_2 and the distance s from the anode to the plane of the cathode-ring were varied systematically until the maximum intensity of the X-rays could be attained. It was shown by these experiments that, (1) a sufficient sensitivity could be obtained with V_a below 3 kV; (2) the quantity of the X-rays produced by a single discharge was a little insufficient, so that two or more discharges were necessary for obtaining film densities sufficient for photodensitometry; (3) the most satisfactory results were obtained with $V_t = 4$ kV, $s = 20$ mm, $C_1 = 5\ \mu$F and $C_2 \fallingdotseq 0.5\ \mu$F for the case of $V_a = 1.65 \sim 2.75$ kV. The use of larger capacitances might increase the X-ray intensity, but it was not possible in the present tube, because, when C_2 was large, the trigger discharge was followed by a detrimental discharge between the cathode and some other metallic parts in the tube due perhaps to an electric oscillation in the discharge circuit, and this made the intensity of the X-rays emitted from the anode quite indefinite. The authors consider that this can be avoided by improving the design of the tube and minimizing the inductance in the trigger discharge circuit, and then it will be possible to produce X-rays strong enough for taking a photograph by a single flash.

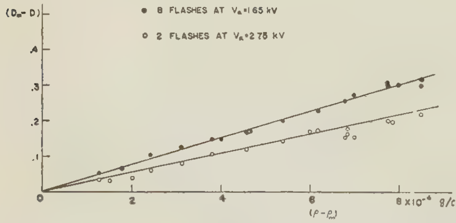

Fig. 4. Relation between air density and film density.

After these preliminary experiments, the apparatus was used for the measurement of the density distribution between the detached shock and the nose of a circular cylinder, placed in the hypersonic flow established in the shock tube. Mach number M_∞ of the free stream as determined from schlieren observation of Mach waves was 5.5, and the corresponding density ρ_∞ of the free stream was estimated to be 1.0×10^{-4} g/cm³. The diameter of the cylinder was 6 mm, and the span was 55 mm. Clearances of 1.5 mm were left between both ends of the cylinder and the tube walls in order to avoid the end effects due to the shock-boundary-layer interaction. Reynolds number based on the cylinder diameter and the free-stream condition was 1.6×10^5. Operations of both the shock tube and the X-ray tube were repeated two or more times for obtaining a radiograph.

Radiographs of the flow with a detached shock wave are shown in Photos. 3(a) and (b). The one was obtained by two flashes at $V_a = 2.75$ kV and the other by eight flashes at $V_a = 1.65$ kV. Following Eq. (10), these values of V_a correspond to the wavelengths of 6 and 10Å, respectively.

Fig. 4 shows calibration curves which represent the relation between air density and film density for these cases. Both quantities are referred to the free-stream values ρ_∞ and D_∞. Here, D_∞ was determined by evacuating the test section to the density ρ_∞.

Fig. 5 shows the density distribution behind the detached shock wave. Interferometric results obtained by the junior author for $M_\infty = 1.8$ and 4.0 are also reproduced in the

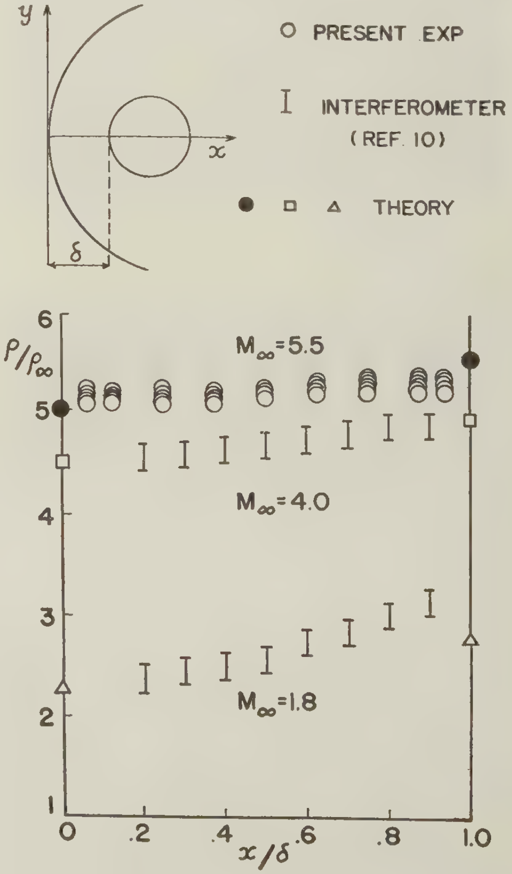

Fig. 5. Density distribution between shock wave and stagnation point.

figure. It can be seen that the present method gives good quantitative density data.

The stand-off distance δ between the shock wave and the stagnation point is shown in Fig. 6, together with the previous data obtained by optical methods.

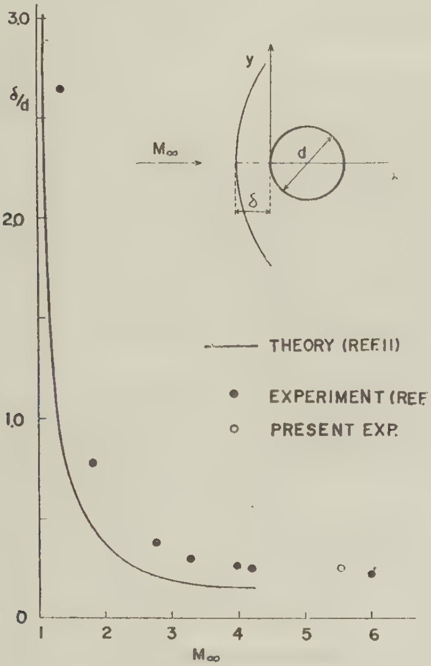

Fig. 6. Stand-off distance between shock wave and stagnation point.

As photographic materials, "Fuji High Speed X-Ray Film, Type 200" and "Fuji Developer, Rendol" were used, developing time of 5 minutes being strictly kept throughout the experiments. Measurements of film densities were made by using a photo-cell type microphotometer with a slit pick-up of 0.01 mm width.

It is concluded from these experiments that the present radiograph method is very promising for the density measurement in low-density hypersonic flows, especially for the investigation of a narrow region with a steep density gradient, such as the region near the body nose or the boundary layer.

The authors wish to express their cordial thanks to Prof. Hirata and Dr. Tachibana for their valuable advices in the course of the present experiments.

On the New Reverberation Chamber with Nonparallel Walls (Studies on the Measurement of Absorption Coefficient by the Reverberation Chamber Method, II)

By Kozi Sato and Masaru Koyasu

Kobayasi Institute of Physical Research, Kokubunji, Tokyo, Japan

(Received August 18, 1958)

The details of the new reverberation chamber are given. It has a volume of 513 m^3 and is surrounded by nonparallel walls. The results of model room experiments previously reported have been used to determine the shape and volume of this chamber. At 500 cps., the reverberation time of empty chamber was 22 seconds. The position of the microphone and the sound absorbing material did not affect the reverberation time of this chamber. This fact would show that the sound field of this chamber would fulfill the requisite for the diffuse sound field which is the premise of the reverberation chamber method.

§ 1. Introduction

From the fundamental researches described in the Report I$^{1)}$, it has come to be clear that to make the shape of a reverberation chamber irregular is one of the effective means to get diffuse sound field which is indispensable for a reverberation chamber. Furthermore, relation between the size of the chamber and the uniformity of the sound field has been investigated. Based upon the results of these researches, a new reverberation chamber was constructed. This chamber has a volume of 513 m^3 and is surrounded by nonparallel walls.

We inquired into the various characteristics of this chamber without sound absorbing materials. Further we pursued the effects of the warble tone and the loudspeaker upon the above characteristics. It was experimentally proved that the reverberation time of the chamber was longer than 20 seconds at 500 cps. and that the fluctuation of repeatedly measured reverberation time under the same condition was quite small. It was also confirmed that this was true in any part of the chamber.

However, when a sound absorbing material is put into the chamber to measure the absorption coefficient, the sound field would be different from that when the chamber is empty. Thus, special regard has been paid to the position of the sample material and the arrangement of the microphone in the conventional reverberation chambers.

The effect of the several factors affecting the sound field of our new reverberation chamber was investigated. As for the sample materials, we selected fibrous acoustic tiles and mineral wool board as typical examples from the viewpoint of the magnitude of absorption coefficient and its frequency characteristics. The results of these experiments showed that the position of the microphone and the sample material did not affect the absorption coefficient. This fact would show that the sound field of this chamber would fulfill the requisite for the diffuse sound field which is the premise of the reverberation chamber method.

§ 2. Construction of the Reverberation Chamber

2.1. Design and construction of the reverberation chamber

Since the irregular chamber used in the three-dimensional model room experiments was found more suitable as a reverberation chamber than a rectangular one, we designed a chamber after this irregular model. Next, the dimensions of the chamber was determined by consideration of the lowest frequency to be measured, which was around 60 cps. in this case. For this purpose, it was decided to make the frequency of 2000 cps. in the model chamber correspond to 100 cps. in the actual chamber. Accordingly the length of each side of the chamber was made 20 times as long as that of the model chamber, and thus the chamber of about 500 m³ became necessary. On the other hand, if the volume of the chamber is V, and the surface area is S, the number of normal modes $\varDelta N$ in the frequency range between ν and $\nu+\varDelta\nu$ is approximately given by[2)]

$$\varDelta N \doteqdot \left(\frac{4\pi V}{c^3}\nu^2+\frac{\pi S}{2c}\nu\right)\varDelta\nu\,.$$

If the number of normal modes is calculated in the rectangular chamber (the ratio of the sides is 1.00 : 0.80 : 0.64) under the conditions of $V=500\ \mathrm{m}^3$, the number of normal modes included within a 1/3 octave band with center frequencies of 60 and 100 cps. are 9.5 and 38.4 respectively. This shows that the chamber dimensions as large as these are necessary from the viewpoint of the number of normal modes.

Next, the finish of the interior of the reverberation chamber offers an important problem as to the accuracy in measurement. Conventionally, the wall surfaces are finished with concrete (plastered or painted), parquet tiles, etc. We decided to adopt the polished concrete, taking into consideration the fact that its sound absorption is small and its maintenance is easy due to small quality change caused by time element.

Table I. Details of the reverberation chamber

Volume	513 m³
Surface area	382 m²
Shape	Nonparallel Walls
Wall thickness	40 cm
Wall surface material	Steel-framed concrete with polished concrete

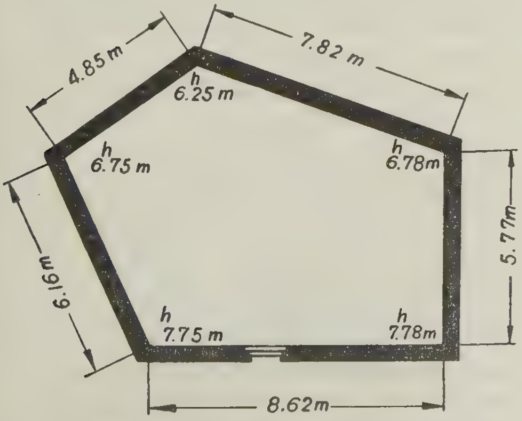

Fig. 1. Plan of the reverberation chamber. h shows the height of each corner.

Important data for this chamber which was made so as to match the previously mentioned conditions are shown in Table I. Dimensions of the chamber is given in Fig. 1 and photo Fig. 2 shows the interior of the chamber.

2.2. Reverberation time measuring apparatus

The most important section of the rever-

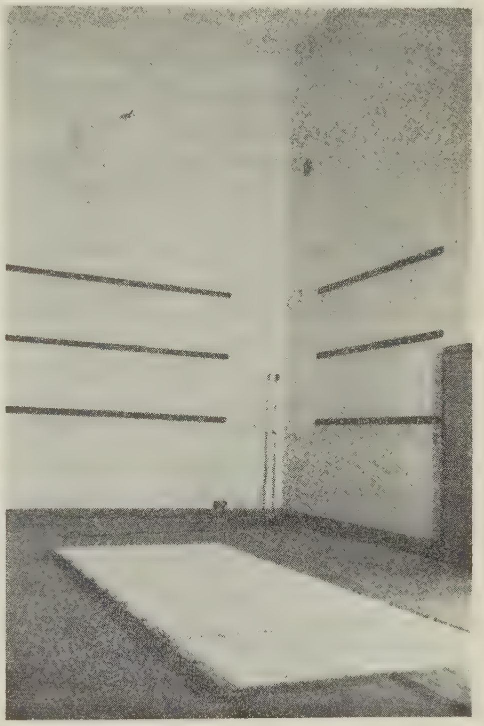

Fig. 2. Interior of the reverberation chamber.

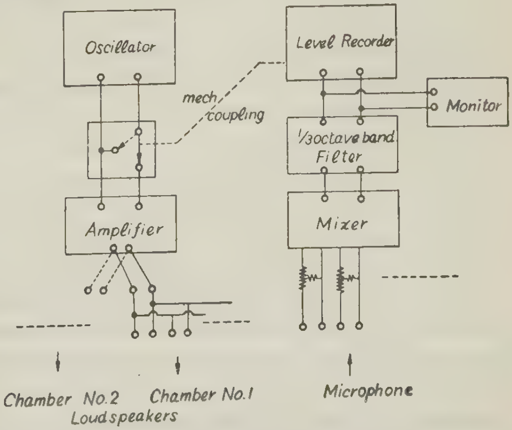

Fig. 3. Block diagram of the apparatus for the measurements of reverberation time.

beration time measuring apparatus is the one which measures or records the decay process of sound. Here, we used a high speed level recorder for this purpose. Furthermore, since the reverberation time to be measured is relatively long, the make and break of the simple mechanical contact point, which work in linkage with the level recorder, were adopted for the switching-on and -off of the oscillator. The block diagram of the measuring apparatus is shown in Fig. 3.

§ 3. Characteristics of the Empty Reverberation Chamber

3.1. Researches on measuring system

(i) *Characteristics of warble tone*

When the center frequency is ν_0, modulation swing $\pm\varDelta\nu$ and the modulation frequency α, the warble tone given by them has a spectrum consisting of $2\varDelta\nu/\alpha$ components lined up at intervals of α cycles within the range of $\nu_0\pm\varDelta\nu$[3]. If the dimensions of the chamber and the center frequency are given, the minimum permissible value of $\varDelta\nu$ is given by the condition that it should include sufficient number of normal modes to uniformize the sound field. Under the given conditions that ν_0 equals 100 cps. and the number of normal modes equals 30, an inequality $\varDelta\nu>9$ results. It was also found that if $\varDelta\nu$ is made larger, unevenness in absorption within the range becomes sometimes intolerable. In the present experiments, $\varDelta\nu$ was made 10 percent of center frequency at lower frequencies and 50 cps. at higher frequencies.

Next, for the purpose of exciting all the normal modes within the range, the interval α of spectrum offers a problem. In the chamber with sharp resonant characteristics (that is, long reverberation time), some of the normal modes are not excited unless the intervals are sufficiently small. On the other hand, if α is so small that one sweep takes too long a time, the normal modes at the far end of frequency range are considerably decayed, and accordingly it means little to use warble tone. Such being the case, α must be decided in connection with the reverberation time of the chamber. A conventional rule for the suitable range of α is given by an inequality $8/T>\alpha>4/T$[4]. However, as will be mentioned later, our reverberation chamber has far longer reverberation time than the ordinarily used ones, and consequently we thought it necessary to confirm the above inequality by the experiments as the first step.

An example of decay curves obtained by observing the variation with modulation frequency α is shown in Fig. 4. The reverberation time T was 22 seconds. When α became more than 8, fluctuation of sound pressure level in the steady state became small and minute changes on the way of decay were not observed. However, large undulations were seen over the whole decay curves. When α is small, the fluctuation in the steady state became large but the decay showed a perfectly logarithmic curve (The ordinate in the records is a decibel scale and so the ideally exponential decay is recorded as the straight line.) From these results, we came to the conclusion that the modulation frequency must be around $10/T\sim20/T$.

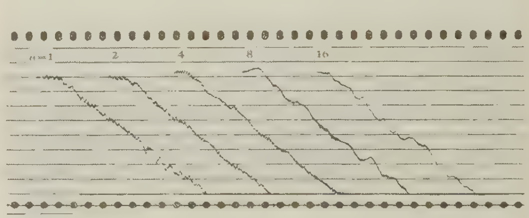

Fig. 4. Variation of decay curve with modulation frequency of warble tone.
$\nu_0=500$ c/s, $\varDelta\nu=30$ c/s

(ii) *Selection of loudspeakers*

A loudspeaker was selected by considering the following two points. That is, it has a sufficient power output so as to show at least the decay curve of 40 decibels before reaching the noise level, and also it is intended to decrease the added absorption due to the loudspeaker.

At first, we used a 25 cm cone type loudspeaker which was housed in a closed enclosure of $0.18\ \mathrm{m}^3$ cubical content. In this condition, the minimum resonant frequency of the loudspeaker is around 50 cps. There was observed an absorption around 100 cps. caused probably by the vibration of the closed enclosure panels. As a result, the decay curve showed a slight bend around this frequency and the reverberation times derived from the decay curves measured under the same conditions showed inconsistent values.

In the second experiment, a horn-speaker driver unit was used. It did not produce any trouble regarding the measurement of the decay curve at the frequencies higher than about 100 cps., though the power output was a bit insufficient. Further, the reverberation time showed about the same values in each experiment, and the reverberation time became remarkably longer, especially at frequencies below 300 cps.

Then the reverberation time was measured at 125 cps. with several types of loudspeakers.

Table II. Effects of loudspeaker on the reverberation time. $\nu_0=125$ cps., $\Delta\nu=15$ cps., $\alpha=1$.

Type of loudspeaker	Average of 10 measurements	Standard deviation
Horn-speaker unit	46.0 sec	0.35 sec
25 cm cone (naked)	40.0	0.90
25 cm cone (with buffle board of 50 cm × 50 cm)	39.0	1.2
20 cm cone (built in a closed cubical enclosure of 0.027 m³)	35.5	1.5
25 cm cone (built in a closed enclosure of 0.18 m³)	25.7	1.2

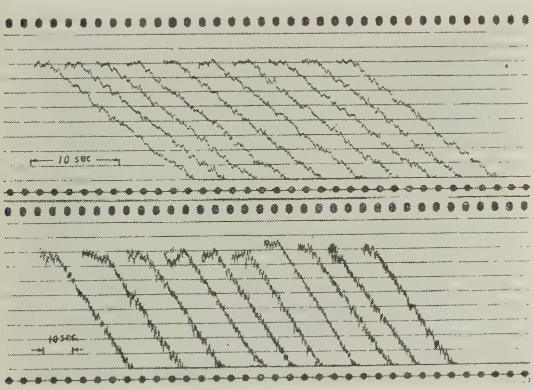

Fig. 5. Decay curve for empty chamber.
Upper: $\nu_0=500$ c/s, $\Delta\nu=30$ c/s, $\alpha=1$
Lower: $\nu_0=125$ c/s, $\Delta\nu=15$ c/s, $\alpha=1$

The results of these experiments are shown in Table II which includes the average and standard deviation of reverberation times for ten measurements. From these experiments, it was decided to use the horn-speaker driver unit in most experiments.

3.2. Reverberation time and sound pressure distribution

(i) *Reverberation time*

Firstly, we measured the reverberation time of the chamber, using the horn-speaker unit as the source of sound. The examples of the decay curves measured respectively at 500 and 125 cps. are shown in Fig. 5. These show an almost perfect logarithmic decay. Though we moved the microphone to five corners (including the position of the loudspeaker) and then to the center of the chamber, reverberation times were scarecely affected by the changes of the position of the microphone at any frequency between 125 and 4000 cps.

Table III. Reverberation time of empty chamber (measured in June 21, 1956)

Frequency	Average	Standard deviation
125 cps.	46.0 sec	0.5 sec
250	37.0	0.5
500	22.5	0.2_5
1000	14.0	0.1_0
2000	10.0	0.1_0
4000	5.3_8	0.0_7

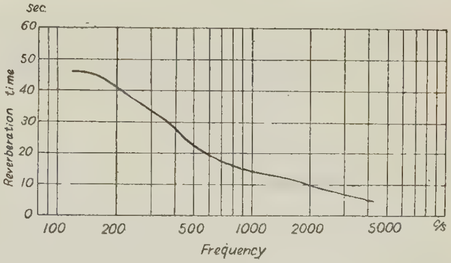

Fig. 6. Reverberation times for empty chamber.

Table IV. Sound pressure distribution in the chamber. Microphone position; M_1.

Frequency	Position of microphone					
	M_1	M_2	M_3	M_4	M_5	M_c
125 cps.	5 db	2 db	0 db	2 db	1 db	0 db
250	1	1	1	0	2	0
500	1	−1	−1	−1	0	0
1000	1	−2	−2	−1	0	0
2000	0	−1	−1	−1	0	0
4000	0	−2	−2	−2	0	0

Table III and Fig. 6 show the results. Each row in Table III shows the average and standard deviation of the reverberation times for five measurements. Reverberation times at high frequencies depend largely on weather conditions. We shall report the detailed results on this subject in the near future.

(ii) *Sound pressure distribution*

The unevenness in sound pressure level in the steady state which are measured at six positions used previously for measuring the reverberation time, is shown in Table IV. The marks which indicate the positions of the microphone in Table IV correspond to those of Fig. 7 and will be used in all subsequent experiments. The difference of sound pressure level in different positions is quite small, being about 2 decibels even at 125 cps. except at the position of the loudspeaker.

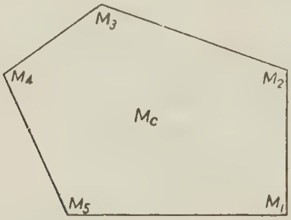

Fig. 7. Positions of microphone for reverberation measurements.

§ 4. Examinations of Various Factors that have an Influence upon the Measuremens of Absorption Coefficient

As was discussed in Report I, the sound field in the reverberation chamber must fulfill the assumption of the diffuse sound field. The effect of several factors which might affect the sound field, was investigated in our reverberation chamber. We used the fibrous acoustic tiles and mineral wool board, as the sample materials for these experiments. The former has a large absorption at low frequencies, and on the contrary, the latter has a large absorption at high frequencies.

4.1. Patterns of decay curves

First, we examined the influence upon decay curves of two kinds of sample materials up to 30 m² fixed respectively on three or four faces of the reverberation chamber. The decay was completely logarithmic in this case as in the empty chamber, within the frequency range of 125 to 4000 cps. Thus it was made clear that we could determine the reverberation time uniquely from this result. No extraordinary decay was observed at 200 cps. corresponding to the maximum absorption of the fibrous acoustic tiles and neither at high frequencies where a large absorption occured in case of the mineral wool. Fig. 8 are examples of respective decay curves.

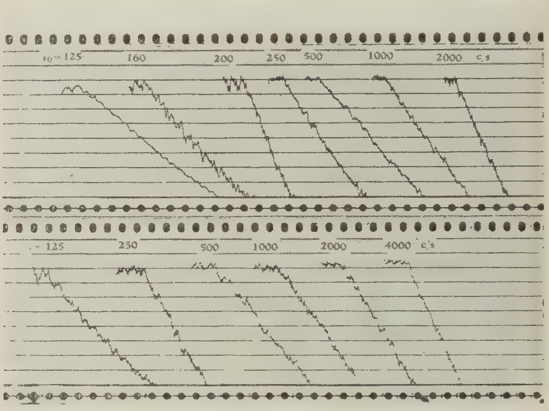

Fig. 8. Decay curves for the chamber, sample material present.
Upper: fibrous acoustic tiles, 10 m² (floor)
Lower: mineral wool, 16.5 m² (floor and two walls)

4.2. Effect of the position of the microphone

Using the sample material of 25 or 30 m², we investigated the effect of the position of the microphone on the absorption coefficient. The results are shown in Figs. 9 and 10. It was found that, for any sample material used, the position of the microphone exerted little influence upon the absorption coefficient. It is conspicuous that no effect upon absorption coefficient was found not only in any corner of the chamber but even in the center.

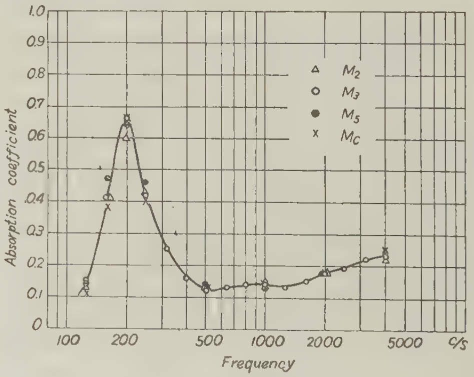

Fig. 9. Effect of microphone position on absorption coefficient of fibrous acoustic tiles. Sample area 25 m² (floor and two walls)

The uniformity of the reverberation time is the most important property of the reverberation chamber, and so we investigated this in detail. At the seven microphone positions which were arbitrarily chosen in the chamber, we measured twenty decay curves at each position. The average and standard deviation of reverberation times thus obtained are shown in Table V. Consequently, one microphone placed in an optional position may be enough for this kind of measurements.

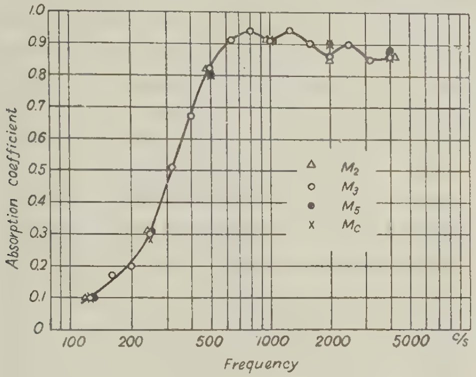

Fig. 10. Effect of microphone position on absorption coefficient of mineral wool. Sample area 30 m² (floor and three walls)

Table V. Reverberation time of the chamber when the mineral wool 10 m² was placed on the center of the floor. Seven microphone positions were chosen arbitrarily in the chamber and twenty decay curves were measured at each position.

Frequency	Average	Standard deviation
125 cps.	28.9 sec	0.97 sec
250	14.4	0.22
500	7.0_1	0.05
1000	5.8_0	0.07_2
2000	4.8_7	0.09_3
4000	2.8_3	0.08_4

4.3. Effect of area of the sample material

Next, placing the microphone in a fixed position, we examined the effect of the sample area upon absorption coefficient. Fibrous acoustic tiles having areas from 10 to 25 m² were fixed on three faces of the reverberation chamber. In case of mineral wool, the areas were from 3.3 to 30 m². The one with 30m² area was fixed on four faces of the chamber, the one with 3.3 m² area was fixed on the floor only, and all others were fixed on three faces of the chamber. The measured results of absorption coefficient are shown in Figs. 11 and 12.

In case of mineral wool, the absorption coefficient obtained for the sample area of 3.3 m² became larger than that of other sample areas for the frequencies above 500 cps. This is considered to be the area effect explained by Chrisler's experiments⁵⁾. However, when the area is reduced to this extent, the measuring accuracy falls off extremely. Therefore, we are furthering a more precise investigation. However, in either of sample materials, no significant difference in absorption coefficient was found against the area change of more than 10 m².

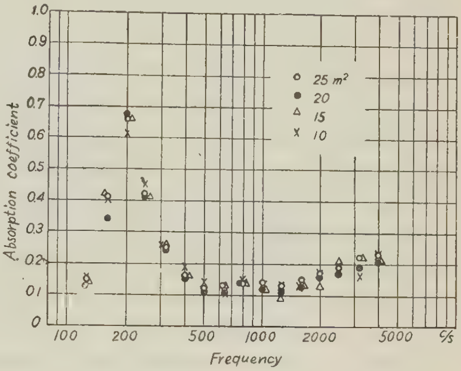

Fig. 11. Effect of sample area on absorption coefficient of fibrous acoustic tiles.

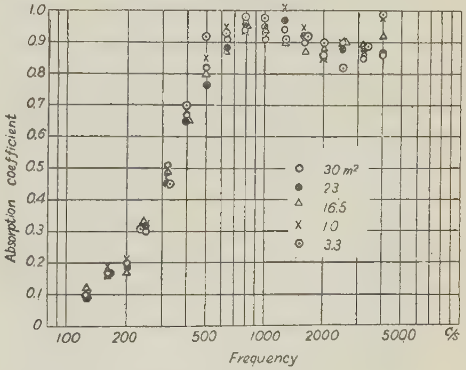

Fig. 12. Effect of sample area on absorption coefficient of mineral wool.

4.4. Effect of the mounting position of sample materials

We compared the absorption coefficients obtained respectively in three mounting positions of sample materials. In one case the sample material of 10 m² was separated on three faces, while in the other two cases the sample material of the same area was concentrated only on the floor (at floor center and edge). The results are shown in Figs. 13 and 14. We found out that, in case of areas in this experiment, the absorption coefficient was not affected by the mounting position of sample material at any frequency.

4.5. Case of a large quantity of sample material being placed only on the floor

When mineral wool of 30 m² was placed on the floor, decay curves showed a bend for the frequencies between 1000 and 2000 cps. So, we measured the decay curves for various areas, within the range of 400 to 4000 cps. at intervals of 1/3 octave. The results are shown in Fig. 15. As the area decreases, the range of frequency for which a bend takes place becomes narrower and it is not discernible below 16.5 m². We showed in the same figure the results obtained when the sample material was placed on three faces separately. In this case, the decay curves were all straight

lines, without any influence of area and frequency.

When the decay curve shows a bend, we can no longer assume that the sound field in the chamber is diffuse. However, we tentatively determined the absorption coefficient using the slope at the beginning part of the decay curve. Above 500 cps., where the absorption coefficient is large, it decreases as the area increases (Fig. 16). This is rather an expected matter, because the sound field in the chamber differs from that in the empty chamber.

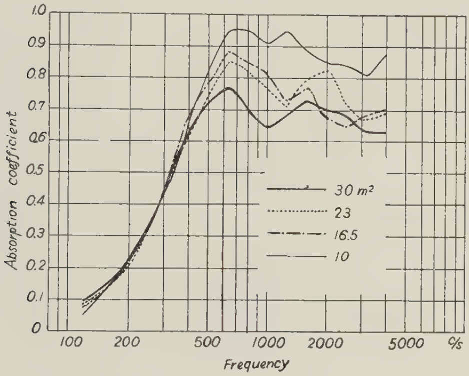

Fig. 16. Effect of sample area on absorption coefficient of mineral wool (sample placed on the floor only)

§ 5. Conclusion

The outline of our newly constructed reverberation chamber and the various characteristics of this chamber concerning the absorption coefficient measurements are presented. The shape of the chamber was decided by the experiments conducted with the model rooms described in Report I, in order to fulfill the essential condition of diffuse sound field. The volume of the chamber was decided upon 513 m³ for the purpose of measurements down to 60 cps.

Investigation on measuring system using the empty chamber, has shown that the absorption by the loudspeaker has a considerable effect on reverberation time at low frequencies and that the modulation frequency in warble tone has a considerable effect on decay curves. The reverberation time at 500 cps. is 22 seconds when the chamber is empty.

We investigated the various factors which were supposed to have influences upon the absorption coefficient measurements. The decay curve showed the logarithmic decay even when the sample material was present. The position of microphone was found immaterial in the measurements and also, when the sample material was about 10 m², the mounting position of the sample had no effect upon the absorption coefficient. These results would show that the sound field of this chamber would fulfill the requisite for the diffuse sound field, and that this chamber would have characteristics as expected from the fundamental experiments. This will bear witness to the fact that the sound field in our reverberation chamber has been much more improved than in the conventional ones, in which a special regard had to be paid in such things as to use several microphone positions and also to choose proper mounting position of sample materials.

This chamber was completed by the cooperation of Shimizu Construction Co., Ltd. Members of the Acoustical Material Association of Japan provided us with sample materials used for these researches. The fundamental experiments were conducted in cooperation with Mr. J. Sakagami. We should like to express our sincere appreciation for their cooperation.

This work was partly supported by the Scientific Research Fund of the Ministry of Educations.

A Visualizing Method of Electron Temperature and Plasma Density

By Hajime TAMAGAWA and Junji FUJITA
Department of Physics, Faculty of Science, University of Tokyo

(Received March 6, 1959)

On the measurement of a transient plasma, it is desirable to obtain the informations about the plasma within a sufficiently short time interval during which the plasma quantities may be regarded to remain constant. The usual single probe method is unsuitable for the investigations of a rapidly changing plasma. A floating double probe method was devised[1] for a research of decaying plasmas, it fits, however, only for the measurements of repeatable and reproducible phenomena. Some trials were made[2,3] to get informations from the oscillograms of probe characteristics.

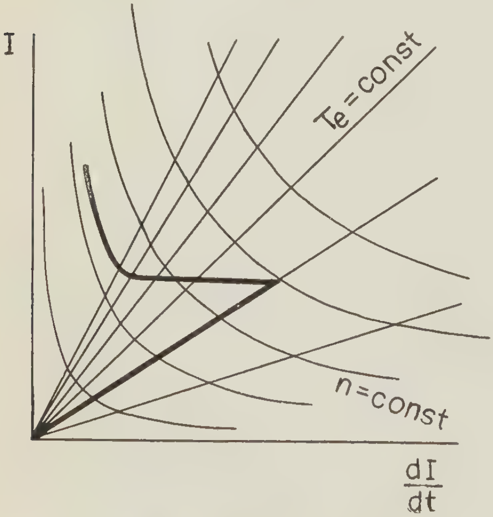

Fig. 1.

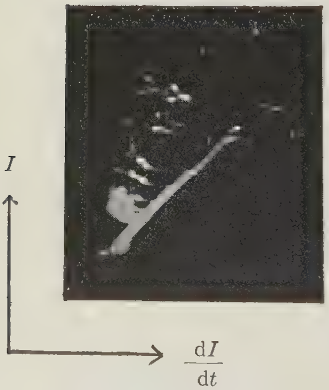

Fig. 2.

The authors succeeded to visualize electron temperatures as well as plasma densities of a transient plasma directly on the pattern of cathode-ray-tube. The principle is based on the Langmuir's single probe method. Electron temperature is obtained by differentiating a logarithm of the probe current with respect to the probe potential, that is

$$\frac{e}{kT_e}=\frac{\mathrm{d}}{\mathrm{d}V}(\log I)=\frac{1}{I}\frac{\mathrm{d}I}{\mathrm{d}V}=\frac{1}{I}\frac{\mathrm{d}I}{\mathrm{d}t}\Big/\frac{\mathrm{d}V}{\mathrm{d}t}$$

Then, if the probe potential is changed linearly with time, electron temperature is given by the ratio of probe current to its time-derivative. Above quantities are represented on the pattern of cathode-ray-tube as the slopes of straight lines which start from the origin, when the probe current is introduced to the Y-axis, and the time-derivative to the X-axis.

When the prove potential exceeds the space potential, electron current to the probe no longer increases with probe potential and saturation occurs, which results abrupt discontinuity of $\mathrm{d}I/\mathrm{d}t$ at the space potential. Once electron temperature is determined, plasma density is obtainable from the electron current density at the space potential.

$$n=\frac{J_{es}}{e}\sqrt{\frac{2\pi m}{kT_e}}$$

Fig. 1 will be helpful for understanding this principle, and an example of oscillograph pattern is shown in Fig. 2.

One of the chief difficulties of this method is to need extremely wide-band amplifiers and a high-fidelity oscilloscope. Next, the output impedance of the saw-tooth-wave generator should be as low as possible, otherwise the linearlity of voltage is affected by the drain of the probe current, and $\mathrm{d}V/\mathrm{d}t$=constant is no longer valid. These difficulties are, however, purely technical problems.

The authors wish to express their sincere thanks to Prof. K. Honda for the valuable discussions, and Japan Atomic Energy Research Institute for the instrumental facility. This work is supported by the Scientific Research Expenditure of the Ministry of Education.

An Abnormal Saturation Behavior in High Resolution Proton Magnetic Resonance Spectra

By Michihiko NAGUMO and Yoshinobu KAKIUCHI
Institute for Solid State Physics, University of Tokyo

(Received March 20, 1959)

In the experiments of high resolution nuclear magnetic resonance, asymmetry of the line shapes depending on the sweep direction is often experienced[1].

A remarkable anomaly in saturation behavior, however, which is essentially different from the usual ones is observed in the spectra of some benzene substituents.

The apparatus used is Varian V-4300 N. M. R. Spectrometer at 40 mc, and the measurements were conducted at room temperature. The magnetic field is swept slowly as usual

Spectra of nitrobenzene, for example, are of multiplet structure due to the indirect I-I coupling between ring protons. It is diluted to less than about twenty per cent with cyclohexane, acetone, etc., the proton resonance line of each solvent being in higher field side compared with that of nitrobenzene.

No saturation is observed under moderate radiation field when the magnetic field is swept from lower to higher value, whereas the decrease of the *signal intensity as a whole* as well as the distortion of the line shape *does* appear when the field is swept from higher to lower value.

This phenomenon becomes the more conspicuous, the stronger H_1, the intensity of the radiation field, and the slower the rate of the sweep through the solute signal as is naturally expected, but is quite independent of the H_1 while the field is swept through the solvent signal.

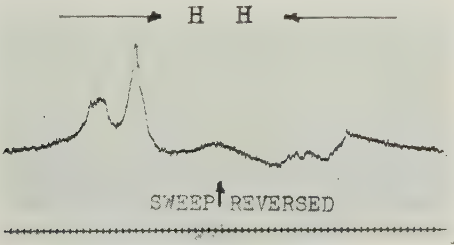

Fig. 1. Proton Resonance Spectra of Nitrobenzene Diluted in Cyclohexane.

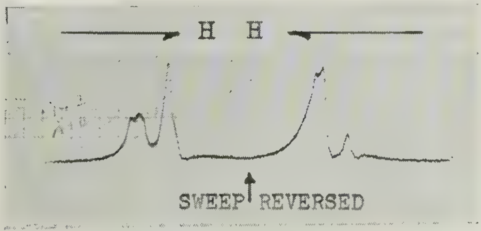

Fig. 2. Proton Resonance Spectra of Nitrobenzene Diluted in Carbon Tetrachloride.

The choice of the solvent is immaterial in so far as it contains protons, and its proton resonance line appears in higher field side with respect to that of the solute.

On the other hand, in concentrated solutions or with solvent which contains no protons, carbon tetrachloride for example, such an asymmetry in the total area of the signal for the forward and reversed sweep directions does not appear.

Similar phenomena are also found in many other substances; say aniline, pyridine, p-nitrochlorobenzene, etc., which have at least two kinds of non-equivalent ring protons as is the case in nitrobenzene, thus forming multiplet spectra, whereas in benzene, or monochlorobenzene, whose spectra consist of almost a single line, such an anomaly is not observed. This abnormal saturation behavior occurs irrespective of the relative positions of each proton group with respect to the substitute groups.

Examples are illustrated in the figures. The figure 1 is the data for 9.7 mole per cent solution of nitrobenzene in cyclohexane with $H_1=84$ microgauss, and the sweep rate 1.0 milligauss per second. The line of cyclohexane is out of the sweep range, and locates in higher field. The figure 2 is contrasted with the former. It is the spectra of the same substance, when diluted with carbon tetrachloride to 15.9 mole percent, with $H_1=84$ microgauss and the sweep rate 1.0 milligauss per second.

Wertz et al previously reported[1] an asymmetry of the proton magnetic resonance spectra of methyl alcohol in backward sweep following the initial.

The total area of the signal as a whole in that case, however, is almost unchanged by reversing the sweep direction. In this respect, the phenomena here reported differ essentially from theirs.

Their case is rather similar to the result of our observation with stronger H_1 in concentrated solutions or in non-protonic solvents, and the interaction within the spin system seems to be the dominant mechanism in this case.

For the mechanism of the abnormal saturation phenomena stated above, however, it is quite plausible that the solvent spins play an important rôle through some interaction with solute spin systems. Further studies are now in progress.

The authors wish to express their sincere thanks to Professors G. Hazato, T. Ikenoue and T. Isobe of Tohoku University, who enabled the authors to use the apparatus and gave them great helps throughout the experiment.

Phase Transition in Tungsten Trioxide

By Sigetosi Tanisaki
Faculty of Literature and Science, Yamaguchi University

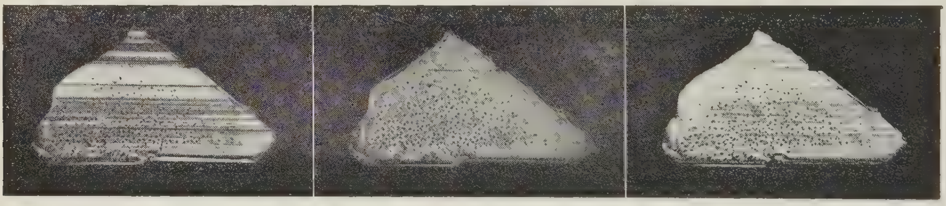
(Received March 7, 1959)

The dielectric constant-temperature curve of the ceramics of tungsten trioxide WO_3 exhibits a maximum near 20°C1), and there is a possibility that this material might be ferroelectric below this temperature. On the other hand, it has been shown by the X-ray investigation that this material has a monoclinic structure in room temperature in which ions are arranged in an antiparallel manner2) and it transforms to an orthorhombic phase near 350°C on heating and transforms near −40°C on cooling to a lower temperature form which has been supposed to be trigonal3). The phase transition of this material near 20°C has not been known. In the present note the phase transition from monoclinic to triclinic near 17°C is described.

The tabular crystal of WO_3 with c-surfaces well developed has usually two kinds of domains whose walls are (110) and (100) in room temperature, but sometimes another kind of domains which are formed by twinning on (010) plane is found below 17°C. This (010) domain structure can be easily observed with the polarizing microscope between crossed nicols as shown in Fig. 1 (a), because, when c-surface of the crystal is observed, the extinction position of each domain differs from those of its adjacent domains by about 6°. And also the difference of the extinction positions of neighbouring domains is observed on a-surface of the crystal. These facts suggest that the crystal constructed by (010) domains may have a triclinic structure, and this suggestion is ascertained by the X-ray method. The lattice constants of the triclinic phase determined from X-ray rotational photographs are as follows:

$$a=7.30\text{Å},\quad b=7.52\text{Å}\quad c=7.69\text{Å}$$
$$\alpha=88°50',\quad \beta=90°55',\quad \gamma=90°56'.$$

The triclinic crystal transforms to the monoclinic phase near 17°C on heating and the monoclinic crystal thus obtained has few or no (100) walls (Fig. 1 (b)). The transition from the triclinic phase to the lower temperature phase is observed near −40°C on cooling (Fig. 1 (c)). These two phase transitions can be repeatedly observed with the polarizing microscope showing a thermal hysteresis in some extent.



(a) (b) (c)

Fig. 1. (a) Triclinic phase observed between crossed nicols (10°C).
(b) Monoclinic phase (25°C). Only one (100) wall is seen near the right corner of the crystal.
(c) Lower temperature phase (−55°C).

The monoclinic crystal which has many fine (100) domains is hard to transform to triclinic even in low temperature below 0°C and an apparently direct phase transition from the monoclinic phase to the lower temperature phase is frequently observed near −40°C, but the transition from the lower temperature phase to the triclinic phase on heating is always observed. The monoclinic multidomain crystal can be changed to the single domain crystal easily by the external stress4), and the obtained single domain crystal always shows the monoclinic-triclinic transition near 17°C. On the other hand, whenever the crystal which shows the monoclinic-triclinic transition is heated once above 350°C, the monoclinic-orthorhombic transition temperature, it has many fine (100) domains in room temperature and does not show the monoclinic-triclinic transition near 17°C. It seems to be due to this effect of (100) domains that the existence of the triclinic phase between the monoclinic phase and the lower temperature phase has been overlooked by many investigators.

The dielectric properties of this triclinic phase should be studied in future.

The author wishes to express his sincere thanks to Prof. K. Tanaka for his continual encouragement.

Absorption Spectrum of Copper-Coloured Cuprous Oxide

By Masakazu HAYASHI

Department of Physics, Faculty of Science, Hokkaido University, Sapporo

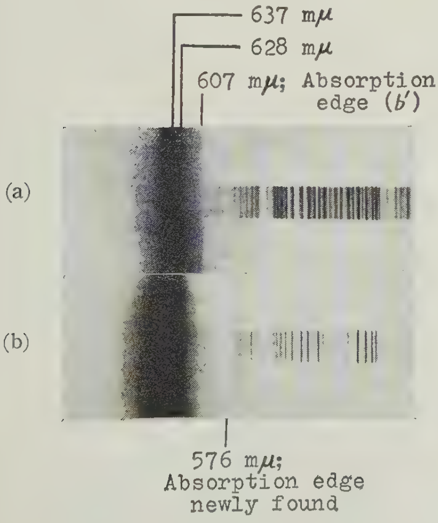
(Received March 4, 1959)

By heating a cuprous oxide film 0.1 mm thick in a vacuum electric furnace maintained at 900°C, a copper-coloured specimen of partially reduced cuprous oxide was obtained. The absorption spectrum of the specimen revealed an interesting band as will be described in the following.

The spectrograph of Hilger's constant deviation type was used with an incandescent lamp as the light source. The transparency of the specimen was so poor that very long exposure was necessary to obtain the clear absorption spectrum.

In Fig. 1, two spectrograms taken at room temperature are shown: (*a*) is the spectrogram of the normal cuprous oxide film of 0.1 mm thickness and (*b*) is the spectrogram of the copper-coloured specimen obtained by the above-mentioned procedure.

In (*a*), we can observe three absorption edges at the wavelengths 637 mμ, 628 mμ and 607 mμ. The writer has already given the interpretation of these as follows¹⁾:



637 mμ
628 mμ
607 mμ; Absorption edge (b')
(a)
(b)
576 mμ; Absorption edge newly found

Fig. 1.

1) The two sharp absorption edges at 637 mμ and 628 mμ correspond to the transitions from the doublet states ^2P of O^- to the empty band;

2) The third at 607 mμ is the limit of the long wavelength tail of the characteristic absorption of the cuprous oxide film of 0.1 mm thickness. (The shift of the edge towards the shorter wavelength side is always observed not only with the decrease of temperature, but also with the decrease of film thickness. In the previous work²⁾, this edge was called "the absorption edge (b')".)

In (*b*) of Fig. 1, we can also identify two sharp absorption edges at 637 mμ and 628 mμ, but cannot observe the absorption edge corresponding to that designated as (b') in (2). Instead a new absorption edge is found at the wavelength 576 mμ where a broad band starts towards the longer wavelength side extending over the two sharp edges stated in (1). The disappearance of the absorption edge (b') can be explained by assuming that the reduction process makes the cuprous oxide film so thin that the absorption edge (b') moves towards the wavelength shorter than 607 mμ and is missed there.

Lange³⁾ measured extensively the spectral sensitivity of photo-e.m.f. of copper-cuprous oxide photo-cells at various temperatures. According to his results for the room temperature, (i) the maximum sensitivity is obtained at about 630 mμ; (ii) the long wavelength limit of sensitivity is about 1.4μ; and (iii) towards the wavelength shorter than 630 mμ, the sensitivity rapidly decreases and beyond 575 mμ no photo-e.m.f. can be detected. This sharp drop at 575 mμ has hitherto been interpreted⁴⁾ as due to the increase of the absorption coefficient of cuprous oxide to values so large that the light cannot penetrate the material.

The broad absorption band newly found in the present study might be inferred to be responsible for the photo-e.m.f. of the copper-cuprous oxide photo-cells mentioned above. This consideration comes from the circumstances that the shortest wavelength of the new absorption band happens to coincide with that of the spectral distribution of photo-e.m.f. at room temperature.

The writer is now preparing further experiment to see if the above experiment can be asserted to be valid.

Visible Light Emission from Metal-Silicon Contact

By Makoto Kikuchi
Electrotechnical Laboratory, Tokyo, Japan

(Received March 12, 1959)

It has so far been observed that visible light was emitted from a reverse biased p-n junction in silicon crystals[1]. On the course of study on this kind of phenomena, we have found out that the light was emitted even from a metal-silicon contact. When a small electrode is formed on a silicon crystal surface with silver paste as shown in Fig. 1, the contact shows strongly rectifying characteristic, and small bright radiating spots appear on the periphery of the electrode in the hard flow direction of the characteristic (Fig. 2).

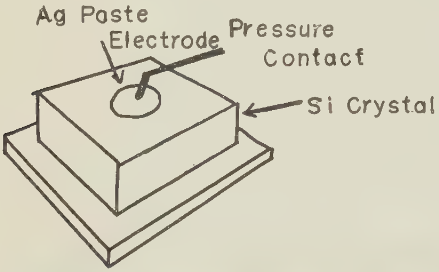

Fig. 1. The sample preparation.

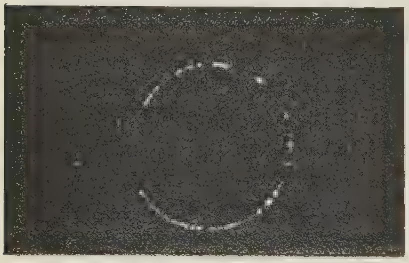

Fig. 2. Photograph of the visible light emission from the Ag-paste electrode on the silicon crystal.

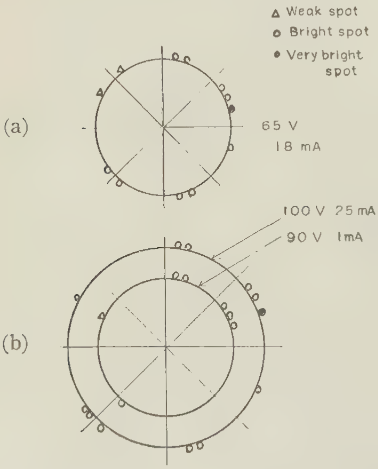

Fig. 3. Appearance of the radiating spots (a) before, and (b) after the application of castor oil.

Many kinds of experiments have been performed to clarify whether these light spots are of the same nature as those observed in the p-n junctions (i.e. microplasma). Fig. 3. (b) shows the appearance of the spots on the periphery of the electrode when it is immersed in castor oil. As is shown, the spots appear at the same positions as before applying the castor oil (Fig. 3 (a)), although the backward current is reduced and the voltage necessary to get the same pattern is increased. This result may serve as an evidence to deny the possibility that the spots are small discharge in the air gap between silver particle and silicon surface.

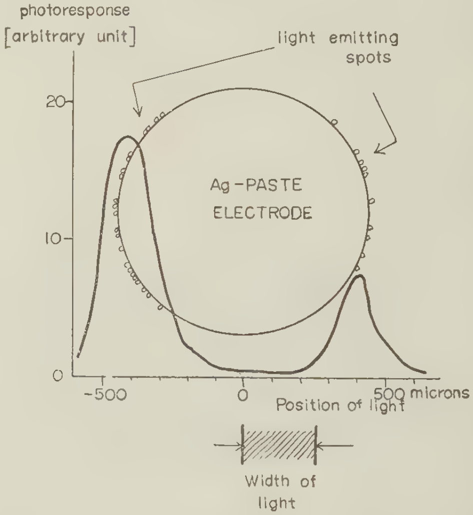

Fig. 4. The local photoresponse of the contact when the spots are being observed. The light is chopped at 245 cps, and the width of the light is 250 microns.

In Fig. 4 is shown the result of the measurement of the local photoresponse of the contact when the spots are being observed. A chopped light from a slit is focused and scanned in one direction on the electrode. As is shown, remarkable multiplication is observed at the light emitting spots.

Some of the spots are reddy and blue, but most are yellow or white. Almost the same pattern could be observed down to the liquid oxygen temperature. The appearance of the spots seems to have strong correlation with the magnitude of the current and also with its fluctuation.

The experimental details and the discussion will be reported in the near future.

Nuclear Spin-Spin Coupling between Protons in Vinyl Derivatives

By Tatsuo SHIMIZU, Shin-ichi MATSUOKA,
Shuzo HATTORI and Kantaro SENDA
Department of Physics, Kanazawa University, Kanazawa

(Received March 24, 1959)

In order to examine the spin-spin coupling constants between protons in vinyl group, we have chosen styrene and trans-cinnamic aldehyde by the reason that the shift between protons in their vinyl groups is relatively large. We have assigned their proton spectra as 3-spin system, neglecting the interactions with protons in benzene ring*. We have taken the Hamiltonian for such a system as follows:

$$\mathscr{H}=\sigma_1 I_{z1}+\sigma_2 I_{z2}+\sigma_3 I_{z3}+J_1\mathbf{I}_1\cdot\mathbf{I}_2+J_2\mathbf{I}_2\cdot\mathbf{I}_3+J_3\mathbf{I}_3\cdot\mathbf{I}_1\ ,$$

where

$$\sigma_i=(\gamma/2\pi)H_i\ .$$

We rewrite this as the sum of the following $\mathscr{H}^{(0)}$ and $\mathscr{H}^{(1)}$,

$$\mathscr{H}^{(0)}=\sigma_1(I_{z1}+I_{z2}+I_{z3})\ ,$$

$$\mathscr{H}^{(1)}=\sigma' I_{z2}+\sigma I_{z3}+J_1\mathbf{I}_1\cdot\mathbf{I}_2+J_2\mathbf{I}_2\cdot\mathbf{I}_3+J_3\mathbf{I}_3\cdot\mathbf{I}_1\ ,$$

were

$$\sigma'=\sigma_2-\sigma_1,\qquad \sigma=\sigma_3-\sigma_1\ .$$

Considering J_1, J_2, J_3 as perturbations, we have determined the parameters as follows: $\sigma'=20.6$ cps, $\sigma=59.8$ cps; $J_1=1.6$ cps, $J_2=17.2$ cps, $J_3=10.6$ cps for styrene, and $\sigma'=-117.8$ cps, $\sigma=-93.0$ cps; $J_1=7.4$ cps, $J_2=15.2$ cps, $J_3<0.5$ cps for trans-cinnamic aldehyde.

The calculated patterns with these values reproduce the experimental spectra which are shown in Fig. 1 and Fig. 2. The signs of J's have not been able to be determined at all in this approximation.

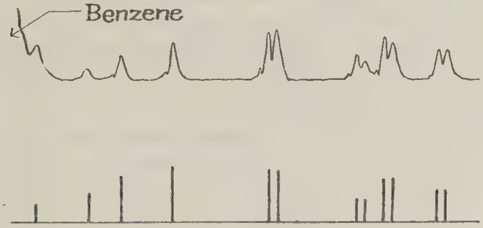

Fig. 1. Calculated and experimental spectra of styrene.

In order to make the assigned coupling constants correspond to the chemical structures, we first consider trans-cinnamic aldehyde. In this case, the shift between aldehyde group and benzene group is known¹⁾ approximately and the coupling constant between the farthest protons is considered to be nearly zero. So we have been able to make them correspond to the chemical structures as shown in Fig. 3 (a), where the cis-form of CHO is shown, but the coupling constants obtained above are average values of the spectra in the cis- and the trans-form. From this, it is inferred that the coupling constant between protons in vinyl group in the trans-position is approximately 15 cps.

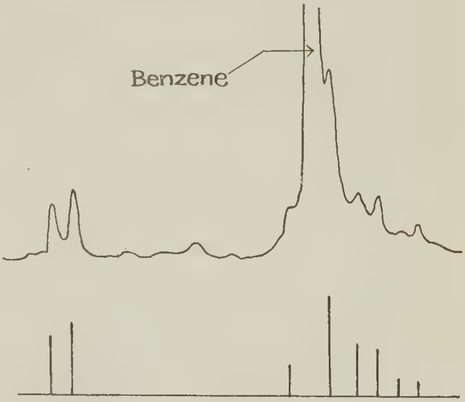

Fig. 2. Calculated and experimental spectra of trans-cinnamic aldehyde.

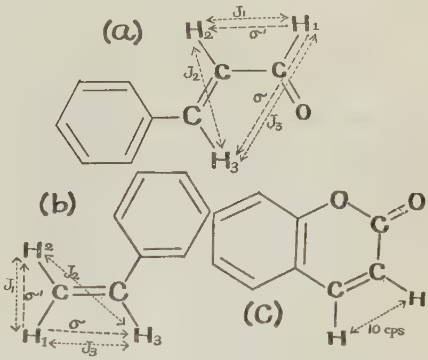

Fig. 3.

Further we have examined the spectrum of coumarine (see Fig. 3 (c)) and have found the coupling constant between protons in the cis-position to be approximately 10 cps. From these results, we have made the assigned coupling constants of styrene correspond to the chemical structures as shown in Fig. 3 (b). From the results obtained above, we have ascertained that the coupling constant between protons bonded to the same carbon atom in vinyl group is small²⁾,³⁾, and that the coupling constants between protons in the cis- and trans-positions separated by two carbon atoms are far larger than this[4].

---

* In trans-cinnamic aldehyde, the coupling J_3, between H_1 and H_3 (see Fig. 3 (a)) is expected to be very small in the same order as the coupling between H_1 and ortho proton in benzene ring, but only J_3 is taken into accunt formally to treat this spectra as 3-spin system.

The coupling constants, J_1, J_2 and J_3 of styrene obtained above are in very good agreement with the corresponding values, 1.4, 17.5 10.8 cps and 1.9, 17.4, 10.4 cps, for 3,3-dimethyl-1-butene and 1-butene respectively which Alexander has reported[4]. Though the assignment of the observed coupling constants to the cis- and trans-coupling was not made clear in his paper, we have been able to distinguish the cis- and trans-coupling constants. And the values of the cis- and trans-coupling constants we obtained are consistent with the theory of Karplus[5], appeared after this work was carried out.

The good agreement of the coupling constants among styrene, 3,3-dimethyl-1-butene and 1-butene shows that the substitutional radical does not alter coupling constants appreciably, while it has an effect on chemical shifts considerably.

The measurements were performed at Japan Electron Optics Laboratory Co., Ltd. using JNM-3 type NMR spectrometer operated at 40 Mc.

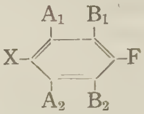
Fine Structures of Proton Resonance Spectra of Fluorobenzene Derivatives

By Minoru KIMURA, Shin-ichi MATSUOKA, Shuzo HATTORI and Kantaro SENDA
Department of Physics, Kanazawa University, Kanazawa

(Received March 20, 1959)

We have studied the high resolution proton resonance spectra of *p*-bromo-fluorobenzene and *p*-iodo-fluorobenzene.

Their spectra show the fine structures due to spin-spin couplings, and we have analyzed them as 5 spin system of XA_2B_2 type with C_{2v} symmetry. In this analysis, we have adopted the notations as shown in Fig. 1 in which the symmetrical property has been taken into account, and have neglected $J_p(\mathrm{HH})$, as reported to be approximately zero by Richards and Schaefer[1], Bak et al[2], and by Gutowsky et al[2]. Then, if we neglect $J_m(\mathrm{HH})$, the secular equation of the Hamiltonian for this system have been able to solve exactly. To such approximation that $J_m(\mathrm{HH})$ has been neglected, the main intense lines are expected to be eight lines, divided into two groups each having four lines. The separations of these two groups are due to the chemical shift between the protons at the *ortho*- and the *meta*-position.



$$J(\mathrm{F}-\mathrm{A}_1)=J(\mathrm{F}-\mathrm{A}_2)\equiv J_o(\mathrm{FH})$$
$$J(\mathrm{F}-\mathrm{B}_1)=J(\mathrm{F}-\mathrm{B}_2)\equiv J_m(\mathrm{FH})$$
$$J(\mathrm{A}_1-\mathrm{A}_2)=J(\mathrm{B}_1-\mathrm{B}_2)\equiv J_m(\mathrm{HH})$$
$$J(\mathrm{A}_1-\mathrm{B}_1)=J(\mathrm{A}_2-\mathrm{B}_2)\equiv J_o(\mathrm{HH})$$
$$J(\mathrm{A}_1-\mathrm{B}_2)=J(\mathrm{A}_2-\mathrm{B}_1)\equiv J_p(\mathrm{HH})$$

Fig. 1.

The contribution of $J_m(\mathrm{HH})$ to the energy shift has been calculated by making use of a perturbation theory to the first order. In the observed spectra, it happened that the two lines in the intense ones overlapped. These intense lines in the observed spectra have enabled us to determine the coupling constants $J_o(\mathrm{FH})$, $J_m(\mathrm{FH})$, $J_o(\mathrm{HH})$ and the chemical shift, σ. Their values thus obtained are:

$\sigma=18.97$ cps; $J_o(\mathrm{FH})=9.47$ cps, $J_m(\mathrm{FH})=6.11$ cps, and $J_o(\mathrm{HH})=9.65$ cps for p-bromo-fluorobenzene; $\sigma=32.6$ cps; $J_o(\mathrm{FH})=9.35$ cps, $J_m(\mathrm{FH})=6.08$ cps and $J_o(\mathrm{HH})=9.30$ cps for *p*-iodo-fluorobenzene.

$J_m(\mathrm{HH})$ is to be determined by performing the assignments of the other weaker lines which are separated from the intense lines by the effect of $J_m(\mathrm{HH})$. In our estimation, it is probable that the value of $J_m(\mathrm{HH})$ is approximately 2 cps in both molecules and has the same sign with $J_o(\mathrm{HH})$. However, in order to determine the value of $J_m(\mathrm{HH})$ accurately, the resolving power of the spectrometer must be improved a little more.

The investigations about the benzene derivatives have been reported by Richards and Schaefer[1], Bak et al[2], and Gutowsky et al[3]. They investigated *p*-fluoro-aniline, deuterium substituted fluorobenzenes and other substituted fluorobenzenes and found the chemical shift between protons in the *ortho*- and the *meta*-position, and determined the values of the spin-spin coupling constants between nuclei. The coupling constants obtained here agree almost with their results.

The spectra were observed with JNM-3 type NMR spectrometer of Japan Electron Optics Laboratory Co., Ltd. operated at the fixed frequency 40 Mc.

A Metastable Phase in Sn-Mg Alloy Film

By Ryōji SUGANUMA
Physical Institute, Kyōto Prefectural Medical College

(Received February 5, 1959)

Through the electron diffraction study of Sn-Mg alloy films, a new phase was observed which seemed to be metastable.

The thin films were made in vacuum (about 10^{-5} mmHg) by successive evaporation of Sn and Mg on Formvar films at room temperatures. The compositions of films as a whole were 7~55 at. % Sn and the total amount of the evaporated metals was about 10 mg.

The diffraction pattern of the films whose compositions as a whole are Mg-rich compared with that of Mg_2Sn is composed of the patterns of Sn, Mg, Mg_2Sn and an unknown new phase at room temperatures. When these films are heated in the electron diffraction apparatus, the new phase immediately disappeared at about 150°C and the diffraction patterns of these specimens only show the existence of Mg and Mg_2Sn, which do not show any change even after the cooling to the room temperatures. While, in the case of Mg-poor specimens which are composed of Sn, Mg_2Sn and the new phase at room temperatures, the most part of the film indicates only two phases of Sn and Mg_2Sn at about 150°C, but a part of the same film remains in the state of three phases, namely, the melt of Sn, Mg_2Sn and the new phase, at about 315°C. The diffraction patterns of these specimens show no changes by the cooling to the room temperatures as the case of Mg-rich ones. The unknown new phase was always observed for the specimens before heat treatments, independently of the compositions of films as a whole and no matter which constituent metal was deposited as the primary layer. The specimens, which are composed of two phases of Sn and Mg_2Sn by the heating up to 150°C, do not show the existence of the new phase even after the annealing for about one hour at the temperatures of about 100°C, 150°C and 240°C (the melting point of Sn being 232°C), respectively, and in addition, the bulk specimens prepared by the vacuum melting of Sn and Mg (about 65 at. % Sn) only show two phases of Sn and Mg_2Sn, but not the new phase. From these facts, the new phase seems to be metastable at least in the temperature ranges studied (i.e. from room temperatures to about 150°C for the Mg-rich specimens and to about 315°C for the Mg-poor ones).

The diffraction rings of the new phase and Sn mostly overlap each other. But, in the diffraction patterns obtained at the temperatures higher than the melting point of Sn, the halo pattern of Sn appears in place of the ring pattern of Sn so that the diffraction pattern of the new phase can be easily distinguished from that of Sn.

The diffraction pattern of this new phase could not be compatibly explained by assuming the tetragonal or hexagonal systems. Therefore, Lipson's method[1] for the orthorhombic crystals was applied. It was successful in this case and approximate values of three axes of the orthorhombic unit-cell were obtained graphically. After refined numerical calculations, the three axes were determined to be a=15.23Å b=8.90Å and c=13.10Å. For example, the observed and calculated spacings for the specimen of about 50 at. % Sn, which was made by the deposition of Mg on the primary Sn deposit, are tabulated in Table I. The spacings of Mg_2Sn observed with the specimens, which indicate

* These lines are superposed on the reflections of Mg_2Sn, so that they might have to be disregarded.

two phases of Sn and Mg_2Sn, are also shown in Table I. These values agree well with the data obtained from the X-ray diffraction.

When the systematic absence in the diffraction lines, except the (013) reflection superposed on the (111) reflection of Mg_2Sn, is considered, the space group of the new phase may be supposed to be P_{bnn} and the symmetry does not become higher than P_{bnn} even though all the reflections superposed on those of Mg_2Sn are neglected. However because only powder diffraction data with thin films are available in the present stage, further studies will be required for the accurate determination of the space group.

Anomalous Hall Effect due to an s-d Interaction in the Dilute Alloys Containing the Transition Elements

By Mikio TSUJI

General Education Department, Kyushu University, Otsubo-machi, Fukuoka

(Received March 30, 1959)

Since the discovery of the anomalous behaviour of the electrical resistivity of noble metal alloys by Geritsen and Linde¹⁾, the mechanism causing the anomaly has been the subject of a number of investigation. Recently Yosida²⁾ has presented a theory in which the anomalous decrease of the electrical resistivity at low temperature and the anomalous negative magnetoresistance of the noble metals containing traces of the transition elements have been interpreted as an effect of the s-d exchange interaction between the conduction electrons and the magnetic ions. Here, we shall show that, if the mechanism of Yosida is true, the alloys would show also an anomalous Hall effect*.

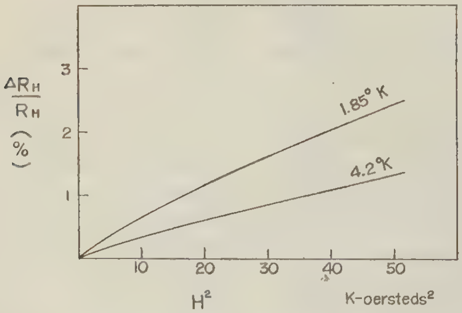

Fig. 1. Change in Hall coefficient vs. square of magnetic field for the 0.2 at. per cent Mn in Cu. (Estimated from Schmitt and Jacobs' data and Eq. (5)).

Now, in a dilute alloys having total magnetization of the transitions ions M, the relaxation times $\tau_\pm$ of the conduction electrons of + and − spins are,

$$\tau_\pm \propto 1/(W_0 \mp wM)\ , \tag{1}$$

respectively²⁾. Here $W_0 \mp wM$ is the transition probability of the electrons. From (1), Yosida has obtained the resistivity of the alloys as

$$\rho \propto (\tau^+ + \tau^-)^{-1} = \frac{W_0}{2} - \frac{w^2}{2W_0} M^2\ . \tag{2}$$

The Hall coefficient R_H is given by

$$R_H = 2R_0 \frac{\tau_+{}^2 + \tau_-{}^2}{(\tau_+ + \tau_-)^2}\ , \tag{3}$$

where R_0 is the Hall coefficient in the limit of small magnetic field ($\tau_+ = \tau^-$). Inserting (1) into (3), we have

$$R_H = R_0\left(1 + \frac{w_2}{W_0{}^2} M^2\right)\ . \tag{4}$$

Eq. (4) shows that an anomalous Hall effect $\Delta R_H = R_0(w^2/W_0{}^2)M^2$ would appear in the alloys, which is proportional to the square of the total magnetization and causes an increase of the absolute value of the Hall coefficient. From (2) and (4), we have a relation

$$\frac{\Delta R_H}{R_H} = -\frac{\Delta\rho}{\rho}\ . \tag{5}$$

Schmitt and Jacobs³⁾ have measured the magnetoresistance of the dilute Cu-Mn alloys at low temperatures. Therefore, we can estimate the order of magnitude of the expected anomaly in the Hall effect and its temperature dependence by using the relation (5). As an example, the estimated values $\Delta R_H/R_H$ for 0.2 at % Cu-Mn alloys are shown in Fig. 1.

We should like to thank Prof. Y. Sibuya, Tohoku University, who called this problem to our attention.

Changes of Ultrasonic Attenuation during Creep of Aluminum

By Akira HIKATA and Masayoshi TUTUMI

Government Mechanical Laboratory,
132 Sumiyoshi-cho, Suginamiku, Tokyo

(Received December 2, 1958)

It has been reported[1-4] that ultrasonic attenuation is very sensitive to the plastic deformations of metals. On this basis, changes of ultrasonic attenuation during creep experiments of aluminum (99.97 per cent purity) at room temperature were investigated.

Ultrasonic pulses of 5 MC/sec are transmitted to the specimen at its one end using a quartz transducer and multiple echoes reflected from the other end of the specimen are received by the same transducer. The electric signals thus obtained are then amplified and displayed on the screen of the synchronized oscilloscope. The specimens are subjected to a constant load, and attenuation of the ultrasonic waves and strain are measured as a function of time.

One of the results is shown in Fig. 1. Curve *S* shows the usual strain-time relation of this experiment in which the load was increased or decreased several times by a small amount during the creep process. Curve *R* is for the strain rate-time relation calculated from the curve *S*. Curve α is for the corresponding attenuation-time relation.

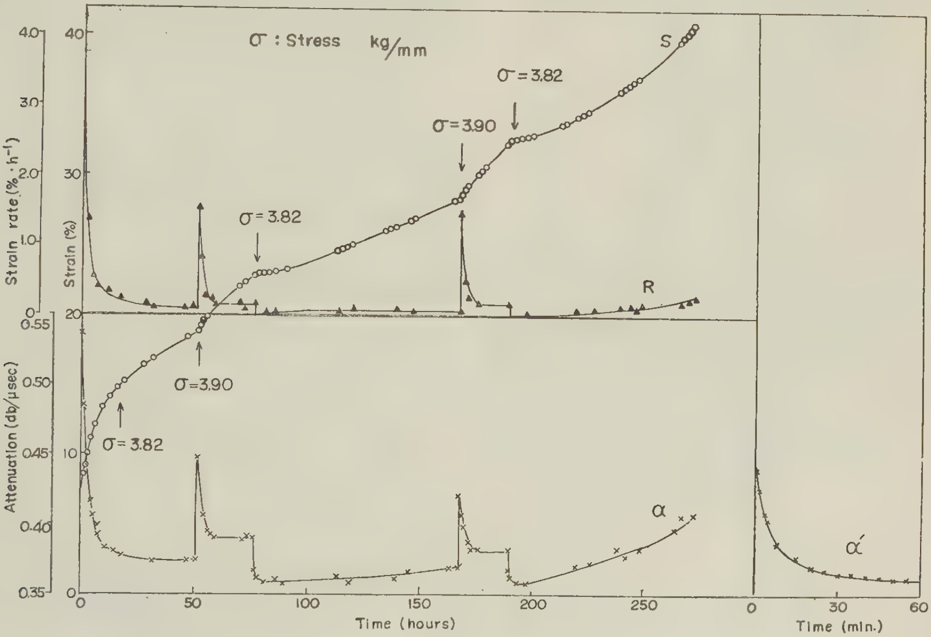

Fig. 1. Curve S: Creep strain-time relation. Curve R: Creep rate-time relation.
Curve α: Attenuation-time relation. Curve α': Recovery of attenuation.

It becomes clear from this experiment that there is a close relationship between the strain rate and ultrasonic attenuation.

According to Granato and Lücke[5),6)] ultrasonic attenuation is determined by the effective loop length and density of dislocations. It is plausible that during the creep process, the effect which increases the attenuation, such as the increase of dislocation density and bulging out of dislocation loops, and the effect which decreases the attenuation, such as the pinning of those dislocations by vacancies created during the deformation, are always competing each other. When there is any disturbance between these two effects by changing the load slightly, the balance will not be held anymore and sharp increase or decrease of attenuation is observed until it reaches the new equilibrium state. The details of this mechanism together with the experiments now undergoing will be published later.

Curve α' of the Fig. 1 is for the recovery of the attenuation when the load is completely removed at the end of the experiment. This curve clearly shows that the increase of attenuation at the final stage of the creep process does not come from the decrease of the cross sectional area of the specimen by necking.

Size Effects on the Ferrimagnetic Resonance Absorption of Polycrystalline Ferrites and Garnets

By Hiroo Yonemitsu

Matsuda Research Laboratories,
Tokyo Shibaura Electric Co.,
Kawasaki, Japan

(Received January 19, 1959)

Polycrystalline ferrites and garnets are prepared by the usual ceramic technique, and their size effects on ferrimagnetic resonance absorptions are investigated. Samples are ground in the form of sphere by the Bond's method and put into the rectangular cavity resonator having the TE_{101} mode. Measuring apparatus is composed of the source modulation balanced bridge type spectrometer using the magic-tee, and operates at the frequency of 9,345 Mc.

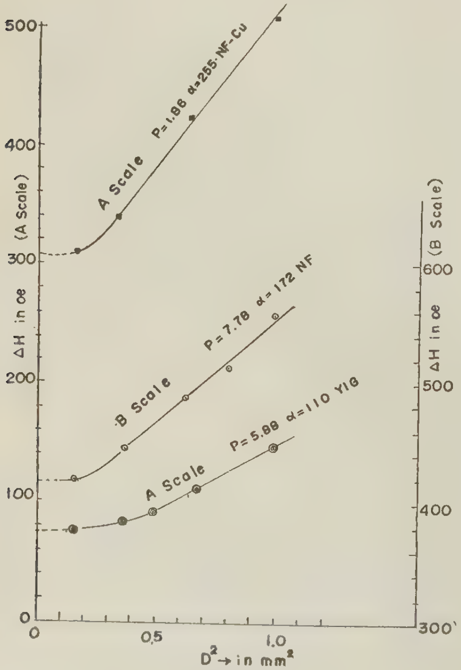

Fig. 1.

Effects of size on the microwave properties of ferrites have been already investigated by several authors[1-6]. But most of their works chiefly dealed with the shift in resonance field.

This paper deals with the size effect which is defined here as the variation of resonance line-width ΔH with the diameter D of sample.

The typical data are shown in Fig. 1, where one may notice that ΔH has a certain constant value provided D^2 is sufficiently small, while ΔH increases linearly with D^2 if D^2 is rather large. It can be approximated by the following empirical formula

$$\Delta H = a + \alpha D^2$$

where α is the proportional constant.

Since α is strongly dependent upon the porosity

◎ YIG $5Fe_2O_3 \cdot 3YeO_3$

p (in %) of each sample, an attempt is made here that α is plotted against p. Several such results are shown in Fig. 2.

In most ferrite samples α decreases with p until p is equal to about 10%. Since these materials were fired at high temperatures with long keeping times, they should contain many ferrous ions. It is verified by their very high conductivities. While in the garnet samples α is initially small and increases gradually with p. As for the yttrium iron garnet (YIG), it is verified by X-ray and thermomagnetic analysis that the possibility of the presence of ferrous ions is very small. This difference in the content of the ferrous ions between the two materials might have some contribution to the observed different character of the two materials.

Further considerations will be presented soon later.

An Application of the FA-Modified TF Model to the Singly Ionized Negative Ion

By Shigehiro KOBAYASHI

Department of Physics, Kagawa University, Takamatsu

(Received February 9, 1959)

It is well known[1)] that the Thomas-Fermi (TF) model modified by Fermi and Amaldi (FA), taking as its TF function the ordinary one φ_0 with the modified unit μ^*, enables us to treat the free states of singly ionized negative ions as well as atoms and positive ions.

By the use of this model, Jensen[2)] has already calculated the values of molar diamagnetic susceptibilities of neon-like negative ions and obtained fairly good results.

As another application of this model, we have calculated the mean excitation energy and the X-ray scattering factor with the use of our table of $\varphi_0(x)$[3)].

Fig. 1 shows the nearly linear dependence of the mean excitation potential V_M and energy E_M on atomic number Z, both in logarithmic scale.

Fig. 2 shows the variation of the coherent scattering factor $\mathfrak{f}_0$ and the incoherent scattering factor s_0^2 per electron† *versus* $\sin\theta/\lambda$.

Fig. 3 shows the coherent scattering factor f_0 for several negative ions. As there has been no calculated values of f_0 using the Hartree-Fock (HF)

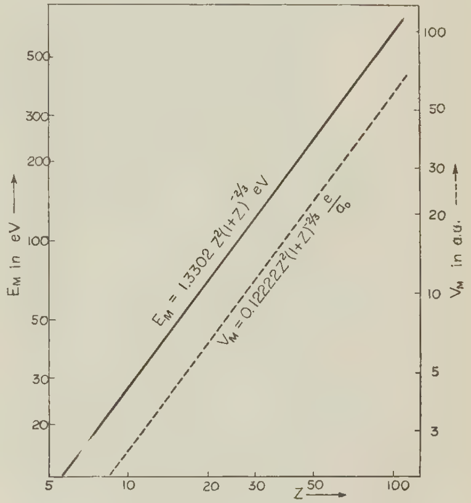

Fig. 1.

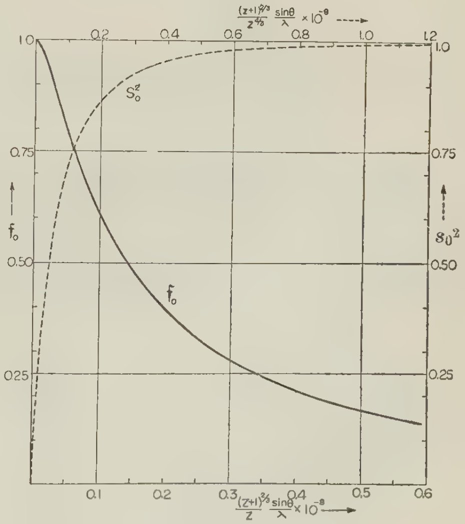

Fig. 2.

---

† Definition of $\mathfrak{f}_0$ and s_0^2 are due to Bethe [Ann. Physik V **5** (1930) 325] and Heisenberg [Phys. Zs. **32** (1931) 737] and these quantities have been obtained as definite functions of $\frac{(Z+1)^{2/3}}{Z}\frac{\sin\theta}{\lambda}$ and $\frac{(Z+1)^{2/3}}{Z^{4/3}}\frac{\sin\theta}{\lambda}$ only, respectively.

field for heavy negative ions, we have plotted those values for F^- and Cl^-, for comparison[4]. Though these are not heavy enough, we did so because we found no better means. It is noticeable that the discrepancy changes its sign alternately with the increase of $\sin\theta/\lambda$ for both ions.

The author wishes to express his sincere thanks to Professor K. Umeda of Okayama University for his continued guidance and kind encouragement throughout this work.

Evaluation of the Nuclear Quadrupole Moment of N^{14}

By Yoshifumi KATO
Osaka Municipal Technical Research Institute, Osaka
and Osamu NAKAHARA
Department of Physics, Kyoto University,

(Received March 20, 1959)

The nuclear quadrupole moment of N^{14} nucleus evaluated from the eQq coupling energy in molecules by several people seems to have disagreed values. Owing to the lack of the datum by the atomic beam experiment for this atom, we are forced to evaluate the quadrupole moment from the molecuar data using the calculated field gradient.

Townes et al[1] have estimated $Q(N^{14})=2\times10^{-26}$ cm² from the experimental datum on cyanide, while Sheriden et al[2] $Q(N^{14})=1\times10^{-26}\,\mathrm{cm}^2$ from the experimental datum on NF_3. These are derived from the field gradient calculated by the simple approximation which was offered by Townes and Dailey[3]. Recently, Bassompierre[4] has calculated the field gradient by LCAO SCF MO which was set up by him for the HCN molecule and obtained $Q(N^{14})=0.71\times10^{-26}\,\mathrm{cm}^2$ from the experimental datum on HCN.

In views of these facts, it seems worthwhile for us to estimate $Q(N^{14})$ from the experimental datum on the NH_3 molecule by calculating the field gradient at the N nucleus, using the LCAO SCF MO set up by Duncan[5] for this molecule. Duncan's function gives 99.2% and 72% of the experimental total and binding energy respectively. This seems a fairly good result as the quantum-mechanical calculation of this kind[6]. The NH_3 molecule has three-fold symmetry around the principal axis of symmetry, so that we only have to calculate the mean value of $\delta^2V/\delta Z^2(=q)$, where Z is taken along the principal axis of symmetry and V is the electrostatic potential in the molecule. Now q can be divided into two parts; $q=q_n+q_e$, where q_n and q_e respectively represent the contribution to the field gradient from the three protons all the electrons in the molecule. q_e can be written in the scheme of LCAO MO as follows,

$$
\begin{aligned}
q_e&=-2e\sum_{i.p.q}\alpha_{ip}\alpha_{iq}\int\chi_p{}^*\frac{3\cos^2\theta_z-1}{r_N{}^3}\chi_q dV\\
&=-2e\sum_i q'_{\phi i\phi i}\ , \qquad (1)
\end{aligned}
$$

where i stands for the suffix of the occupied MO; $\phi_i=\sum_p \alpha_{ip}\chi_p$, χ's represent Slater AO and r_N, θ_Z are the distance from the N nucleus and the polar angle from the Z axis. e is the protonic change. For the evaluation of the integrals in Eq. (1), we have made use of the Barnett-Coulson method[7] which enables us to expand 1s orbitals centered on three protons in terms of r_N, θ_Z and φ. A three-center integral is also expanded in the same manner and its radial part is reduced to a doubly infinite series; $\sum_{n,n'}^{\infty}\int\zeta_{1,n}(1,r_N:R)\times\zeta_{1,n'}(1,r_N:R)r_N{}^{-2}dr_N$. The convergence is rather poor, yet we think it is sufficient to take several terms because of the small contribution to q_e from this integral. The contributions to q_e from each occupied MO (ϕ_i) are as follows;

$$\begin{aligned} q'_{\phi_1\phi_1} &\quad +0.03164\ 38\ \text{a.u.},\\ q'_{\phi_2\phi_2} &\quad +1.65281\ 69\ \text{a.u.},\\ q'_{\phi_3\phi_3} &\quad +0.00001\ 604\ \text{a.u.},\\ q'_{\phi_5\phi_5}=q'_{\phi_7\phi_7} &\quad -0.49257\ 03\ \text{a.u.}, \end{aligned} \tag{2}$$

here the number of suffix i is the same as Duncan's one. Then we obtain $q_e=1.39467e$ a.u..

For the field gradient q_n due to protons, we have taken into account of the effect of the nuclear vibration in the molecule. A study of the normal modes of vibration in this molecule[8] shows that at ordinary temperature, we have only to take an average value over symmetric bending vibration of protons corresponding $\nu_2(a_1)=950\,\text{cm}^{-1}$, and therefore we have estimated the average regarding this mode as the simple harmonic oscillation. Following these considerations, we have obtained $q_n=-0.224115e$ a. u.. If all the nuclei are assumed to be fixed in the equilibrium positions, q_n becomes $-0.246876e$ a.u.. In order to take the effect of the nuclear vibrations on q_e into accunt, we must know the adiabatic dependence of q_e on the normal coordinates of vibration. However this is a very difficult task and therefore we have assumed that q_e is independent on the nuclear vibrations. This is probably allowed since the electrons, which give a great effect to the field gradient, are in vicinity of the N nucleus and they would be scarcely perturbed by small vibration of protons.

Now the total field gradient q becomes $-1.61879e$ a.u. for the vibrating nuclei and $-1.64155e$ a.u. for the static nuclei. The nuclear quadrupole coupling energy of the NH_3 molecule is known to be -4.10Mc.[9], from which we obtain $Q(\text{N}^{14})=1.08\times10^{-26}\,\text{cm}^2$ for the vibrating nuclei and $1.06\times10^{-26}\,\text{cm}^2$ for the static nuclei. It is interesting to note that our estimated value has fallen into the intermediate value between Townes et al's and Bassompierre's estimation.

Absolute Cross Sections of the (γ, n) Reaction for Cu^{63}, Zn^{64} and Ag^{109}

By Teruo NAKAMURA, Kunio TAKAMATSU, Kiyoji FUKUNAGA,
Minoru YATA and Shinjiro YASUMI

Department of Physics, Faculty of Science, University of Kyoto

(Received January 14, 1959)

The photonuclear reaction cross section of $Cu^{63}(\gamma, n)Cu^{62}$ has been frequently used as the standard for the (γ, n) reactions, but the measured values by many workers do not agree with one another and can be roughly divided into two groups, namely, about 100 mb group and about 50 mb group. It appears that the former group contains the values obtained mainly by measurements by use of bremsstrahlungs, while the latter those obtained mainly with Li–p γ-rays.

We attempted to re-determine the (γ, n) cross section for copper, zinc and silver by Li–p γ-ray. Absolute measurement of γ-quanta was performed by Hough's method, and reaction yields were determined by the activation method in which the absolute numbers of activated nuclei in samples were determined by measuring the β-ray with a 4π-proportional counter and applying the "method of extrapolation". The cross sections of Cu^{63}, Zn^{64} and Ag^{109} for 17.6 Mev γ-rays were found to be 42.5 mb±15%, 23.3 mb±18% and 61.5 mb±16% respectively. Experimental cross sections so far obtained by many workers are compiled in Table II and some discussions are given.

§ 1. Introduction

The absolute cross sections of (γ, n) reactions have been studied by many workers.$^{1)-13)}$ Especially, for Cu^{63}, its cross section has been customarily used as the standard of (γ, n) reaction cross sections and has been frequently measured for both lithium-gamma rays and bremsstrahlungs by using various methods as indicated in Table II.

It seems curious, however, that experimental cross section values of this reaction never agree with one another and the discrepancies between them sometimes exceed over about 100%. So far as the $Cu^{63}(\gamma, n)Cu^{62}$ reaction cross section value is used as the standard, this uncertainty introduces directly the ambiguities of the same order into the integrated cross section value $\int \sigma dE$ which is often compared with the sum rule of the photonuclear reaction. Therefore further investigation on the cross section seems to be extremely desirable. For this reason, we have attempted to re-determine the (γ, n) absolute cross sections of Cu^{63}, Zn^{64} and Ag^{109} for Li–p γ-rays.

§ 2. Experimental Procedure

The γ-rays were produced by the $Li^7(p, \gamma)Be^8$ reaction. Li metal targets of 0.5 mm thick were bombarded with magnetically analysed protons which were accelerated to 500 Kev by a Cockcroft generator and whose intensities were about 50 μA～100 μA. Sample discs made of copper, zinc and silver were irradiated by these γ-rays, and (γ, n) cross sections were determined by the activation method.

The size of the proton beam spot was about 8 mm in diameter, and the distance between the sample disc and the γ-ray source was 14.5 mm, the former having been fixed on the target box with an aluminium jig$^{14)}$.

Sample discs used were all 20 mm in diameter and 1 mm thick for copper and silver, and 0.6 mm thick for zinc respectively. These dimensions were the same as those of the monitor discs, which had been used by one of authors (S. Y.) in the measurement of the 14 Mev neutron reaction cross section$^{15)}$.

The γ-ray intensities were measured by using an end-window Geiger counter with a 5 mm lead converter on the front and its counting efficiency for Li–p γ-ray was calibrated by

Hough's method16). Hough's method may be summarized as follows: When a thin metal foil is placed in front of a Geiger counter on the passage of γ-rays, the counting rate of the counter will increase due to secondary electrons from metal foil produced by γ-rays. From this excess counting rate and the electronic cross section of γ-ray for a converter metal, we can obtain the γ-ray flux at the position of the converter foil. In our case, when the counter was situated at a distance of 31.7 cm from the target, one count of this counter corresponds to $(1.63\pm0.20)\times10^4\ \gamma$ quanta per 4π steradians14).

Produced activities were measured by use of an end-window Geiger counter with the disc in front of the window. To hold the disc, a jig was used, which is the same one as that used in the β-counting described in ref. 15).

Using the activation method, the cross section is obtained as follows. γ-quanta were measured for every one minute interval for copper and zinc, and for every half a minute interval for silver, and we considered that the γ-ray intensity was kept constant in that interval and the fluctuation of the intensity was considered as errors. Then the cross section σ for copper and zinc is given by*

$$\sigma=\frac{M\left[N\Big/\sum_{i=1}^{T} n_{\gamma i}\exp\{-(T-i+t_0)\lambda\}\right]S\cdot G_G\cdot C_k}{N_0\eta[(1-e^{-\lambda})(1-e^{-\lambda t'})/\lambda]}.$$

and that for silver is given by

$$\sigma=\frac{M\left[N\Big/\sum_{i=1}^{2T} 2n_{\gamma i}\exp\{-(T-i/2+t_0)\lambda\}\right]S\cdot C_G\cdot C_k}{N_0\eta[(1-e^{-\lambda/2})(1-e^{-\lambda t'})/\lambda]},$$

where

N_0: Avogadro's number,

M: molecular weight of the sample,

η: isotopic abundance ratio,

λ: decay constant of the activity,

S: correction factor related to the self-absorption and scattering of the sample, which was measured by the method of extrapolation,

C_G: geometrical correction factor for the β-counting concerning the absorption by the air and the mica window, the back scattering and the solid angle, which was measured by a 4π-proportional counter,

C_k: correction factor concerning the branching ratio between the positron emission and the orbital electron capture, namely

$C_k=1$ for the case of β^- activity

$C_k>1$ for the case of β^+ activity,

i: number of the order of each time interval during bombardment (integer),

$n_{\gamma i}$: number of photons reaching the sample disc in one minute or half a minute of i-th interval,

N: β-counts per t' minute on the sample disc,

T: time of irradiation (minute),

t_0: time elapsed from the end of irradiation to the beginning of the beta counting (minute),

t': time of beta counting (minute).

For the correction factors S and C_G, we used the values measured in ref. 15). Then the identity of the properties of both G–M tubes must be assured. So it was checked with the calibration disc of KCl and it was found that they were identical with each other within the statistical error.

The time of the irradiation of γ-rays was about twice the half life for each sample and the time of β-counting was ten minutes for copper and silver, and thirty minutes for zinc respectively.

---

* For the derivation of this formula, see the appendix in ref. 15). Since sample discs used in this experiment, as mentioned above, have the same dimension as those of the monitor discs used in ref. 15), N in this equation corresponds to N_M in ref. 15). In the present case, however, measurements determining S-value were not performed, but we adopted S measured by the method of extrapolation in ref. 15) for that in this equation, because both $(n, 2n)$ and (γ, n) reactions should produce the same residual nucleus.

Consequently, we may regard S-value as the "correction factor" by which counts of comparatively thick sample N can be converted to a value proportional to the specific activity.

§ 3. Results

The cross sections obtained are shown in Table I. As these decay constants, we used the value for copper which was determined in our measurement with Peierls' method and the values from King's table[17] for zinc and silver.

Table I. Results obtained.

Reaction	λ (min^{-1})	σ(Li–$p\gamma$) (mb)	σ(17.6 Mev)** (mb)
$Cu^{63}(\gamma, n)Cu^{62}$	0.0695*±2%	37.7±15%	42.5
$Zn^{64}(\gamma, n)Zn^{63}$	0.018	20.7±18%	23.3
$Ag^{109}(\gamma, n)Ag^{108}$	0.295	54.6±16%	61.5

* The decay constant of Cu^{62} was determined in our measurement.

** For the reduction to 17.6 Mev monochromatic γ-ray, we used the ratio 1:2 as the intensity ratio of 14.8 Mev to 17.6 Mev γ-ray, and the results of bremsstrahlung experiments as the excitation curve for each elements.

For the reactions $Cu^{63}(\gamma, n)Cu^{62}$ and $Ag^{109}(\gamma, n)Ag^{108}$, the contributions of $Cu^{65}(\gamma, n)Cu^{64}$ (half life ~12 hour) and $Ag^{107}(\gamma, n)Ag^{106}$ (half life 24 min) must be considered respectively. In the case of copper, the contribution of β-activity of Cu^{64} for the β counting of Cu^{62} can be neglected because of the long half life, so that the correction was not made but was included in the counting errors.

In the case of silver, on the contrary, the contribution of Ag^{106} β-activity cannot be neglected because of the comparatively short half life. Thus, using the experimental value as obtained by Uemura *et al.*[18] for the ratio of the cross section of $Ag^{109}(\gamma, n)Ag^{108}$ to that of $Ag^{107}(\gamma, n)Ag^{106}$ for Li–p γ-rays, and considering that the geometrical factor C_G and specific activity S are of the same values for both Ag^{108} and Ag^{106} β-activities, the cross section of $Ag^{109}(\gamma, n)Ag^{108}$ becomes as follows:

$$\sigma=\frac{M\cdot S\cdot C_k}{N_0}\,\frac{N}{\Sigma}\ ,$$

with

$$\Sigma=\eta_1[\{1-\exp(-\lambda_1/2)\}\{1-\exp(-\lambda_1 t')\}/\lambda_1]$$
$$\times\sum_{i=1}^{2T}2n_{\gamma i}\exp[-(T-i/2+t_0)\lambda_1]\frac{1}{C_{k1}}$$
$$+\ \frac{\sigma_2}{\sigma_1}\eta_2[\{1-\exp(-\lambda_2/2)\}\{1-\exp(-\lambda_2 t')\}/\lambda_2]$$
$$\times\sum_{i=1}^{2T}2n_{\gamma i}\exp[-(T-i/2+t_0)\lambda_2]\frac{1}{C_{k2}}\ ,$$

$$\frac{\sigma_2}{\sigma_1}=0.903\ ,$$

where suffixes 1 and 2 correspond to Ag^{109} and Ag^{107} respectively.

The source of error was mainly in the measurement of the absolute gamma quanta, being 13%[14], and in the estimation of other errors the upper limits were used if they could not be estimated accurately. They were as follows: ±1% from the calculation of the solid angle of the sample subtended to the γ-source, ±4% from the shift of the position of the γ-source, less than 1.5% from an additional error concerning geometrical factor C_G due to the difference of the irradiation geometry between the present work and ref. 15), and some errors for each sample. The last errors mentioned here were for Cu, the statistical error of β-counting : ±1%; the fluctuation of γ-ray intensities during the irradiation : below ±2.5%; decay constant λ : ±2%; specific activity S : ±3%; geometrical factor C_G : ±2% and the contamination of beta activities of Cu^{64} for the beta counting : below 2%; while for Zn, the statistical error of the beta counting : ±4%; the fluctuation of γ-ray intensities during the irradiation : below 0.2%; the error of λ negligibly small; S : ±10% and C_G : ±4%; and for Ag, the statistical error of the beta counting : 4%; the fluctuation of γ-ray intensity during the irradiation : below ±2%; λ : ±1%; S : ±7% and C_G : ±3%. The errors shown in Table I are the roots of square sums of them.

§ 4. Discussions

Making a list of the experimental values of the reaction cross section of $Cu^{63}(\gamma, n)Cu^{62}$ for 17.6 Mev photons as summarized in Table II, it appears that they are divided into two groups i.e. one group of about 100 mb and the other of about 50 mb. The experiments belonging to the former were all performed by using the bremsstrahlungs of betatrons or a linear accelerator except those of Wäffler and Hirzel[1] and Carver and Kondaiah[10], and (γ, n) excitation curves were obtained from the yield curves with the photon difference

method in which the shapes of spectra of bremsstrahlungs were needed for the analysis of data, and in almost all the cases the theoretical curves were used for the spectrum of bremsstrahlungs. For the measurements of the intensity of bremsstrahlung, a roentgen-meter or an ionization chamber was usually used and its response was theoretically calculated.

Among the measurements with bremsstrahlungs, however, it is noticeable that Krohn and Shrader[7] determined the energy spectra of bremsstrahlungs by the D_2O emulsion and monitored these intensities by the γ-ray pair spectrometer which was calibrated with the cross section of the photodisintegration of deuteron, and Berman and Brown[11] used directly the incident electron intensity from a linear accelerator to determine the intensity of the bremsstrahlung.

In addition, as mentioned above, there are only two measurements by Li–*p* γ-ray in the 100 mb group. Wäffler and Hirzel[1] obtained 120 mb with Li–*p* γ-ray who used a thick aluminium counter for the measurement of the γ-ray intensity and its counting efficiency (γ, *n*) cross sections.

was calculated by Fowler *et al.*[19] Carver and Kondaiah[10] measured neutron yields with the Szilard-Chalmers' method and determined the γ-flux with the brass Geiger counter calibrated experimentally by Barnes *et al.*[20] They calibrated this counter using a thick-walled ionization chamber made of graphite which contained a cylindrical cavity filled with pure nitrogen, whose ionization current was translated into the γ-ray flux by the theory of Lax[21] and the validity of this theory was accertained by the α-counting from the reaction $F^{19}(p, \alpha, \gamma)O^{16}$.

On the other hand, experiments belonging to the 50 mb group were all done with Li–*p* γ-rays including the present work, and the γ-ray intensities were all determined with G–M counters calibrated by Hough's method.

Previously, $Cu^{63}(\gamma, n)Cu^{62}$ reaction cross section had been measured by Shimizu[2] at our laboratory, and with Hough's method we calibrated the γ-intensity monitor which had been used by him and whose efficiency was calculated by Sonoda.[22] This result reduced the cross section value reported by Shimizu to 33 mb as shown in Table II.

It is seen in Table II that in each group the relative cross sections agree fairly well with one another. For this reason, it seems reasonable to us that these discrepancies may be due to the uncertainty of determination of photon intensities.

It should be emphasized that the cross section values belonging to 50 mb-group are obtained by purely experimental methods and therefore considered to be more reliable than 100 mb group.

It is very desirable, however, to find the reason why there are such large discrepancies in the experimental determinations of (γ, n) cross section.

Acknowledgement

The authors wish to express their cordial thanks to Prof. K. Kimura for his continual interest and encouragements. They are also greatly indebted to Prof. S. Shimizu for valuable discussions and to Mr. Y. Saji of Institute for Nuclear Study, University of Tokyo for private communication. Further, they are grateful to Miss T. Hirata for preparing the manuscript.

(Received February 23, 1959)

The gamma rays resulting from the ring scatterers of Mg, Al, Fe and Bi bombarded with 2.95 MeV neutrons have been investigated. The cross sections for the 0.845 MeV gamma ray from Fe^{56} and for the 1.37 MeV gamma ray from Mg^{24} were 1.10 ± 0.13 and 0.66 ± 0.10 in barns respectively. The angular distributions of the gamma rays relative to the direction of the incident neutrons were both symmetric around 90°. These cross sections and angular distributions were compared with the statistical theory by the optical model. Our results were fairly well interpreted by using a diffuse potential well.

§ 1. Introduction

Hauser and Feshbach1) developed the statistical theory by which the inelastic scattering of neutrons could be accounted for. But their theory is not capable of interpreting the details which are shown up in the recent experiments. The fine structure in the excitation curves obtained by Kiehn and Goodman2) would not be interpreted by the statistical theory which assumes a continuous level scheme of the compound nucleus, though this theory holds for an excitation curve smoothed out over energy. Cranberg and Levin3) and Muehlhause et al4) found the asymmetric angular distributions of inelastically scattered neutrons. The associated gamma rays were also found as being asymmetrically distributed by the recent experiment5). These facts show that the statistical assumption fails in some cases.

However, there are some other experimental results which can be accounted for by the statistical theory. For these cases one can calculate the transmission coefficients in the Hauser and Feshbach's formula1), being based on some model. Van Loef and Lind6) have measured the excitation curves of inelastic scattering for neutrons with energies up to 2 MeV and the angular distribution of the 0.845 MeV gamma ray from iron for the 1.77 MeV incident neutrons. Using the statistical theory they calculated the transmission coefficients by the optical model7) to fit their results, and obtained 0.2 for the absorption coefficient for the case of a square well potential. This result is nearly equivalent to that reduced from the continuum theory, and this figure is not consistent with the value determined from the total and elastic scattering cross sections. Cranberg and Levin3) and Muehlhause et al4) measured also the angular distributions of gamma ray from iron for the neutrons of 2.45 and 1.66 MeV respectively. According to our calculation8) which is shown in Appendix, the diffuse potential fits satisfactorily to their results with the values of parameters determined by Beyster et al9), while it could not interprete the Van Loef and Lind's experiment6).

This paper presents the study on the gamma rays from the ring scatterers of Mg, Al, Fe and Bi bombarded by neutrons of energy of 2.85 to 3.00 MeV, and particularly the measurement of angular distributions for the 0.845 MeV gamma ray from Fe^{56} and for the 1.37 MeV gamma-ray from Mg^{24}. By comparing the cross sections and the angular distributions with our calculation using the Hauser and Feshbach's and Satchler's formulas10) respectively, we aimed to determine the most appropriate model and its nuclear parameters for both nuclei.

§ 2. Experimental Procedure and Correction

We used the D–D neutrons produced by a 200 kV Cockcroft-Walton accelerator. Their energies were 2.85 ± 0.10, 2.90 ± 0.10, 2.95 ± 0.10 and 3.00 ± 0.10 MeV. The scatterers used were of doughnut type with the outer diameter of 13 cm and the inner diameter of 7 cm and their diameter of the cross section was 3 cm. They were made of iron, magnesium, aluminum and bismuth all with purity of 99.9%. A carbon ring was used for making correction of the effect of elastically scattered neutrons from the scatterer.

We used a gamma ray spectrometer with a NaI(Tl) scintillator (1″φ×1″) mounted on a Du Monte 6292 photomultiplier with a magnetic shield of mu-metal. Pulses from the photomultiplier were amplified by an A-1 amplifier and analyzed by a single channel pulse height analyzer of Johonstone type or a Gray-Wedge analyzer. Neutron flux was monitored by a calibrated scintillation counter with a stilbene crystal (1″φ×½″).

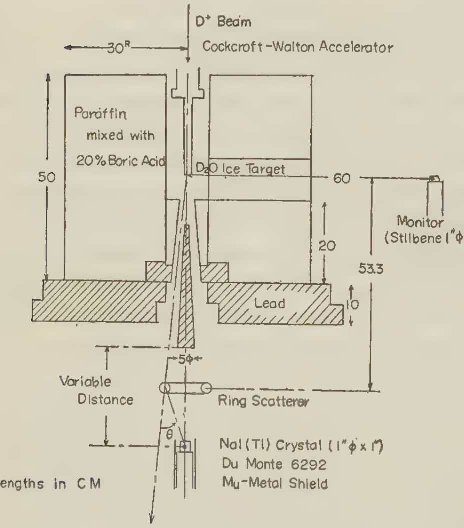

Fig. 1. Experimental arrangement.

The experimental arrangement is shown in Fig. 1. The detector was set at different positions on the central axis of the scatterer for the measurement of the angular distribution of gamma rays. The numerical calculation of the angular resolution of our geometry gave about ±7° at the 90° position, which was the worst case.

The background counting was due to stray neutrons and gamma rays incident on the crystal. The neutrons gave rise to the $I^{127}(n, n')I^{127*}(\gamma)$ and $I^{127}(n, \gamma)I^{128}(\beta)$ reactions which contributed considerably to the background. In order to keep the background from the room wall at a low level, the incident neutrons were canalized by a block of paraffin mixed with 20% boric acid. For example at the 90° position, this shielding reduced the stray neutrons of 1–2.5 MeV to about 4% of the direct neutrons, while this figure was about 9% without the shielding, and the ratio of the counts of the 0.845 MeV gamma ray from the $Fe^{56}(n, n')Fe^{56*}$ reaction to the background counts was increased from 2 to 5 at the 90° position. The background counts due to induced activity in the crystal, mostly attributed to I^{128} with the half-life of 25 minutes, were measured for 4 minutes after every neutron exposure of 4 minutes. The induced background amounted about 15% of the total background. We stopped continuous repetition of measurements before the induced background increased to 40% of the total background.

The net counts N due to the gamma ray for each angle is calculated as

$$N = N_s - C(N_d - N_n) - N_n ,$$

where N_s, N_d and N_n are the counting rates respectively with the sample scatterer, with the dummy scatterer (carbon for the iron sample and aluminum for the magnesium sample) and without the scatterer; the induced background counts have been subtracted from N_s, N_d and N_n. C is the correction factor for the difference of the number of atoms and cross sections of neutron scattering by the dummy and the scatterer. For the determination of the differential cross section of inelastic scattering $\sigma(\theta)$, we took into account the following three factors: multiple scattering of the incident neutrons, absorption of gamma rays in the scatterer, and detection efficiency of the crystal detector.

We assumed that the directional deviation of incident neutron, which might be caused by multiple scattering, is negligiblly small because of great probability of the forward elastic scattering. $\sigma(\theta)$ can be calculated from the equation:

$$N = \sum_j N_j = \sum_j \sum_i Q_i \exp(-\mu_1 l_{ij})\, dV_i n \sigma(\theta_0 + \Delta\theta_{ij}) \frac{\eta_j}{4\pi r_{ij}^2} \exp(-\mu_2 l_{ji}')\, dV_j , \qquad (1)$$

where N_j is the counts given in an elementary volume dV_j in the crystal, η_j the detection efficiency per unit volume for the gamma rays incident on dV_j, Q_i the neutron flux at an elementary volume dV_i in the scatterer which contains n nuclei per unit volume, r_{ij} the distance between dV_i and dV_j, θ_0 the angle between the direction of the incident neutron and the line from the geometrical center of the scatterer to the effective center of the crystal, $\theta_0+\Delta\theta_{ij}$ the angle between the directions of r_{ij} and the incident neutrons, and l_{ij} and μ_1 are the path length and absorption coefficient of the gamma ray in the scatterer and l_{ji}' and μ_2 are the corresponding quantities in the crystal. Day[11] calculated Eq. (1) numerically by using an Analogue Computer. We used the following method of approximation:

Expanding $\sigma(\theta_0+\Delta\theta_{ij})$ at the point θ_0 we get from Eq. (1)

$$N\propto\sigma(\theta_0)\left\langle\frac{Q_i\exp(-\mu_1 l_{ij}-\mu_2 l_{ji}')\eta_j}{4\pi r_{ij}^2}\right\rangle_{AV}+\sigma'(\theta_0)\left\langle\frac{\Delta\theta_{ij}Q_i\exp(-\mu_1 l_{ij}-\mu_2 l_{ji}')\eta_j}{4\pi r_{ij}^2}\right\rangle_{AV}+\cdots. \tag{2}$$

Then we rewrite

$$\left\langle\frac{Q_i\exp(-\mu_1 l_{ij}-\mu_2 l_{ji}')\eta_j}{4\pi r_{ij}^2}\right\rangle_{AV}\equiv\gamma(\theta_0)\left\langle\frac{\exp(-\mu_2 l_{ji}')\eta_j}{4\pi r_{ij}^2}\right\rangle_{AV}. \tag{3}$$

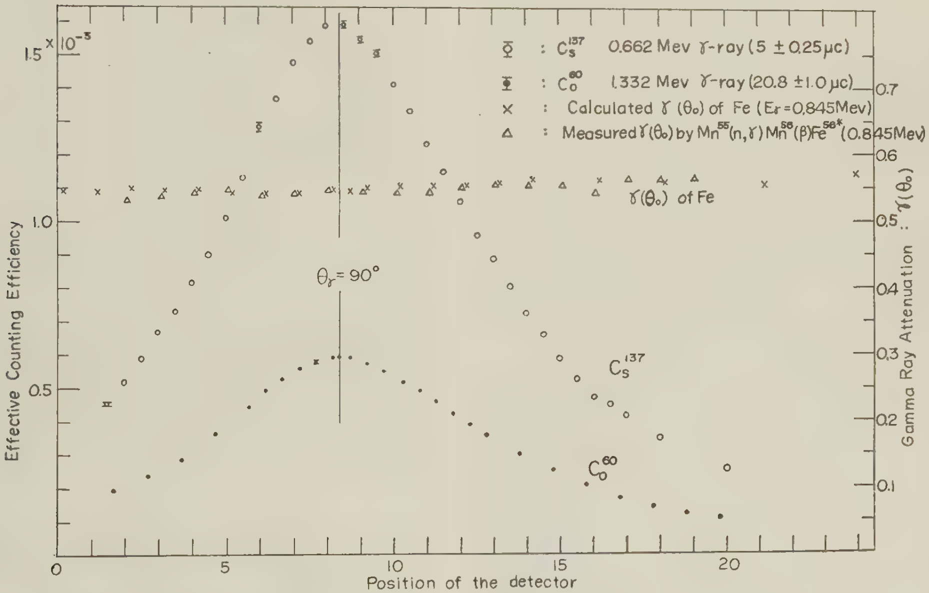

Fig. 2. Variation of the effective counting efficiency for the gamma rays of 0.662 MeV (Cs^{137}) and 1.332 MeV (Co^{60}) with the positions of NaI(Tl) crystal, and the gamma ray attenuation in the doughnut ring of iron: $\gamma(\theta_0)$.

The factor $\left\langle\frac{\exp(-\mu_2 l_{ji}')\eta_j}{4\pi r_{ij}^2}\right\rangle_{AV}$ means the effective counting efficiency of the detector system. We determined this value experimentally by using a dummy source of Cs^{137} ($5\pm0.25\,\mu c$) or Co^{60} ($20.8\pm1.0\,\mu c$) which was contained in a polyethylene container with the same size as the scatterer. The experimental results are shown in Fig. 2. The effective center of the crystal was also determined from these curves. The factor $\gamma(\theta_0)$ is a function of $Q_1, Q_2, \cdots$ beside θ_0 and means correction for the attenuations of the gamma ray by self-absorption and of the incident neutrons in the scatterer. This factor would be expected to be nearly constant against θ_0 for the case of uniform value of Q_i, because of circular cross section of the scatterer, but in general $\gamma(\theta_0)$ is larger for backward angles than forward on account of flux attenuation of the incident neutrons. In order to estimate variation of $\gamma(\theta_0)$ with θ_0, and to make use of the value for calculation of the differential cross section, we calculated numerically $\gamma(\theta_0)$ by the following approximated formula:

$$\left\langle\frac{Q_i\exp(-\mu_1 l_{i0})}{r_{i0}^2}\right\rangle_{AV}\Big/1/r_0^2\,, \tag{4}$$

where r_0 is the distance between the geometrical center of the cross section of the scatterer and the effective center of the crystal. We calculated the formula (4) for the following three cases of Q_i. For the first case, the neutron flux was assumed to be constant throughout the scatterer[11]; this means no attenuation of the incident neutrons. As seen in Fig. 2, the value obtained was independent of θ_0 within the error of the calculation. For the second case, the neutron flux decreased by the total cross section of neutron[6] along its incident direction; this means complete neglect of multiple scattering. The variation of $\gamma(\theta_0)$ with the angle θ_0 was, for example, $+9\%$ for 140° and -9% for 40° relative to the 90° value. The above assumptions might be the two extreme cases. For the third case, the calculation was made for the assumption that the neutron flux decreased only by the inelastic scattering cross section, giving the result that the variation of $\gamma(\theta_0)$ was $\pm 4\%$ for the both angles mentioned above relative to the 90° value. For the determination of the cross section we took the third case.

In order to test the reliability of the calculated values of $\gamma(\theta_0)$, we activated uniformly by thermal neutrons a ring of iron alloy containing 30% manganese with the same size as the scatterer. The division of the count of the 0.845 Mev gamma ray from the $Mn^{55}(n, \gamma)Mn^{56}(\beta)Fe^{56*}$ reaction by the count for the dummy gamma ray source gave $\gamma(\theta_0)$ for the first case according to the formula (4). The result is presented in Fig. 2, being normalized to the calculated value at 90°, and is in good agreement with the calculation within 3%. This implies that the approximation under which the formula (4) was derived was satisfactorily accurate for uniform Q_i. For the case of ununiform Q_i, the formula (4) may be used also as a good approximation since $\partial\gamma(\theta_0)/\partial Q_i$ is nearly equal to the differential coefficient of formula (4) with regard to Q_i.

We evaluated also the second term of Eq. (2) in the same way. The contribution to N was only $\pm 0.7\%$ which could be neglected.

In order to estimate the neutron energies and their widths, we measured the differential cross sections and the excitation curve for the elastically scattered neutrons by carbon by using a plastic phosphor ($1''\phi \times 1''$) as a neutron detector in the same geometry. The differential cross sections of carbon are given in Fig. 3, together with the exprimental data of Meier et al[12] and Budde and Huber[13]. It is seen that the large anisotropy due to $D_{3/2}$ resonance of C^{13} at the 2.95 MeV neutron energy is fairly smoothed out in our experiment. This was considered as due to the large energy width of the neutrons ($\Delta E_n \simeq$ 0.10 MeV) and not due to poor angular resolution of the detector. The symmetrical distribution about 90°, together with the manganese test, shows that our experimental arrangement was competent to measure the angular distribution.

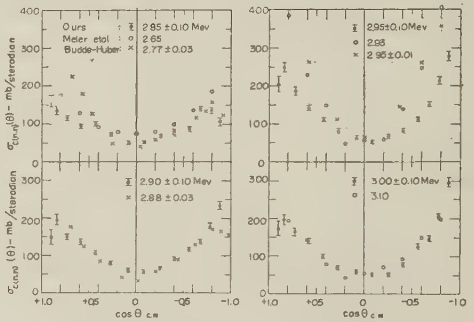

Fig. 3. Differential cross sections of the elastically scattered neutrons by carbon at the 2.85, 2.90, 2.95 and 3.00 MeV neutron energies (full circles). The open circles show the results obtained by Meier et al and the crosses show that by Budde and Huber.

§ 3. Results and Discussion

(1) The inelastic cross section of Mg, Al, Fe and Bi:

Figs. 4, 5, 6 and 7 show the typical pulse height distributions of the gamma rays from inelastic scattering and the detector background. The energy of gamma rays ranged from about 0.5 MeV to 2.2 MeV except for background gamma rays. As we used a small NaI(Tl) crystal to have a good angular resolution, we could not detect gamma rays of higher energies. The results are shown in Table I. The gamma rays from the scatterer and the background are in good agreement in energy with those found by other authors[2), 6),11),14),15),16] except a few points. In the background, several peaks which were not in other authors' results are found. According to Kiehn and Goodman[2], the third excited state of Fe^{56} was 2.25 MeV, but Poppema et al[17] and Morgan[14] assigned it to 2.65 MeV.

The present authors' result agreed with the latter's. This is due to the fact that Kiehn and Goodman might have missed the 1.81 MeV gamma ray resulting from the transition between the third and the first levels. Although Shapiro and Higgs[16] assigned a 2.07 MeV gamma ray to the transition from the second level to the ground state of Fe^{56}, our result indicated that it might come from the transition from the fourth level to the first. For Al^{27}, Morgan has found two gamma rays of 1.45 MeV and 1.75 MeV corresponding to the transitions from the third level to the first and from the fourth level to the second. These gamma rays were missing in our experiment, probably because of being masked by the background.

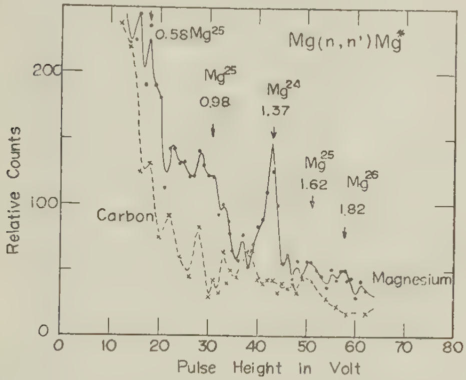

Fig. 4. The pulse height distributions of the gamma rays from magnesium and the background due to a carbon ring at the 2.95 MeV neutron energy. Channel width=1 Volt.

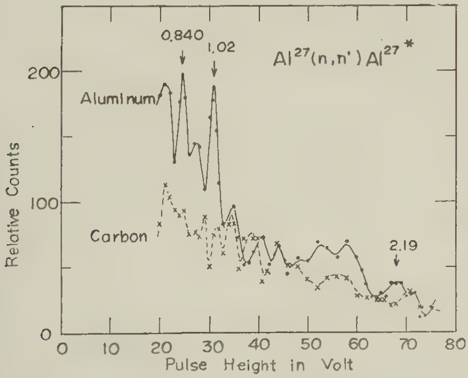

Fig. 5. The pulse height distributions of the gamma rays from aluminum and the background due to a carbon ring at the 2.95 MeV neutron energy. Channel width=1 Volt.

The differential cross sections at 90° for the 2.95±0.10 MeV neutrons were measured only for the cases in which the associated gamma rays had distinct photopeaks. The result is included in Table I. By measuring the angular distributions of the 0.845 MeV gamma ray of Fe^{56} and the 1.37 MeV gamma ray of Mg^{24}, we found the inelastic scattering cross sections $\sigma_{(n,n')}$; $\sigma_{Fe^{56}(n,n')}$ were 1.14±0.13, 1.19±0.14, 1.10±0.13 and 1.06±0.12 in barns at E_n=2.85±0.10, 2.90±0.10, 2.95±0.10 and 3.00±0.10 in MeV respectively, and $\sigma_{Mg^{24}(n,n')}$ was 0.66±0.10 barn at E_n=2.95±0.10 MeV. The errors were computed from the uncertainties of the neutron flux (±9%), of the effective counting efficiency (±5%), of the calculation of $\gamma(\theta_0)$ (±2%), and finally of the geometrical setting, the statistical errors of the counting rate and the fluctuation of the electrical instruments (the last three total

±3%).

We compared our experimental values of the inelastic scattering cross section for Fe^{56} and Mg^{24} with our calculated values[8)] based on the Hauser and Feshbach theory. The calculation was made on the four assumptions listed in Table II. The calculated values of $\sigma_{Fe^{56}(n,n')}$ were 0.803 barn for assumption (I), 0.468 barn for (II), 0.466 barn for (III) and 1.176 barn for (IV) at $E_n=2.90$ MeV and those of $\sigma_{Mg^{24}(n,n')}$ were 0.768 barn for (I) and 0.700 barn for (IV) at $E_n=2.95$ MeV. The comparison of the experimental data with the calculated values shows that our results could be interpreted fairly well by a diffuse potential well with the parameters which were derived from the experiment of Beyster et al.[19)]

the differential cross section of the gamma rays of 0.845 MeV from Fe^{56} and 1.37 MeV from Mg^{24} respectively, being normalized to the values at 90° for the 2.95 MeV neutrons. The points refer to the experimental results and the curves to the theoretical values. The corrections which we mentioned before have been applied to these data. The angular distributions are symmetric around 90° and are in the best agreement with the theoretical calculation on the assumption of the diffuse potential well. Our calculation showed that the same conclusion was drawn with the other experimental data of iron which have been published already by Muehlhause et al[4)] using the 1.66 MeV neutrons and by Cranberg and Levin[3)] using the 2.45 MeV neutrons.

If the assumption of the statistical model is not satisfied, we could expect an asymmetry around 90° by using a neutron beam with the narrow energy width. However, it might be due to the broadness of energy of neutrons that our experiment failed to find any significant change in the angular distribution by using the neutrons of energy from 2.85 MeV to 3.00 MeV, if this existed any.

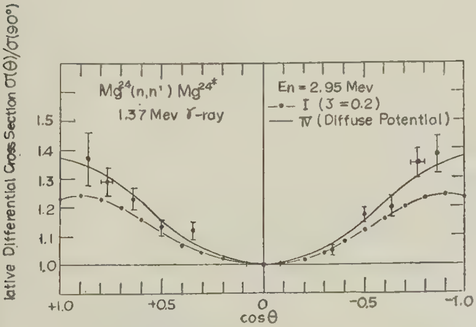

Fig. 9. Angular distribution of the 1.37 MeV gamma ray from the inelastic scattering of magnesium at the 2.95 MeV neutron energy. The full and dashed curves are the theoretical angular distributions calculated using a diffuse potential (Assumption IV) and a square well potential (Assumption I, $\zeta=0.2$).

Acknowledgements

The authors wish to express their great gratitude to Professor E. Tajima and Assistant Professors I. Ogawa and M. Hattori for their encouragement and many useful discussions. Also they wish to thank Assistant Professor M. Tsukuda for the electric equipment and Mr. T. Sasaki of Tokai Electrode Ltd. for his offer of pure carbon rings. They are grateful to Mr. T. Hamada of Scientific Research Institute who offered them calibrated liquid Cs^{137} and Co^{60} gamma ray sources.

This study was supported in part by the Scientific Research Expenditure of the Ministry of Education.

Appendix

Here are appended the outline of the theoretical calculation which we quoted in this text[8)].

We calculated numerically (1) the Hauser and Feshbach's formula of the inelastic scattering cross section of neutrons and (2) the modified Satchler's formula of the angular distribution of the gamma ray resulting from the inelastic scattering of the even-even nuclei for the four assumptions about the transmission coefficients $T_l(E)$ and the other nuclear parameters which are shown in Table II in the text.

In this calculation, we assumed the orbital angular momenta l_0 (incidental) and l_i (scattered) less than 3 for the cross section and less than 2 for the angular distribution on account of avoiding complexity. For the case of Fe^{56}, we took into consideration the contribution of the 2nd and 3rd excited states in our calculation. We used the level scheme of Fe^{56} which was assigned by Poppema et al.[17] For Mg^{24}, there are no contribution from the 2nd and higher excited states for the energy region used in this experiment.

The following are the statistically averaged scattering matrix, according to Satchler[10],

$$\begin{aligned}&\langle S(J;\, j_i l_i;\, j_0 l_0) S^*(J';\, j_i' l_i';\, j_0' l_0')\rangle_{AV}\\&\quad = S(J;\, j_i l_i;\, j_0 l_0) S^*(J;\, j_i' l_i';\, j_0' l_0')\delta(JJ')\delta(l_i l_i')\delta(l_0 l_0')\\&\quad \simeq \frac{T_l(E)T_{l_i}'(E_i)}{\Sigma \varepsilon_{l'}{}^J T_l'(E_q)}\delta(JJ')\delta(l_i l_i')\delta(l_0 l_0')\,,\end{aligned} \tag{5}$$

where J is the nuclear spin of the compound nucleus, $j = l \pm \frac{1}{2}$, $\varepsilon_{l'}{}^J$ is the factor defined by Hauser and Feshbach, and summation Σ extends over all channels (l', E_q) through J. We denoted the energy of neutron scattered leaving the nucleus to the i-th level as E_i.

The differential cross section is given by

$$\frac{d\sigma(\theta)}{d\omega} = \frac{\lambda^2}{4(2J_0+1)(2s+1)} W(\theta, \varphi)\,, \tag{6}$$

where s is the spin of incident neutron, J_0 is the ground state spin of target nucleus, and $W(\theta, \varphi)$ is the angular distribution function between the associate gamma ray and the incident neutron. Neglecting the contribution of channels higher than the 4th excited state and the effect of interferences between channels, $W(\theta)$ can be written as follows,

$$W(\theta) = \frac{1}{2\pi}\int_0^{2\pi} W(\theta, \varphi)\, d\varphi = W(\theta)_{1st} + W(\theta)_{2nd} + W(\theta)_{3rd}\,. \tag{7}$$

(a) Contribution of the channel through the 1st excited state (2^+):

$$\begin{aligned}W(\theta)_{1st} = 2\Bigg[&\frac{2T_0(E)T_2'(E_1)}{T_0(E)+2T_2'(E_1)+2T_2'(E_3)} + \frac{T_1(E)T_1'(E_1)}{T_1(E)+T_1'(E_1)+T_1'(E_3)}\\&+\frac{T_1(E)T_1'(E_1)}{T_1(E)+2T_1'(E_1)+2T_1'(E_3)}\{4+P_2(\cos\theta)\} + \frac{T_2(E)T_0'(E_1)}{A}\{2+P_2(\cos\theta)\}\\&+\frac{T_2(E)T_0'(E_1)}{B}\{3+1.711P_2(\cos\theta)-1.713P_4(\cos\theta)\}\\&+\frac{T_2(E)T_2'(E_1)}{A}\{4-0.7148P_2(\cos\theta)\}+\frac{T_2(E)T_2'(E_1)}{B}\{6+0.8598P_4(\cos\theta)\}\Bigg]\,,\end{aligned} \tag{8}$$

where

$$A = T_2(E)+T_0'(E_1)+2T_2'(E_1)+T_2'(E_2)+T_0'(E_3)+2T_2'(E_3)$$

and

$$B = T_2(E)+T_0'(E_1)+2T_2'(E_1)+2T_2'(E_2)+T_0'(E_3)+2T_2'(E_3)\,.$$

(b) Contribution of the channel through the 2nd excited state (4^+):

$$W(\theta)_{2nd} = 2\left[\frac{T_2(E)T_2'(E_2)}{A}\{2+0.5612P_2(\cos\theta)\} + \frac{T_2(E)T_2'(E_2)}{B}\{6+2.436P_2(\cos\theta)\}\right]. \tag{9}$$

(c) Contribution of the channel through the 3rd excited state (2^+):

$$W(\theta)_{3rd} = \{\text{Eq. (8) with permutation of } E_1 \text{ and } E_3\}\,. \tag{10}$$

The Satchler's formula[10] is a special case of Eq. (7).

Angular Distributions of the Reaction $F^{19}(p, \alpha)O^{16}$ at 8.0~14.2 Mev*

By Hiroshi OGATA

Department of Nuclear Science, Faculty of Science, Kyoto University

(Received February 16, 1959)

The alpha particles from the reaction $F^{19}(p, \alpha)O^{16}$ resulting in the ground state of O^{16} have been measured, making use of a proportional counter method.

The excitation curve has been measured at a laboratory angle of 50° from 12.9 to 14.1 Mev. The curve changes smoothly with incident proton energy. The angular distributions of the alpha particles have been measured at 14.2, 13.5, 13.0, 12.0, 11.0, 10.0, 9.0, and 8.0 Mev, which can be qualitatively explained by the simple triton pickup theory. Although fairly good agreements with the theory can be seen at 14.2, 13.5 and 9.0 Mev, the angular distributions for the other energies deviate from the theory to some extent. The deviation is generally larger for backward angles and especially at 11.0 and 8.0 Mev striking backward peaks are observed. It is considered that for detailed explanation of the results, refinement of the theory or introduction of other processes of the reaction or both are required.

§ 1. Introduction

It is considered that most of the nuclear reactions which are induced by high energy particles and result in a low-lying level of the final nucleus are predominantly direct reactions. One good example of such a reaction is the well known deuteron stripping or pick-up reaction, for which Butler's stripping theory[1] has been proved to be very useful. Also it is expected that the reactions such as (n, p), (p, p'), (p, α), (α, α'), etc. can be treated in a similar way and show stripping-like angular distributions.

---

* Experiments were performed using the 160 cm cyclotron at the Institute for Nuclear Study, Univ. of Tokyo.

For (p, α) reactions resulting in the low-lying levels of the final nucleus at about 10 or 20 Mev measurements have been reported by several authors. Maxson and Terrell[2)] and Fischer *et al.*[3)] have observed the reaction $C^{12}(p, \alpha)B^9$ at 15.6 and 18.6 Mev and the reaction $Al^{27}(p, \alpha)Mg^{24}$ at about 11 Mev, respectively, and found that the ground state angular distributions for these reactions can be qualitatively fitted by curves obtained from the triton pickup or exchange theories. By Brady[4)] and by Fulmer and Cohen,[5)] (p, α) reactions have been studied for Rh at 18 Mev and for many targets at 23 Mev, respectively. They have reported that the high energy parts of the spectra, which correspond to low-lying levels of the final nuclei, are strongly forward directed and indicate that they are produced by direct interaction reactions.

For the reaction $F^{19}(p, \alpha)O^{16}$ resulting in the ground state of O^{16}, triton pickup behavior is expected to occur because of the structure of F^{19} which has a proton and two neutrons outside the closed O^{16} core. Likely and Brady[6)] have measured the differential cross sections for the reaction $F^{19}(p, \alpha)O^{16}$ resulting in the ground state of O^{16} at 18.5 and 16.0 Mev. It has been shown that the angular distributions can be fitted approximately by the Born approximation for triton pickup. Their measurements have been performed only at 18.5 and 16.0 Mev for rather forward angles up to 120° and 100°, respectively. It is interesting to observe the behaviors of the angular distributions, extending the measurements to larger angles, and to see if these can be explained in terms of triton pickup, as the incident proton energy varies in a wide range in our case. In this paper it is intended to describe the results of the measurement of the reaction $F^{19}(p, \alpha)O^{16}$ at several energies between 8.0 and 14.2 Mev.

§ 2. Experimental Procedures

The angular distribution of the alpha particles emitted from the $F^{19}(p, \alpha)O^{16}$ reaction was measured in a 100 cm scattering chamber[7)] of the Institute for Nuclear Study, University of Tokyo.

Proton beam obtained from a variable energy 160 cm cyclotron[7)] at the Institute for Nuclear Study passes through two collimating apertures of 5.0 mm in diameter at distances 34.3 cm and 114.3 cm from the target, respectively, and several antiscattering apertures, and then is admitted to the scattering chamber. The beam spot in the center of the chamber was about 0.5 cm in diameter.

A teflon foil, 1.58 mg/cm², served as the target, which was placed at an angle of 45° to the incident beam.

As the detector of the alpha particles, a proportional counter method was employed. Equal energy losses of an alpha particle and a proton in a proportional counter produce pulses of approximately equal height, while for a scintillation counter the alpha particle gives much smaller pulse than the proton. Therefore, even in the present measurement of the reaction for which the emitted alpha particles to be detected have much higher energy than elastically scattered protons, if a conventional scintillation counter be employed, it is considered that the pulse height distributions cannot be free from the disturbances of these protons.

A proportional counter of a finite length can be employed to obtain energy spectra of alpha particles, making use of the difference in energy loss between protons and alpha particles. Now let us consider that an alpha particle or a proton enters into a proportional counter and stops just at the end of its sensitive volume. If the window and the insensitive volume of the counter have no significant effects, the energy ($E_{\alpha\,\max}$) of such an alpha particle is much larger than that of such a proton ($E_{p\,\max}$), which produces the maximum pulse among the protons entering the counter. If there are no alpha particles with so high energy that pass through the counter, one can obtain the energy distribution of the alpha particles with energies between $E_{\alpha\,\min}$ and $E_{\alpha\,\max}$, where $E_{\alpha\,\min}$ is the energy of the alpha particles which produce the same ionization in the sensitive volume of the counter as the protons having $E_{p\,\max}$ and is somewhat larger than $E_{p\,\max}$ owing to the effect of the counter part preceding the sensitive volume. Moreover, as compared with a detector of a practically infinite length such as a conventional scintillation counter the finite length proportional counter method enables one to diminish greatly the pile-up effect of the pulses due to the elastically scattered protons which are predominant at smaller angles. Naturally, these effects can be reduced considerably by using a scintillation counter with a thin crystal, but this is accompanied by a technical difficulty of making very thin crystals. Further with the proportional counter, an energy range of the alpha particle desired to be measured can be easily adjusted by changing the counter pressure.

In this experiment, a counter telescope which consists of two proportional counters as shown in Fig. 1 was used. The telescope was prepared to discriminate the low energy alpha particles from the protons, deuterons and high energy alpha particles by a method of anti-coincidence. For this purpose, the proportional counter has some advantage over the scintillation counter. In this experiment, however, the second proportional counter was not required to be used, because alpha particles to be detected are the most energetic particles among the particles emitted when teflon is bombarded with protons.

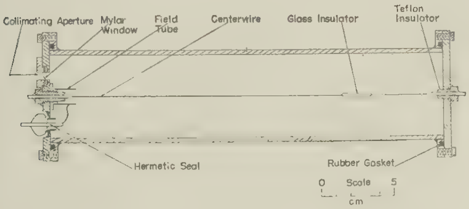

Fig. 1. Proportional counter telescope used for the detection of the alpha particles.

The telescope was mounted on the turn table of the scattering chamber together with the head amplifiers and could be placed at any angle with respect to the proton beam. The distance from the inner surface of the collimator to the target was 18.1 cm. The aperture of the collimator was 0.48 cm in diameter, and the solid angle subtended by the collimator at the target was calculated to be 5.52×10^{-4} steradian. The counter was filled with argon and 5% CO_2 at a pressure of 98 cm Hg. The field tube was prepared to define the sensitive volume of the counter by a plane perpendicular to the counter axis. The mylar window is 1.28 mg/cm² in thickness. The energy loss in the mylar window and the insensitive part of the counter is about 1.4 Mev for 15 Mev alpha particles.

When the incident proton energy is so high and the measurement is carried out at smaller angle, it takes place that the alpha particles pass through the counter volume and give smaller pulses, and pulses of less energetic alpha particles or protons become comparable with the desired ones. In order to be free from this disturbance, an Al absorber of about 50 μ in thickness was attached in front of the collimator for proton energies above 13.0 Mev at angles between 15° and 80°.

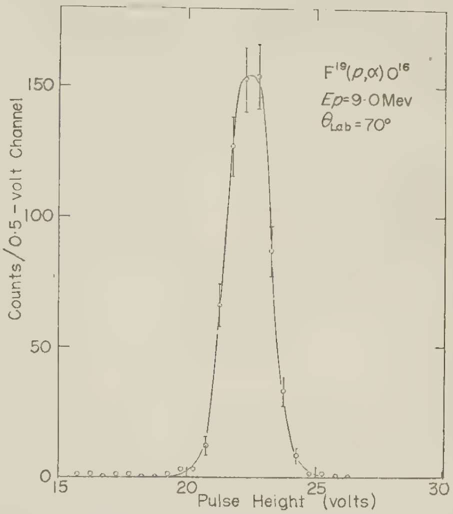

Fig. 2. Typical pules height distribution of alpha particles from the reaction $F^{19}(p, \alpha)O^{16}$ at a laboratory angle of 50° for 9.0 Mev protons.

Pulses from the first counter were amplified and fed into a 20-channel pulse height analyzer. Fig. 2 shows a typical pulse height distribution of alpha particles emitted from $F^{19}(p, \alpha)O^{16}$ resulting in the ground state of O^{15} at a laboratory angle of 70° for 9.0 Mev protons. Owing to the large Q-value of the reaction (+8.12 Mev[8)]) and the large level distance between the ground and first excited states of O^{16}(6.06 Mev[8)]), the background and the overlapping between the alpha particle groups are not observed in the energy spectrum.

After bombarding the target and passing through the scattering chamber, the beam was collected in a Faraday cup connected to a current integrator, which was used to determine the absolute cross sections.

To normalize the angular distributions a CsI scintillation counter was used as a monitor at 90° to the incident beam. The detector bias was chosen to count only the pulses due to the protons scattered elastically by carbon and fluorine in the teflon target and those scattered inelastically by carbon through the first excited state.

§ 3. Results and Discussions

The excitation curve for the reaction $F^{19}(p, \alpha)O^{16}$ resulting in the ground state of O^{16} was measured at a laboratory angle of 50°. The proton energy spread was estimated to be about 50 Kev. The result is shown in Fig. 3. It can be seen that the curve changes smoothly with incident proton energy.

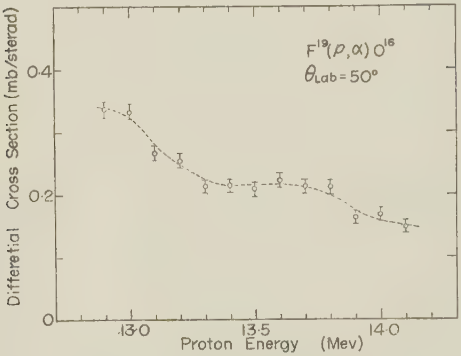

Fig. 3. Excitation curve for the reaction $F^{19}(p, \alpha)O^{16}$ resulting in the ground state at a laboratory angle of 50°.

The angular distributions of this reaction were measured at 14.2, 13.5, 13.0, 12.0, 11.0, 10.0, 9.0, and 8.0 Mev. These results are shown in Fig. 4.

The angular distribution changes gradually with incident proton energy, this can be expected by the smooth excitation curve. These angular distributions show undoubtedly evidence for a surface direct interaction and it is very difficult to explain these behaviors by compound nucleus process.

For the simplest explanation of these behaviors one can consider that the reaction occurs through the triton pickup process because F^{19} has a proton and two neutrons outside the closed O^{16} core. In the pickup process, the incident proton captures these nucleons which would be virtually separated from F^{19} as a triton with $l=0$, the only possible value consistent with the spins and parities of the triton $(1/2^+)$, $F^{19}(1/2^+)$, and $O^{16}(0^+)$.

According to the simple theory[9] of the triton pickup reaction the angular distribution

Fig. 4. Angular distributions of the reaction measured at 14.2, 13.5, 13.0, 12.0, 11.0, 10.0, 9.0, and 8.0 Mev. Dashed curves were calculated from the triton pickup theory.

of the reaction $F^{19}(p, \alpha)O^{16}$ can be expressed as follows:

$$\frac{d\sigma}{d\Omega} \propto \left[\frac{1}{Q^2+k^2} W\{j_0(Qr),\ h_0(i\kappa r)\}_{r_0}\right]^2, \quad (1)$$

where

$$Q=\left|\boldsymbol{k}_\alpha-\boldsymbol{k}_p \frac{m_f}{m_i}\right| \qquad (2)$$

is the characteristic momentum transfer, $\boldsymbol{k}_p$ and $\boldsymbol{k}_\alpha$ are relative momenta in units of $\hbar$ for the incident proton and the outgoing alpha particles respectively, m_i and m_f are masses of F^{19} and O^{16} respectively; κ is related to the triton binding energy $\mathcal{E}_t$ of F^{19} with the following expression:

$$\mathcal{E}_t=\left(\frac{\hbar^2}{2\mu}\right)\kappa^2, \qquad (3)$$

μ is the reduced mass of the triton and O^{16}; and

$$W\{j_0, h_0\}_{r_0} = \left\{ j_0 \frac{\partial h_0}{\partial r} - \frac{\partial j_0}{\partial r} h_0 \right\}_{r_0}, \qquad (4)$$

j_0 and h_0 being the spherical Bessel and Hankel functions of the first kind of order 0 respectively and r_0 the interaction radius between the triton and O^{16}.

The dashed curves in Fig. 4 were calculated from Eq. (1) for radii of 6.2, 6.2, 6.1, 6.5, 5.2, 5.0, 5.3, and 5.3×10^{-13} cm at the eight incident proton energies from 14.2 to 8.0Mev, respectively. These values of r_0 were chosen rather arbitrarilly to give the best agreement with the experimental results by visual fitting.

For all of the energies at which the angular distributions were measured, it can be seen that the general behaviors of the angular distributions can be reproduced by the triton pickup theory. At 14.2, 13.5, and 9.0 Mev, the angular distributions show fairly good agreement with the theory, but it is noticeable that difference exists between the interaction radii of 6.2×10^{-13} cm for 14.2 and 13.5 Mev and of 5.3×10^{-13} cm for 9.0 Mev. Likely and Brady⁶⁾ have shown that the angular distributions observed at 18.5 and 16.7 Mev are reproduced fairly well by the theoretical curves calculated from Eq. (1) for radii of 7.05 and 7.53×10^{-13} cm respectively, but the periods of oscillation of theoretical curves are too small. Considering the effect of nuclear interaction, they obtained $r_0=6.5\times10^{-13}$ cm for both energies semi-empirically by shifting the phase. Any of these values are not in agreement with the present results.

The angular distributions for the other energies deviate from the theory to some extent. The deviation is generally large for the backward angle, and especially at 11.0 and 8.0 Mev striking backward peaks are observed.

The simple expression (1) was calculated with the plane wave Born approximation assuming the triton-proton interaction of zero range, and neglecting the Coulomb effect, nuclear interactions between the incident and outgoing particles with the final nucleus, and any contribution from the region $r<r_0$. By refining the stripping theory, it is considered that better agreements with the experimental results may be obtained. As Likely and Brady carried out, the discrepancy in the interaction radii may be removed by considering the Coulomb effect¹⁰⁾ or nuclear interaction. Also the variation of the angular distribution with the incident energy may be explained by distorting the incident and outgoing waves.¹¹⁾

For the reaction $F^{19}(p, \alpha)O^{16}$, exchange or knockout process can be considered in analogous to that proposed by Austern *et al.*.¹²⁾ In this process, the incident proton scatters out the alpha particle from the target and is captured to form the final nucleus. The angular distribution from this exchange proceses is essentially expressed also by Eq. (1). In another process for the reaction, the incident proton is captured by the interaction with the core of the initial nucleus while the alpha particle is stripped off from the initial nucleus. This heavy particle stripping process gives the angular distribution having backward peaks for emitted alpha particles. Owen and Madansky¹³⁾ explained their $B^{11}(d, n)C^{12}$ angular distribution, which shows a large energy dependence, including the heavy particle stripping reactions. For the reaction $F^{19}(p, \alpha)O^{16}$, it is considered that the contribution from these processes other than the triton pickup process cannot be neglected. Indeed the backward peakings appeared in the 11.0 and 8.0 Mev results show possibly the evidence for considerable contribution of the heavy particle stripping process.

In conclusion, the simple triton pickup theory can explain the general features of the angular distributions of the present reaction. For detailed explanation of the results, however, refinement of the theory of the triton pickup reaction or introduction of other processes of the reaction or both are necessary.

Acknowledgements

The author wishes to express his sincere thanks to Professor K. Kimura, Professor S. Yasumi and Dr. I. Kumabe for their valuable suggestions, continual encouragements and many discussions. He is also indebted to the cyclotron crew of the Institute for Nuclear Study, University of Tokyo, for their kind hospitality and patient cooperation. His thanks are also due to Mr. C. L. Wang, Mr. M. Kawashima, and Mr. M. Yada for their cooperative efforts throughout this work.

Excitation Functions and Angular Distributions of the Reactions $Al^{27}(p, \alpha)Mg^{24}$ at 12.7~14.1 Mev and $Cr^{52}(p, \alpha)V^{49}$ at 9.0~14.2 Mev*

Kyoto University*

(Received February 16, 1959)

Making use of a proportional counter, alpha particles have been observed from the reactions $Al^{27}(p, \alpha)Mg^{24}$ resulting in the ground and first excited states of Mg^{24} and $Cr^{52}(p, \alpha)V^{49}$ resulting in the lowest three and a few higher states. Excitation curves have been measured at a laboratory angle of 50° with respect to the bombarding beam, from 12.7 to 14.1 Mev for $Al^{27}(p, \alpha)Mg^{24}$ and from 9.0 to 14.8 Mev for $Cr^{52}(p, \alpha)V^{49}$. The former shows a sharp energy dependence, while the latter shows a fairly smooth structure. Angular distributions have been measured at 14.1, 13.0 and 12.8 Mev for $Al^{27}(p, \alpha)Mg^{24}$ and at 14.2, 13.0, 12.0, 11.0, 10.0, 9.5 and 9.0 Mev for $Cr^{52}(p, \alpha)V^{49}$. Although the $Al^{27}(p, \alpha_0)Mg^{24}$ data can be partially fitted by $[j_2(Qr_0)]^2$ of Butler's theory, some angular distributions show strong backward peaking. Either interference between various direct interaction processes or between direct interaction and compound nuclear precesses, or both are responsible for this reaction. The approximate 90° symmetry of $Cr^{52}(p, \alpha)V^{49}$ angular distribution does not appear to be inconsistent with the statistical theory of nuclear reactions. However, the conspicuous forward peak at higher energies, especially at 14.2 Mev, is considered to indicate the increasing contribution of direct interaction processes.

§1. Introduction

The angular distributions of alpha particles resulting from the bombardment of various elements with high energy photons, especially when the incident proton energy varies in a wide region, are expected to be an important source of information regarding the basic mechanism of nuclear reactions. While the (n, α) reactions of medium weight nuclei at 14.8 Mev in our previous work[1] appeared to be in favor of the compound mechanism, it has been of interest to investigate the (p, α) reactions of these elements also as an analogous nuclear reaction in the same energy region.

---

* Experiments were performed using the 160 cm cyclotron of the Institute for Nuclear Study, Univ. of Tokyo.

For (p, α) reactions, measurements have been carried out by several workers. For a light element, Maxson and Terrell[2] have observed the reactions $C^{12}(p, \alpha)B^9$ resulting in the ground state and a level at 2.39 ± 0.08 Mev. It has been reported that $C^{12}(p, \alpha)B^9$ ground state angular distributions at 15.6 and 18.6 Mev are qualitatively in agreement with the triton pickup or Butler knockon theories. Likely and Brady[3] have measured the angular distributions of alpha particles from the reaction $F^{19}(p, \alpha)O^{16}$ at 18.5 and 16.0 Mev resulting in the ground state of O^{16}. They have found that the angular distribution shows three maxima, which can be fitted approximately by the Born approximation for triton pickup. Similar prominent characteristics of the direct interaction of the reaction $F^{19}(p, \alpha)O^{16}$ have also been reported at $8.0 \sim 14.2$ Mev proton energies in the preceding paper[4].

For a heavy element, Brady[5] has measured the angular distribution of alpha particles from the reaction $Rh^{103}(p, \alpha)Ru^{100}$. The particles "evaporating" with low energy show almost isotropic angular distributions. However, the angular distribution of fast particles resulting in the ground state of Ru^{100} is strongly forwark directed and is considered to be the product of direct interaction. By Fulmer and Cohen[6], the (p, α) reactions induced by 23 Mev protons in targets of a wide range of atomic number have been studied. They have reported that, for targets of atomic number $\lesssim 50$, the energy spectra and angular distributions indicate that most of the alpha particles are produced in compound nucleus reaction as observed by us for the (n, α) reactions, while the alpha particles from the heaviest elements and the high energy parts of the spectra from lighter targets are strongly forward peaked, indicating that they are produced by direct interaction reactions.

Fischer *et al.*[7] have reported an anomalous behavior of $Al^{27}(p, \alpha)Mg^{24}$ differential cross sections, in spite of the partial success of Butler's direct interaction theory in fitting the experimental $C^{12}(\alpha, p)N^{15}$ angular distributions. They have measured the angular distributions of the reactions $Al^{27}(p, \alpha)Mg^{24}$ resulting in the ground and the first excited states of Mg^{24} at about 11 Mev, as well as the excitation curves for these reactions in the energy region between 9.6 and 11 Mev. The sharp energy dependence of these excitation curves observed by them is entirely unexpected from the view-point of direct interaction theories. Their result suggests an additional interest in observing the same reaction in the higher energy region.

The reaction $Cr^{52}(p, \alpha)V^{49}$ has been of special interest, because the atomic weight of Cr is between those of Al and Rh, and these nuclei of intermediate mass are expected to give results which are more closely related to the result of the (n, α) reaction. It is also of interest to see how the angular distribution changes as the energy of the incident proton varies in a wide region.

In the present paper, the results of measurements on angular distributions as well as excitation curves of alpha particles from proton bombardment of Al and Cr are given.

§ 2. Experimental Arrangement and Procedure

Proton beam was obtained from a 160 cm variable energy cyclotron[8] at the Institute for Nuclear Study, University of Tokyo. The detector is a proportional counter filled with argon and 5% CO_2 at such pressures that the fast alpha particles from the individual (p, α) reaction lose their energy completely inside the sensitive volume of the counter. In this way, alpha particle groups were easily separated from proton and deuteron groups. Although no detailed calculation was made, the multiple Coulomb scattering in the mylar foil window and A–CO_2 gas is expected to have a a negligible effect on the proportional counter spectra. Since the general experimental method has been described in the preceding paper[4], we will mention only procedures which were peculiar to individual targets.

For the study of the reaction $Al^{27}(p, \alpha)Mg^{24}$, a foil of aluminum having a thickness of 0.68 mg/cm² was used as the target. In order to stop completely the alpha particles resulting in the ground state of Mg^{24}, the counter was filled with A–CO_2 up to 97 cm Hg.

For the reaction $Cr^{52}(p, \alpha)V^{49}$, the target used was a self-supporting foil of Cr metal having a thickness of 0.366 mg/cm², obtained by an electrolytic method. The proportional counter pressure was 98 cm, 52 cm, 28 cm and 22 cm Hg for 14.2 Mev, 13.0∼12.0 Mev, 11.0∼10.0 Mev, and 9.5∼9.0 Mev incident proton energies, respectively.

§ 3. Results and Discussion

(1) Case of $Al^{27}(p, \alpha)Mg^{24}$

A typical pulse height distribution of the alpha particles from the reaction $Al^{27}(p, \alpha)Mg^{24}$ measured at a laboratory angle of 60° for a proton energy of 14.1 Mev is shown in Fig. 1.

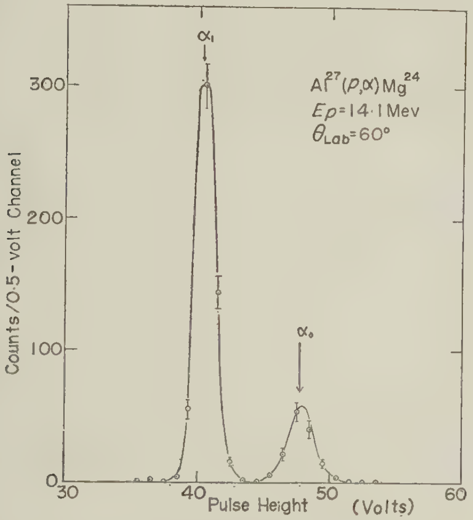

Fig. 1. Typical spectrum of alpha particles from the reactions $Al^{27}(p, \alpha)Mg^{24}$ resulting in the ground and first excited states of Mg^{24} at a laboratory angle of 60° for 14.1 Mev protons.

Two peaks appeared in Fig. 1 correspond to the reaction $Al^{27}(p, \alpha_0)Mg^{24}$ ($Q=+1.593$ Mev[9]) resulting in the ground state and the reaction $Al^{27}(p, \alpha_1)Mg^{24*}$ ($Q=+0.225$ Mev[9]) in the first excited state of Mg^{24}. The energy resolution is about 5%, and complete separation of these two peaks is obtained. Although the separation is slightly worse for larger angles and the analysis of the peaks should be imposed on the spectra, the ambiguity accompanied by this analysis is rather small. Background due to oxygen and carbon contamination and reactions other than (p, α) reactions, for instance (p, p') reaction, are expected to have no influence upon the spectra, considering the Q values ($Q=-5.204$ Mev for $O^{16}(p, \alpha)N^{13}$ and $Q=-7.559$ Mev for $C^{12}(p, \alpha)B^{9}$[10]) and the energy losses in the counter volume.

Fig. 2 shows the excitation curves at a laboratory angle of 50° for the reactions $Al^{27}(p, \alpha_0)Mg^{24}$ and $Al^{27}(p, \alpha_1)Mg^{24*}$. The dashed curves were obtained merely by connecting smoothly the data, so it must not be considered that these represent the true excitation curves. However, no doubt these data provide evidence for the sharp energy dependence of these differential cross sections in the energy region between 12.7 and 14.1 Mev.

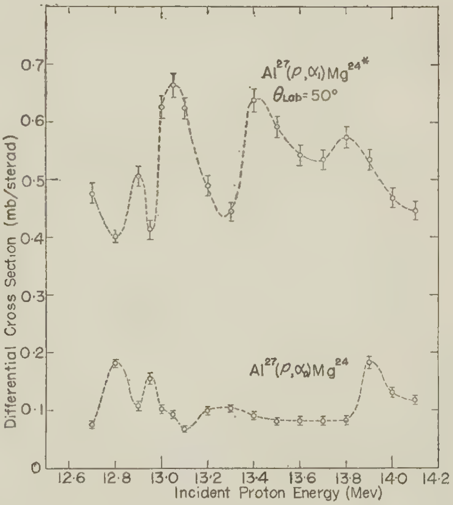

Fig. 2. Excitation functions for $Al^{27}(p, \alpha_0)Mg^{24}$ and $Al^{27}(p, \alpha_1)Mg^{24*}$ at a laboratory angle of 50°.

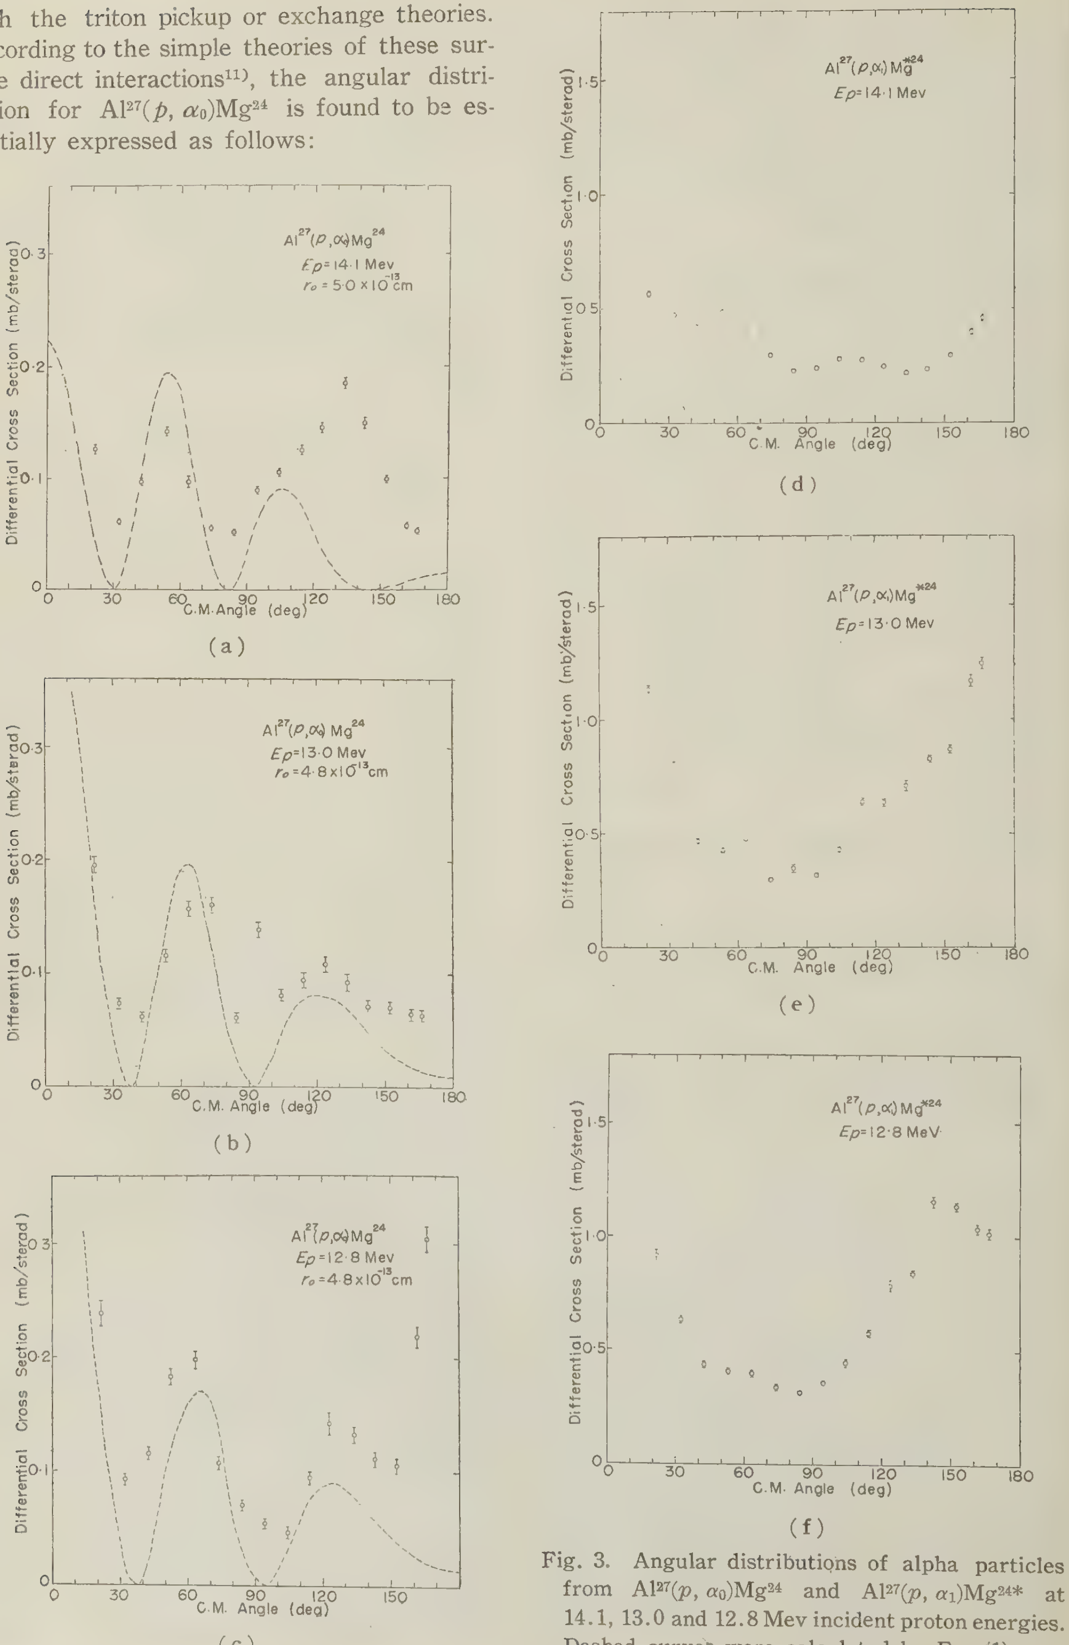
Fig. 3 shows the angular distributions of alpha particles from these reactions at 14.1, 13.0 and 12.8 Mev incident proton energy. Comparing the results at 12.8 and 13.0 Mev, where the excitation curves seem to show the sharpest energy dependence in the measured energy region, it should be remembered that a mere 200 Kev change in incident proton energy results in a remarkable change of the angular distribution for $Al^{27}(p, \alpha_0)Mg^{24}$, that is, the angular distribution shows a strong backward peaking at 12.8 Mev but a low backward tail at 13.0 Mev, while for $Al^{27}(p, \alpha)Mg^{24*}$ the angular distribution is not so much affected as for $Al^{27}(p, \alpha_0)Mg^{24}$ by this change of incident proton energy except for larger angles where an appreciable difference can be seen.

It is interesting to compare these results with the triton pickup or exchange theories. According to the simple theories of these surface direct interactions11), the angular distribulion for $Al^{27}(p, \alpha_0)Mg^{24}$ is found to be essentially expressed as follows:



(a)

(b)

(c)

(d)

(e)

(f)

Fig. 3. Angular distributions of alpha particles from $Al^{27}(p, \alpha_0)Mg^{24}$ and $Al^{27}(p, \alpha_1)Mg^{24*}$ at 14.1, 13.0 and 12.8 Mev incident proton energies. Dashed curves were calculated by Eq. (1).

$$\frac{d\sigma}{d\Omega} \propto [j_2(Qr_0)]^2 \,, \qquad (1)$$

where j_2 is the spherical Bessel function of order 2, and Q is the momentum transfer as obtained by following equation:

$$Q = \left| \boldsymbol{k}_p - \frac{M_i}{M_f} \boldsymbol{k}_\alpha \right| ,$$

where $\boldsymbol{k}_p$ and $\boldsymbol{k}_\alpha$ are the center of mass momenta in units of $\hbar$ of the incident protons and the emergent alpha particles, respectively, and M_i and M_f are the masses of Al^{27} and Mg^{24}, respectively, and r_0 is the interaction radius. The dashed curves in Fig. 3 were calculated from Eq. (1) for the reaction $Al^{27}(p, \alpha_0)Mg^{24}$. No theoretical curves from direct interaction theories can be expected to fit the angular distributions for $Al^{27}(p, \alpha_1)Mg^{24*}$, because of the absence of the characteristic maxima and minima in the experimental results.

As having been observed by Fischer *et al.* in the energy region between 9.6 and 11.0 Mev, the rapid change of angular distribution for $Al^{27}(p, \alpha_0)Mg^{24}$ with the incident energy, as well as the sharp energy dependent excitation curve for either reaction was observed. Also the angular distributions can be partially fitted by Eq. (1) with radii of 5.0, 4.8 and 4.8×10^{-13} cm at 14.1, 13.0 and 12.8 Mev, respectively. Fischer *et al.* have used a radius of 4.50×10^{-13} cm for a fit to their data. It must be noted that these values for the radius are not very different from one another. For $Al^{27}(p, \alpha_1)Mg^{24*}$ it is noteworthy that although for smaller angles the angular distribution does not seem to change so rapidly as for $Al^{27}(p, \alpha_0)Mg^{24}$, an appreciable difference can be seen between the angular distributions at 12.8 and 13.0 Mev for larger angles than 140° where measurements have not been performed by Fischer *et al.* at 10.87 and 10.97 Mev. By Kobayashi *et al.*12), very sharp energy dependence of the differential cross section has been observed also for the reaction $Ne^{22}(p, p')Ne^{22}$ resulting in the first excited state in the incident energy region between 8.6 and 9.7 Mev at laboratory angles of 45° and 60°.

The partial fit of the $Al^{27}(p, \alpha_0)Mg^{24}$ data by a curve of the general form $[j_2(Qr_0)]^2$ suggests that the surface direct interaction such as the triton pickup or exchange reaction plays an important role.

The observed sharp energy dependence cannot be explained by the simple theories of direct interaction which predict very slowly changing differential cross sections. Modification of the direct interaction theories,13),14) including the distorted wave treatments, would probably also not produce such a sharp energy dependence. Owen and Madansky15) have obtained good qualitative agreement with their angular distributions for $B^{11}(p, n)C^{12}$, which show a large energy dependence, extending the ordinary deuteron stripping theory to include the effect of heavy particle stripping. By an analogous treatment, the present results of the reaction $Al^{27}(p, \alpha)Mg^{24}$ may be explained. On the other hand, assuming that the reaction $Al^{27}(p, \alpha)Mg^{24}$ occurs through the compound nucleus formation, the sharp energy dependence cannot be expected from the statistical theory16), which is based on the assumptions that there are many levels of all types at the excitation energy of the compound nucleus (continuum assumption), and the corresponding wave functions have a random phase so that when phase averages are performed all interference terms will vanish (statistical assumption). Therefore the continuum or statistical assumption must not be satisfied. However, in this case, since the continuum assumption is probably satisfied, the statistical assumption might be considered to be violated. Then it is considered that either interference between various direct interaction processes or between direct inter-

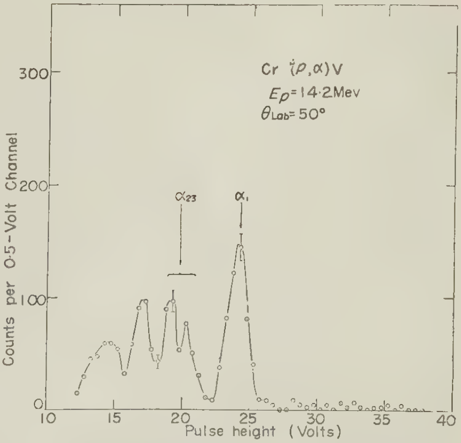


Fig. 4. Typical spectrum of alpha particles from the reaction $Cr(p, \alpha)V$ at a laboratory angle of 50° for 14.2 Mev protons.

action and compound nucleus processes, or both are responsible for the present reaction.

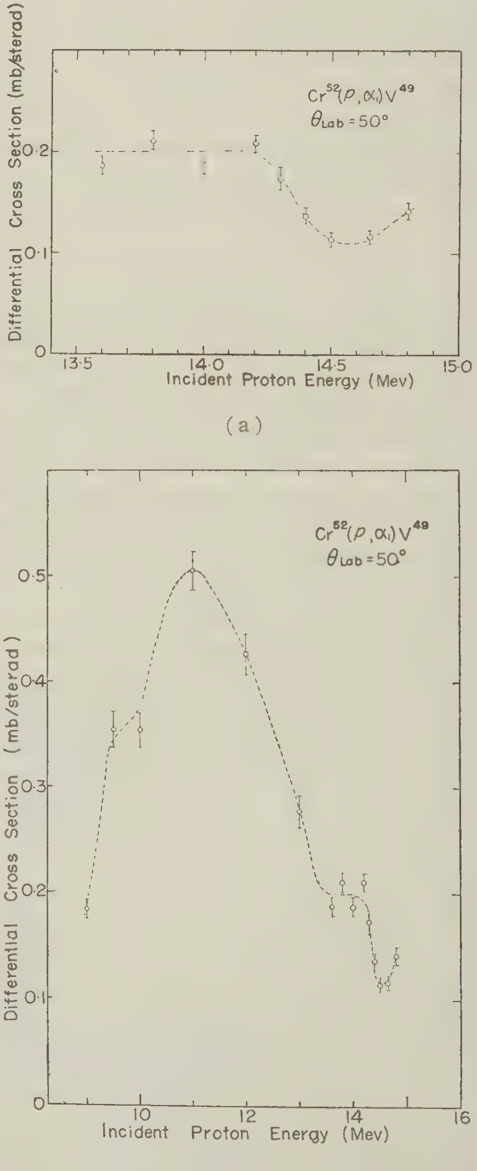
(2) Case of $Cr^{52}(p, \alpha)V^{49}$

In Fig. 4, a typical pulse height distribution of the alpha particles from the reaction $Cr(p, \alpha)V$, measured at a laboratory angle of 50° and 14.2 Mev proton energy is shown. Natural chromium has four stable isotopes of mass number 50, 52, 53 and 54 and their abundance ratios are 4.31, 83.75, 9.55 and 2.3%, respectively, among which Cr^{52} is the most abundant. Then the peaks appeared in Fig. 4 are probably responsible for the reaction $Cr^{52}(p, \alpha)V^{49}$. The level scheme of V^{49} remains almost unknown except the first three states, that is, ground, 0.08 Mev and 0.152 Mev states[17], which are very close to one another. From the energetics by comparing the pulse height of the present reaction with that of the reaction $Al^{27}(p, \alpha)Mg^{24}$, the first peak of the alpha particle spectrum is considered to correspond to the reactions resulting in these states of V^{49}, while it is not known to which levels of V^{49} the second or third peaks of the pulse height distribution refers. The small but discernible tail which appears at the high energy side of the first peak is probably attributed to alpha particles from the (p, α) reactions of Cr^{50}, Cr^{53} and Cr^{54}. Supposing that the (p, α) cross sections are of the same order for all Cr isotopes, the background of these isotopes is considered to have no significant effect on the spectra, since these isotopic abundance ratios are small as compared with Cr^{52}. Background due to carbon or oxygen contamination does not effect the measurement as in the case of Al, since the Q value of $Cr^{52}(p, \alpha)V^{49}$ is merely -2.59 Mev, which was calculated from mass data[18].

Fig. 5 shows the excitation curve at a laboratory angle of 50° for the first peak of the pulse height spectrum corresponding to the reaction $Cr^{52}(p, \alpha_1)V^{49}$ resulting in the first three states of V^{49}. Since no sharp energy dependence but smooth structure was observed in the energy region between 13.6 and 14.8 Mev, the angular distribution was measured at intervals of about 1 Mev for the proton energy.

Fig. 6 shows the angular distribution of this reaction at 14.2, 13.0, 12.0, 11.0, 10.0, 9.5 and 9.0 Mev proton energies. The angular distributions of alpha particles (α_{23}) responsible for the unsufficiently resolved second and third peaks of the pulse height spectrum, which correspond to the levels of V^{49} up to about 1 Mev excitation except the first three levels, was measured at 14.2, 13.0 and 12.0 Mev proton energies. These are also shown in Fig. 6.

In Fig. 6, it can be seen that, though a forward peak is discernible prominently at 14.2 Mev and slightly at 13.0 and 12.0 Mev, the angular distribution for the reaction $Cr^{52}(p, \alpha_1)V^{49}$ is nearly symmetrical about 90°



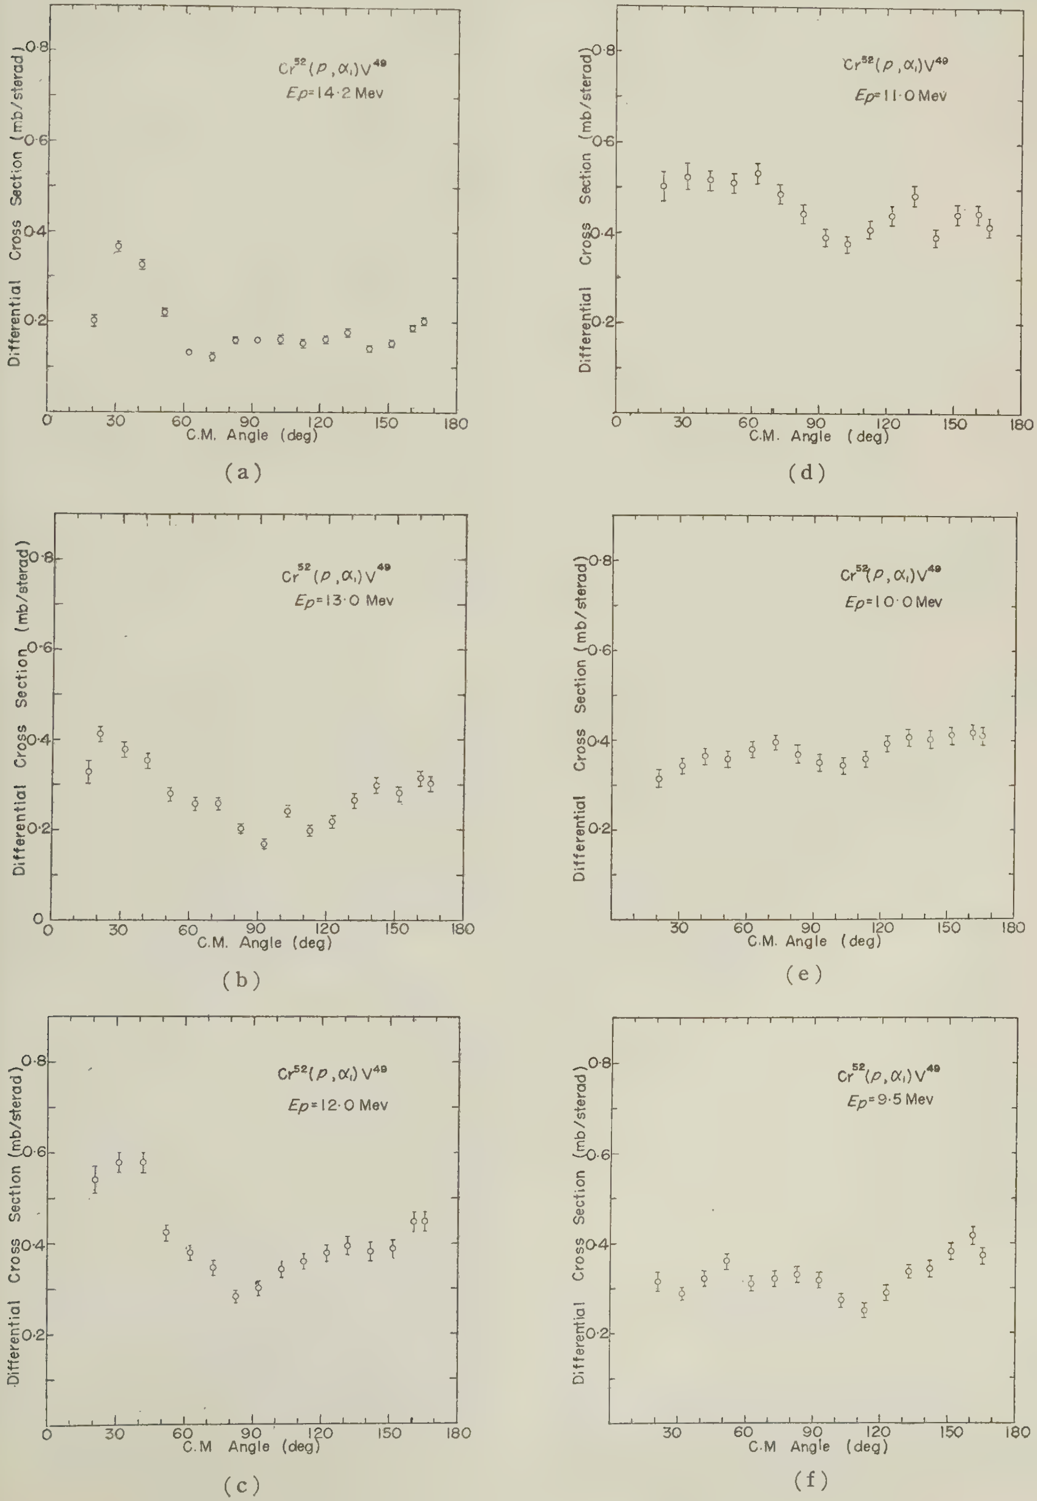
(a)

(b)

Fig. 5. Excitation function for $Cr^{52}(p, \alpha_1)V^{49}$ at a laboratory angle of 50°.

except at 14.2 Mev. Also for $Cr^{52}(p, \alpha_{23})V^{49}$, the angular distributions do not deviate appreciably from 90° symmetry.

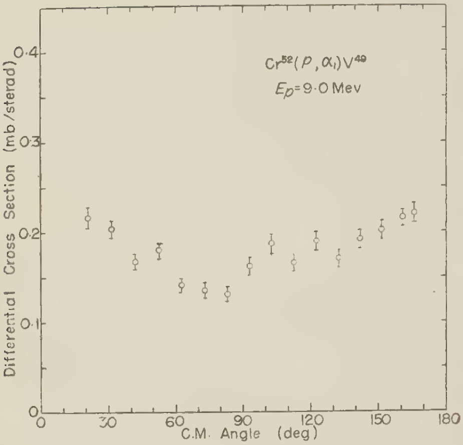
The approximate symmetry about 90° of the angular distribution is consistent with the prediction of the statistical theory of nuclear reactions[16], and suggests that most of the reactions occur through the compound nucleus



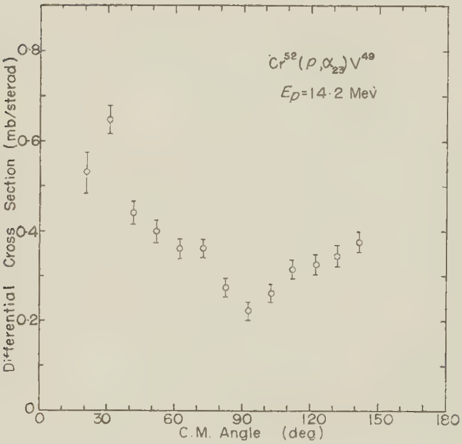
(a) (d)

(b) (e)

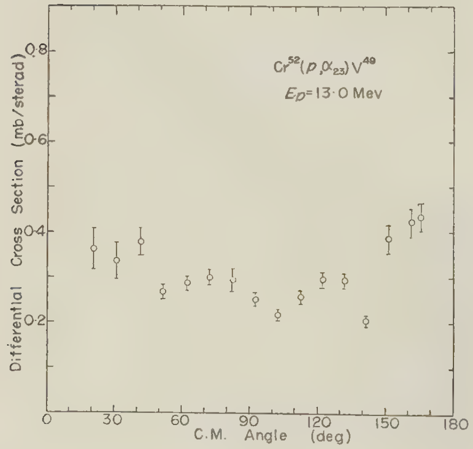
(c) (f)



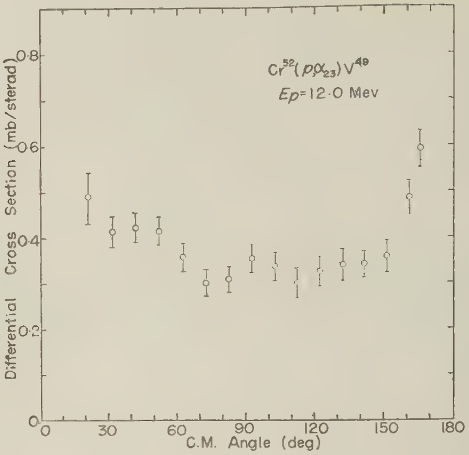
(g)



(h)



(i)



(j)

Fig. 6. Angular distributions of alpha particles from $Cr^{52}(p, \alpha_1)V^{49}$ at 14.2, 13.0, 12.0, 11.0, 10.0, 9.5, and 9.0 Mev proton energies and from $Cr^{52}(p, \alpha_{23})V^{49}$ at 14.2, 13.0 and 12.0 Mev proton energies.

formation. From the view-point of the compound nucleus theory, the cross section for the reaction to a particular state of the final nucleus varies with incident energy depending upon the number of the competing open channels, including that of other types of reactions such as (p, n) or (p, p') reaction, and upon the Coulomb barrier penetrability of the emergent particles. Therefore, the cross section is expected to reach its maximum value near the Coulomb barrier height for the emergent particles and to decrease with either increasing or decreasing incident energy from there. Indeed, for the reaction $Cr^{52}(p, \alpha_1)V^{49}$, we can see in Figs. 5 and 6 that the cross section can be seen to have its maximum at an incident energy of about 11.0 Mev which corresponds to an emergent alpha particle energy of 8.13 Mev, whereas the Coulomb barrier is 9.9 Mev for a radius of $1.5\times10^{-13}\,A^{1/3}$ cm. This behavior of the cross section is not inconsistent with the compound nucleus process for this reaction.

On the other hand, the forward peak discernible in the angular distribution for the reaction $Cr^{52}(p, \alpha_1)V^{49}$ above 12 Mev proton energy seems to suggest an appreciable contribution of direct interaction at these energies.

Fulmer and Cohen have measured the energy distribution of alpha particles from (p, α) reactions induced by 23 Mev protons at several angles in elements from Al to Au. It has been reported that for Ni, the nearest element to Cr among the elements measured by them, the high energy part of the spectrum is strongly forward peaked and suggests to be produced by direct interaction reactions.

It may be said that the reaction $Cr^{52}(p, \alpha_1)V^{49}$ occurs mostly through the compound nucleus formation at lower incident energies below 11 Mev and then the contribution from the direct interaction becomes significant gradually.

In conclusion, for the reactions $Al^{27}(p, \alpha)Mg^{24}$ and $Cr^{52}(p, \alpha)V^{49}$ resulting in the lower excited states of the final nuclei, the opposite aspects of the nuclear interactions, that is, the direct interaction and the compound process, are observed, which is considered to be due to the difference in the structures of the target. However, the behaviors of the emergent alpha particles are not explained merely by the simple theory of direct interaction or by the statistical theory of the nuclear reaction but it is considered that the various direct interactions and compound processes contribute in a complicated manner. It is hoped that further meassurements of (p, α) reactions for other elements will be carried out.

Acknowledgements

The authors wish to express their sincere thanks to Professor K. Kimura and Professor S. Yasumi for their valuable suggestions and continual encouragements throughout this work. Their thanks are also due to the cyclotron crew of the Institute for Nuclear Study, University of Tokyo, for their kind hospitality and patient cooperation.

On the Brownian Motion of a Classical Oscillator

By Morikazu Toda

Department of Physics, Tokyo University of Education

(Received March 6, 1959)

The Brownian motion of a classical harmonic oscillator is treated mechanically throughout. The oscillator is coupled with thermostat which is composed of a great number of harmonic oscillators. By use of a transformation which eliminates the coupling to the first order, the second order quantities like the friction force in obtained. Correlation of random force is also discussed.

§1. Introduction

Brownian motion is usually treated by the theory of stochastic processes[1], which has quite wide applicability providing us with one of the most beautiful and powerful methods in many problems. In this theory, however, we have to assume several hypothesis, e.g. the existence of the friction force and the nature and the correlation of random force. The friction force and the random force come from the same origin, namely the interaction with other part of the system. But they are introduced by separate assumptions and the relation between them is derived by use of *ad hoc* assumption that the system is to approach the state of thermal equilibrium if it is left undisturbed. And this kind of theory has no direct connection to the general theory of irreversible processes.

There were several attempts to formulate the theory of irreversible processes or of random processes on purely mechanical basis. Kirkwood[2] derived friction constant and the Fokker-Planck equation in classical mechanics. Zwanzig[3] wanted to have the Fokker-Planck equation in quantum mechanics. Callen and Welton[4] treated quantum mechanics of dissipative system. In these calculations, it was necessary, in principle, to solve the equation of motion for a suitable time interval, which must not be too small and not too large. Evolution of the system was then given by connecting the time intervals. Kubo[5] developed a method which deals with systems not far from equilibrium.

One of the aims of this paper is to get rid of and to clarify the nature of the stochastic theory. We start with a well defined system with definite interaction. We show that the interaction gives rise to friction and that the remaining force is random force. We employ a method similar to that used in the general theory of irreversible processes[6],[7]. The method used in this paper is applicable to more complicated systems. To avoid ambiguity, however, we shall here confine ourselves to the simplest system we can consider. Indeed there are many controversial points in the general theory of irreversible processes, and it is hoped to give more or less sound footings to it, because by so doing we can test some of the concepts and clarify the nature of approximation used in the general theory. We shall treat more complicated problems (relaxation of two-oscillators, spin relaxation, etc.) in the near future.

The system we treat here is an assembly of harmonic oscillators and interaction force is assumed to be linear with respect to displacements. The interaction, assumed small, is introduced from infinite past, and the equations of motion are solved therefrom. We go over to coordinate systems (ξ, η) which rotate with proper frequencies, and then transform to $(\bar{\xi}, \bar{\eta})$ by eliminating the first order terms of the interaction. We take an oscillator and regard the rest of the system as thermostat, for which we assume certain equilibrium properties.

The system is the same as that treated in a previous paper[7] dealt with quantum mechanical density matrix. Though the present paper supplements, in some respects, what were missing in the previous one, the main purpose is to give a very elementary but sound footing to the problem.

It seems worth noting the origin of the friction force. Consider that we displace an oscillator; this implies a work against the other oscillators. A part of this work will give rise to a shift in oscillation frequency and will be conservative, but as there is naturally a tendency to equalize energy of oscillators some part of that work has to be dissipated in the form of friction.

§ 2. Interacting Oscillators

First we shall consider a harmonic oscillator under an external force F. The canonical equations of motion are

$$\dot{x}=p/m\ , \qquad \dot{p}=-m\omega^2x+F\ . \tag{2.1}$$

As is well known if $F=0$ the oscillator describes a circle in the phase space $(x, p/m\omega)$ with angular velocity $-\omega$. It is therefore convenient to refer to a rotating coordinate system and use

$$\left.\begin{aligned}\xi&=x\cos\omega t-(p/m\omega)\sin\omega t\ ,\\ \eta&=m\omega x\sin\omega t+p\cos\omega t\ .\end{aligned}\right\} \tag{2.2}$$

The equations of motion (2.1) then go over into

$$\left.\begin{aligned}\dot{\xi}&=-F\sin\omega t/m\omega\ ,\\ \dot{\eta}&=F\cos\omega t\ .\end{aligned}\right\} \tag{2.3}$$

We see that if there were no external force both ξ and η stay constant.

Now we consider an assembly of harmonic oscillators. We assume that the interaction energy is of the form

$$\lambda V=\sum\lambda_{ij}x_ix_j\ , \tag{2.4}$$

where λ_{ij} is the coupling constant between the i-th and the j-th oscillators, λ stands for the magnitude of the interaction: $\lambda\sim O(\lambda_{ij})$. Let m_i and ω_i the mass and the frequency of the i-th oscillator and define ξ_i and η_i by equations analogous to Eqs. (2.2). The force acting on the i-th oscillator is

$$\begin{aligned}F_i&=-\sum{}'\lambda_{ij}x_j\\ &=-\sum_{j\neq i}{}'\lambda_{ij}\left(\xi_j\cos\omega_jt+\frac{\eta_j}{m_j\omega_j}\sin\omega_jt\right)\ .\end{aligned} \tag{2.5}$$

We shall suppose that the interaction is introduced adiabatically from the past. Under this supposition we replace λ_{ij} by $\lambda_{ij}e^{st}$ and afterwords take the limit $s\to 0$. Then the equations of motion for the oscillator i are combined into

$$\begin{pmatrix}m_i\omega_i\dot{\xi}_i\\ -\dot{\eta}_i\end{pmatrix}=\sum{}'\lambda_{ij}{}^{st}\left(\xi_j\cos\omega_jt+\frac{\eta_j}{m_j\omega_j}\sin\omega_jt\right)\begin{pmatrix}\sin\omega_it\\ \cos\omega_it\end{pmatrix}\ . \tag{2.6}$$

We assume that the coupling constants λ_{ij} are small and solve the above equation using the following method. We notice the fact that if λ were zero ξ and η would stay constant, and put

$$\left.\begin{aligned}\xi_i&=\overline{\xi}_i+\xi_i'(\overline{\xi},\overline{\eta},t)\ ,\\ \eta_i&=\overline{\eta}_i+\eta_i'(\overline{\xi},\overline{\eta},t)\ ,\end{aligned}\right\} \tag{2.7}$$

in which $\overline{\xi}=(\overline{\xi}_1,\overline{\xi}_2,\cdots)$ and $\overline{\eta}=(\overline{\eta}_1,\overline{\eta}_2,\cdots)$ are defined in such a way that their rate of change is of second order in λ:

$$\dot{\overline{\xi}}_i=O(\lambda^2)\ , \qquad \dot{\overline{\eta}}_i=O(\lambda^2)\ . \tag{2.8*}$$

Accordingly the rate of change in ξ' and η' are of first order in λ. Though the way of splitting thus ξ and η is not at all unique, the result is however independent of the way as can be seen easily. In particular we demand that ξ' are of the order λ. The simplest way is to define them by

$$\left.\begin{aligned}m_i\omega_i\xi_i'&=\sum{}'\lambda_{ij}\left\{\overline{\xi}_ic_{ji}(t)+\frac{\overline{\eta}_j}{m_j\omega_j}S_{ji}(t)\right\}\ ,\\ -\eta_i'&=\sum{}'\lambda_{ij}\left\{\overline{\xi}_iC_{ji}(t)+\frac{\overline{\eta}_j}{m_j\omega_j}s_{ji}(t)\right\}\ .\end{aligned}\right\} \tag{2.9}$$

and choose the function c_{ji}, S_{ji}. C_{ji} and s_{ji} in such a way that their time derivative coincide the time factors in the right hand side of Eqs. (2.6). That is

---

* In the previous paper7) an inappropriate terminology "systematic" was used for $\overline{\rho}$, which corresponds to $\overline{\xi}$ or $\overline{\eta}$. These quantities have oscillatory behavior as well.

$$\dot{c}_{ji}(t)=e^{st}\cos\omega_j t\sin\omega_j t\ ,\qquad \text{etc.} \tag{2.10}$$

We may understand change of variables from (ξ,η) to $(\bar{\xi},\bar{\eta})$ as a transformation which is canonical if λ^2 terms are neglected, and c_{ij} etc. as action integrals corresponding to the transformation.

We may also understand the variables $\bar{\xi}$ and $\bar{\eta}$ as follows: When an oscillator is displaced the rest positions of other oscillators will be shifted also. In virture of the interaction, therefore, each oscillator will be seen to oscillate around instantaneous rest position. According to this interpretation $\bar{\xi}$ stands for the displacement from the instantaneous rest position ξ'.

Now we have

$$\left.\begin{aligned} m_i\omega_i\xi_i' &= \sum{}'\lambda_{ij}\left\{\bar{\xi}_j\int_{-\infty}^{t}dt'e^{st'}\cos\omega_j t'\sin\omega_i t'+\frac{\bar{\eta}_j}{m_j\omega_j}\int_{-\infty}^{t}dt'e^{st'}\sin\omega_j t'\sin\omega_i t'\right\}\ ,\\ -\eta_i' &= \sum{}'\lambda_{ij}\left\{\bar{\xi}_j\int_{-\infty}^{t}dt'e^{st'}\cos\omega_j t'\cos\omega_i t'+\frac{\bar{\eta}_j}{m_j\omega_j}\int_{-\infty}^{t}dt'e^{st'}\sin\omega_j t'\cos\omega_i t'\right\}\ ,\end{aligned}\right\} \tag{2.11}$$

If we insert these expressions into Eqs. (2.7) and then into (2.6) we shall see that the rate of change in $\bar{\xi}$ and $\bar{\eta}$ are of the order λ^2 as required (c.f. Eqs. (2.15) below).

It is important for our calculation that ξ' and η' do not increase with time and oscillate in the limit $s\rightarrow 0$. In actual, for $\omega, \omega'>0$,

$$c_{ij}=s_{ji}=\lim_{s\to 0}\int_{-\infty}^{t}dt'e^{st'}\cos\omega_i t'\sin\omega_j t'=-\frac{\cos(\omega_i+\omega_j)t}{2(\omega_i+\omega_j)}+\frac{\cos(\omega_j-\omega_j)t}{2(\omega_i-\omega_j)}\ ,$$

$$\left.\begin{matrix}C_{ij}\\ S_{ij}\end{matrix}\right\}=\lim_{s\to 0}\int_{-\infty}^{t}dt'e^{st'}\left\{\begin{matrix}\cos\omega_i t'\cos\omega_j t'\\ \sin\omega_i t'\sin\omega_j t'\end{matrix}\right\}=\frac{\pi}{2}\delta(\omega_i-\omega_j)\pm\frac{\sin(\omega_i+\omega_j)t}{2(\omega_i+\omega_j)}+\frac{\sin(\omega_i-\omega_j)t}{2(\omega_i-\omega_j)}\ .$$

And we have

$$\left.\begin{aligned} \xi_j' &= \frac{1}{m_j\omega_j}\sum{}'\lambda_{jk}\left[\frac{\bar{\eta}_k}{m_k\omega_k}\left\{\frac{\pi}{2}\delta(\omega_k-\omega_j)-\frac{\sin(\omega_k+\omega_j)t}{2(\omega_k+\omega_j)}+\frac{\sin(\omega_k-\omega_j)t}{2(\omega_k-\omega_j)}\right\}\right.\\ &\qquad\left.+\bar{\xi}_k\left\{-\frac{\cos(\omega_k+\omega_j)t}{2(\omega_k+\omega_j)}+\frac{\cos(\omega_k-\omega_j)t}{2(\omega_k-\omega_j)}\right\}\right],\\ \eta_j' &= -\sum{}'\lambda_{jk}\left[\bar{\xi}_k\left\{\frac{\pi}{2}\delta(\omega_k-\omega_j)+\frac{\sin(\omega_k+\omega_j)t}{2(\omega_k+\omega_j)}+\frac{\sin(\omega_k-\omega_j)t}{2(\omega_k-\omega_j)}\right\}\right.\\ &\qquad\left.+\frac{\bar{\eta}_k}{m_k\omega_k}\left\{-\frac{\cos(\omega_k+\omega_j)t}{2(\omega_k+\omega_j)}-\frac{\cos(\omega_k-\omega_j)t}{2(\omega_k-\omega_j)}\right\}\right].\end{aligned}\right\} \tag{2.12}$$

In virtue of these equations, after inserting Eqs. (2.7) into the right hand side of (2.6), we get

$$\begin{pmatrix} m_i\omega_i\dot{\xi}_i\\ -\dot{\eta}_i\end{pmatrix}=-F_i(t)\begin{pmatrix}\sin\omega_i t\\ \cos\omega_i t\end{pmatrix} \tag{2.13}$$

where

$$F_i(t)=-\sum\lambda_{ij}\left(\bar{\xi}_j\cos\omega_j t+\frac{\bar{\eta}_j}{m_j\omega_j}\sin\omega_j t\right)+\tilde{F}(t)\ , \tag{2.13'}$$

$$\begin{aligned}\tilde{F}(t)=-\sum_{j\neq i}{}'\frac{\lambda_{ij}}{m_j\omega_j}\sum_{k\neq j}{}'\lambda_{jk}&\left[\bar{\xi}_k\left\{-\frac{\pi}{2}\delta(\omega_k-\omega_j)\sin\omega_j t+\frac{\omega_j}{\omega_k^2-\omega_j^2}\cos\omega_k t\right\}\right.\\ &\left.+\frac{\bar{\eta}_k}{m_k\omega_k}\left\{\frac{\pi}{2}\delta(\omega_k-\omega_j)\cos\omega_j t+\frac{\omega_j}{\omega_k^2-\omega_j^2}\sin\omega_k t\right\}\right].\end{aligned} \tag{2.13''}$$

This is the equation of fundamental importance in the present calculation.

Further we have to prove Eqs. (2.8) that $\dot{\xi}$ and $\dot{\bar{\eta}}$ are second order in λ. To verify this we make $\dot{\xi}$ and $\dot{\eta}$ from Eqs. (2.7) and (2.11) or (2.9) and insert them into the left-hand side of (2.13) to get

$$m_i\omega_i\dot{\bar{\xi}}_i-\sum \lambda_{ij}\{\dot{\bar{\xi}}_j c_{ji}+(\dot{\bar{\eta}}_j/m_j\omega_j)S_{ji}\}=-\tilde{F}_i(t)\sin\omega_i t \tag{2.14}$$

and similar equations for $\dot{\bar{\eta}}_i$. In these simultaneous equations $\tilde{F}_i(t)$ is of second order in λ and does not contain $\dot{\bar{\xi}}$ nor $\dot{\bar{\eta}}$. So except for very unusual cases we may replace the set of simultaneous equations by

$$\begin{pmatrix} m_i\omega_i\dot{\bar{\xi}}_i \\ -\dot{\bar{\eta}}_i \end{pmatrix}=-\tilde{F}(t)\begin{pmatrix} \sin\omega_i t \\ \cos\omega_i t \end{pmatrix} \tag{2.15}$$

where $\tilde{F}_i(t)$ is give by Eq. (2.13″). Therefore the rate of change in $\bar{\xi}$ and $\bar{\eta}$ is second order in λ, and stays very small all the time.

In the following it is sometimes convenient to use the notations,

$$\left.\begin{aligned} \bar{x}_i&=\bar{\xi}_i\cos\omega_i t+\frac{\bar{\eta}_i}{m_i\omega_i}\sin\omega_i t\ , \\ \bar{p}_i&=-m_i\omega_i\bar{\xi}_i\sin\omega_i t+\bar{\eta}_i\cos\omega_i t\ . \end{aligned}\right\} \tag{2.16}$$

§ 3. Damped Oscillation

Let us pay special attention to the oscillator $i=0$ (central oscillator) and consider the assembly of other oscillators $1, 2, \cdots, j, \cdots, k, \cdots$ $(\neq 0)$ as forming thermostat.

Further, we assume that the thermostat is always in the state of thermal equalibrium with temperature T. The most logical way to introduce this *ad hoc* assumption is to take an ensemble of systems of the same construction and energy (each system is what we have considered in § 2). We are to follow the motion of the central oscillators $i=0$ in all the systems; the representative points belonging to the central oscillators are expected to suffer Brownian motion and to diffuse in a certain way in the phase space (x_0, p_0). The other oscillators $1, 2, \cdots, j, \cdots, k, \cdots$ are the thermostat oscillators and their motion is supposed to be in perfect randomness at every instant. Under this supposition we can speak of the average taken over the configuration of the thermostat.

As to the thermostat in equilibrium state the average of fluctuations, ξ_j' and η_j', will vanish. On the other hand $\bar{\xi}_j$ and $\bar{\eta}_j$ will be distributed symmetrically, their averages being zero. Thus

$$\left.\begin{aligned} \langle\bar{\xi}_j\rangle&=\langle\xi_j'\rangle=\langle\xi_j\rangle=0\ , \\ \langle\bar{\eta}_j\rangle&=\langle\eta_j'\rangle=\langle\eta_j\rangle=0\ . \end{aligned}\right\} \tag{3.1}$$

We see that these requirements are consistent with Eqs. (2.15). Now

The difference between $\langle\xi_j^2\rangle$ and $\langle\bar{\xi}_j^2\rangle$, for instance, is of second order in λ^2. We shall neglect λ^2 terms and formulate the ensemble average:

$$\langle\bar{\xi}_j^2\rangle=\langle\bar{\eta}_j^2\rangle/(m_j\omega_j)^2=kT/m_j\omega_j^2\ . \tag{3.2}$$

Further we assume that

$$\langle\bar{\xi}_j(t)\bar{\xi}_k(t')\rangle=0 \quad (j\neq k)\ , \qquad \langle\bar{\xi}_j(t)\bar{\eta}_k(t')\rangle=0\ . \tag{3.2′}$$

We see again that these requirements are consistent with Eqs. (2.15). Now

$$\left.\begin{aligned} \dot{x}&=p_0/m_0\ , \\ \dot{p}_0&=-m_0\omega_0^2x_0-m_0\omega_0\dot{\xi}_0\sin\omega_0 t+\dot{\eta}_0\cos\omega_0 t\ . \end{aligned}\right\} \tag{3.3}$$

Taking average over the thermostat oscillators we get from Eqs. (2.13),

$$\langle \dot{p}_0\rangle = -m_0\omega_0^2\langle x_0\rangle - \sum \frac{\lambda_{0j}^2}{m_j\omega_j}\frac{\pi}{2}\delta(\omega_0-\omega_j)\left\langle -\bar{\xi}_0\sin\omega_0 t + \frac{\bar{\eta}_0}{m_0\omega_0}\cos\omega_0 t\right\rangle$$
$$-\sum \frac{\lambda_{0j}^2}{m_j\omega_j}\frac{\omega_j}{\omega_0^2-\omega_j^2}\left\langle \bar{\xi}_0\cos\omega_0 t + \frac{\bar{\eta}_0}{m_0\omega_0}\sin\omega_0 t\right\rangle . \tag{3.4}$$

The averages in the right-hand side of this equation are $-\langle\bar{p}_0\rangle/m_0\omega_0$ and $\langle\bar{x}_0\rangle$. Therefore we may write

$$\langle\dot{p}_0\rangle + m_0\omega_0^2\langle x_0\rangle = \Lambda\langle\bar{x}_0\rangle - \zeta\langle\bar{p}_0\rangle/m_0 , \tag{3.5}$$

where

$$\left.\begin{aligned} \Lambda &= \sum_j \frac{1}{m_j}\frac{\lambda_{0j}^2}{\omega_j^2-\omega_0^2} , \\ \zeta &= \frac{\pi}{2}\frac{1}{m_0}\sum_j \frac{\lambda_{0j}^2}{m_j\omega_0^2}\delta(\omega_0-\omega_j) . \end{aligned}\right\} \tag{3.6}$$

As Λ and ζ are of the order λ^2, we may replace $\langle\bar{x}_0\rangle$ and $\langle\bar{p}_0\rangle$ by $\langle x_0\rangle$ and $\langle p_0\rangle$ in the right-hand side of (3.5), because we are neglecting higher orders in λ.

We obtain finally the damping equation,

$$m_0\frac{d^2}{dt^2}\langle x_0\rangle + \zeta\frac{d}{dt}\langle x_0\rangle + (m_0\omega_0^2-\Lambda)\langle x_0\rangle = 0 , \tag{3.7}$$

where ζ is the friction constant and Λ stands for the shift in frequency. If there are

$$g(\omega')\,d\omega'$$

oscillators in the thermostat within the frequency range $\omega'\sim\omega'+d\omega'$, and if their masses are the same,

$$m' = m_j .$$

we have[7)]

$$\Lambda = \frac{1}{m'}\int\frac{\lambda^2(\omega)g(\omega)\,d\omega}{\omega^2-\omega_0^2} ,$$

$$\zeta = \lambda^2(\omega)\frac{\pi}{2}g(\omega_0)/mm'\omega_0^2 .$$

in which we have written $\lambda(\omega_j)$ for λ_{0j}, that is, we look λ_{0j} as a function of the frequency ω_j of the thermostat oscillator. As in the case of a radiation field[8)] or the like, if $g(\omega)\propto\omega^2$ then ζ would become independent of ω, provided if $\lambda(\omega)$ were constant[7)]. In this case, however, Λ would diverge, and we have to cut off high frequency range or to renormarize the frequency of the central oscillator. This is the situation frequently called as the ultraviolet divergence. But in our case we may think of appropriate forms for $\lambda(\omega)$ and $g(\omega)$.

It is easy to see that the term $\Lambda\langle x_0\rangle$ actually represent the reaction due to thermostat oscillator on the central oscillator: Suppose that the central oscillator is oscillating with amplitude a_0. The oscillator j of the thermostat coupled with the central oscillator is then subject to forced oscillation and its motion is given by

$$x_j = a_j\sin(\omega_j t+\delta_j) + \frac{1}{\omega_j^2-\omega_0^2}\frac{-\lambda_{0j}}{m_j}a_0\sin(\omega_0 t+\delta_0) .$$

The influence of the second term on the central oscillator is the reaction force given by

$$f_{0\to j\to 0} = -\lambda_{j0}\frac{1}{\omega_j^2-\omega_0^2}\frac{-\lambda_{0j}}{m_j}a_0\sin(\omega_0 t+\delta_0) = \frac{\lambda_{0j}^2}{\omega_j^2-\omega_0^2}\frac{1}{m_j}x_0 .$$

The summation of this force over j gives $\Lambda\langle x_0\rangle$.

§ 4. Langevin Equation and Correlation of Random Force

Going back to Eq. (3.3) we see that the equation for p_0 is of the form

$$\dot{p}_0+m_0\omega_0{}^2x_0=-\sum\lambda_{0j}\left(\bar{\xi}_j\cos\omega_jt+\frac{\bar{\eta}_j}{m_j\omega_j}\sin\omega_jt\right)+(\Lambda\bar{x}_0-\zeta\bar{p}_0/m)$$
$$+(\text{terms linear in } \bar{\xi}_j \text{ and } \bar{\eta}_j \text{ of thermostat})\,. \tag{4.1}$$

The last term on the right-hand side is fluctuating, but of the order λ^2. The second term is of the order λ^2, but it is not fluctuating and gives rise to the frequency shift and the friction after replacing $\bar{x}_0$ and $\bar{p}_0$ by x_0 and p_0. The fluctuating force is therefore

$$f(t)=-\sum\lambda_{0j}\left(\bar{\xi}_j\cos\omega_jt+\frac{\bar{\eta}_j}{m_j\omega_j}\sin\omega_jt\right)+\mathrm{O}(\lambda^2)$$
$$=-\sum\lambda_{0j}\langle\bar{x}_j\rangle+\mathrm{O}(\lambda^2)\,. \tag{4.2}$$

Consequently we get the Langevin equation,

$$m_0\ddot{x}_0+\zeta\dot{x}_0+(m_0\omega^2-\Lambda)x_0=f(t)\,. \tag{4.3}$$

The correlation function of the fluctuating force is

$$\langle f(t)f(t+\tau)\rangle=\sum\sum\lambda_{0j}\lambda_{0k}\langle\bar{x}_j(t)\bar{x}_k(t+\tau)\rangle\,, \tag{4.4}$$

in which

$$\bar{x}_j(t)\bar{x}_k(t+\tau)=\bar{\xi}_j(t)\bar{\xi}_k(t+\tau)\cos\omega_jt\cos\omega_k(t+\tau)$$
$$+\frac{\bar{\eta}_j(t)\bar{\eta}_k(t+\tau)}{m_jm_k\omega_j\omega_k}\sin\omega_jt\sin\omega_k(t+\tau)$$
$$+\frac{\bar{\xi}_j(t)\bar{\eta}_k(t+\tau)}{m_k\omega_k}\cos\omega_jt\sin\omega_k(t+\tau)$$
$$+\frac{\bar{\eta}_j(t)\bar{\xi}_k(t+\tau)}{m_j\omega_j}\sin\omega_jt\cos\omega_k(t+\tau)\,. \tag{4.5}$$

Now we shall evaluate quantities like $\langle\bar{\xi}_j(t)\bar{\xi}_j(t+\tau)\rangle$. To do this we make the derivative with respect to τ. Replacing t by $t+\tau$ in Eq. (2.15) and multiplying by $\bar{\xi}_i(t)$ we get

$$\langle\bar{\xi}_j(t)\dot{\bar{\xi}}_j(t+\tau)\rangle=\sum_l\frac{\lambda_{jl}\lambda_{lj}}{m_j\omega_jm_l\omega_l}\langle\bar{\xi}_j(t)\bar{\xi}_j(t+\tau)\rangle\left\{-\frac{\pi}{2}\delta(\omega_j-\omega_l)\sin\omega_l(t+\tau)\right.$$
$$\left.+\frac{\omega_l}{\omega_j{}^2-\omega_l{}^2}\cos\omega_j(t+\tau)\right\}\sin\omega_j(t+\tau)\,. \tag{4.6}$$

We take time average of the ensemble average and designate it by $\overline{\langle\ \rangle}$. We have

$$\frac{d}{d\tau}\overline{\langle\bar{\xi}_j(t)\bar{\xi}_j(t+\tau)\rangle}=\frac{\zeta(\omega_j)}{2}\langle\bar{\xi}_j(t)\bar{\xi}_j(t+\tau)\rangle \tag{4.7}$$

where ζ is the friction constant given by Eq. (3.6). We have a similar equation for $\overline{\langle\eta_j(t)\eta_j(t+\tau)\rangle}$. Thus

$$\left.\begin{aligned}\overline{\langle\xi_j(t)\xi_j(t+\tau)\rangle}&=\langle\bar{\xi}_j{}^2\rangle e^{-\zeta\tau/2}\,,\\ \overline{\langle\eta_j(t)\eta_j(t+\tau)\rangle}&=\langle\bar{\eta}_j{}^2\rangle e^{-\zeta\tau/2}\,.\end{aligned}\right\} \tag{4.8}$$

Analogously we can prove that $\overline{\langle\bar{\xi}_j(t)\bar{\xi}_k(t+\tau)\rangle}$ $(j\neq k)$ and $\overline{\langle\bar{\xi}_j(t)\bar{\eta}_k(t+\tau)\rangle}$ vanish if they are zero initially. So that Eqs. (3.2′) are consistent in this sense.

Inserting Eq. (4.8) into (4.5) we get

$$\overline{\langle \bar{x}_j(t)\bar{x}_k(t+\tau)\rangle}=\langle \bar{\xi}_j^2\rangle \delta_{jk} e^{-\zeta\tau/2}\cos(\omega_j\tau)\ . \tag{4.9}$$

The factor $\cos(\omega_j\tau)$ on the right-hand side comes from the nature of the oscillator.

The force acting on the central oscillator under Brownian motion is $f(t)=-\sum \lambda_{0j}\bar{x}_j+O(\lambda^2)$. The correlation of the random force is therefore

$$\overline{\langle f(t)f(t+\tau)\rangle}=\sum \lambda^2(\omega_j)\langle \xi_j^2\rangle e^{-\zeta(\omega_j)\tau/2}\cos\omega_j\tau\ , \tag{4.10}$$

where, as before, we have written $\lambda(\omega_j)$ for λ_{0j}. The spectrum is

$$\begin{aligned}&\int_0^\infty d\tau \cos\omega\tau\overline{\langle f(t)f(t+\tau)\rangle}\\ &\quad=\sum \lambda^2(\omega_j)\langle \bar{\xi}_j^2\rangle\ \frac{1}{2}\left\{\frac{\zeta/2}{(\omega-\omega_j)^2+(\zeta/2)^2}+\frac{\zeta/2}{(\omega+\omega_j)^2+(\zeta/2)^2}\right\}\\ &\quad=\sum \lambda^2(\omega)\langle \bar{\xi}^2(\omega)\rangle\frac{\pi}{2}\{\delta(\omega-\omega_j)+\delta(\omega+\omega_j)\}\ , \qquad (\zeta\to 0)\ .\end{aligned}$$

Thus, in terms of the friction constant ζ of (3.6), we have

$$\int_0^\infty dt \cos\omega\tau\overline{\langle f(t)f(t+\tau)\rangle}=mkT\zeta(\omega)\ . \tag{4.11}$$

This agrees with the Wiener-Khintchine theorem[9]. In particular for $\omega=\omega_0$ Eq. (4.11) is the relation between the correlation of random force and the friction constant for the harmonic oscillator under consideration. In the special case $\omega=0$, Eq. (4.11) reduces to the well-known relation,

$$\int_0^\infty d\tau\overline{\langle f(t)f(t+\tau)\rangle}=mkT\zeta(0)\ . \tag{4.12}$$

§ 5. Concluding Remarks

The essential point of the method of treatment is made clear for a simple example, in which one might understand the physical meaning of every line of the calculation.

We might have used, instead of ξ and η, the variables defined by

$$a=\sqrt{m\omega/2}\,(\xi+i\eta/m\omega)\ ,$$
$$a^*=\sqrt{m\omega/2}\,(\xi-i\eta/m\omega)\ .$$

Then the calculation will admit direct translation into quantum mechanics, which will be discussed in a later article.

The present study was partially financiated by the Scientific Research Fund of the Ministry of Education.

Thermoelectric Power of AgCl

By Yasumasa SUSUKI, Shigeaki ENDŌ
and Eijirō HAGA
Department of Physics, Faculty of Science,
Niigata University

(Received February 11, 1959)

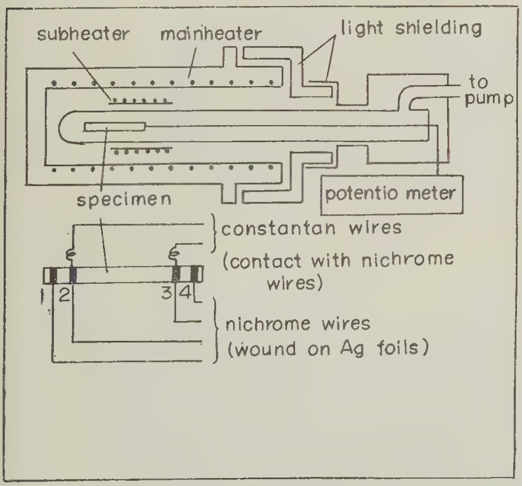
The thermoelectric power of AgCl doped with several concentrations of $CdCl_2$ is measured and compared with the theory.

§ 1. Introduction

Recently the theory of thermoelectric power of ionic crystals[1,2] has been developed as a help of understanding of the electrical property and the Soret phenomenon. The purpose of the present paper is to give an information on thermoelectric properties of AgCl crystals by combining the available theory with measurements on AgCl doped with several concentrations of $CdCl_2$.

§ 2. Experimental Arrangements

We prepared specimens of silver chloride by adding hydrochloric acid to a solution of silver nitrate, and well washing the precipitate away from violet light. The impurities in samples were analysed by a spectroscopic method. Iron, silicon and magnesium were barely detected, so that we estimate that the amount of these impurities is below 10^{-3} Mol-%. Also we used specimens of silver chloride offered from the laboratory of Fuji Photo Film Co., and the both samples showed no material differences.



1, 2, 3, 4: Conductivity measurement probes.
2, 3: Thermoelectric voltage measurement probes.

Fig. 1. The schematic diagram of the experimental arrangements.

After being washed and dried, the precipitate is mixed well with a proper amount of $CdCl_2$ and is put in a hard glass tube with a capillary.[3] The tube is heated up to 580°C while evacuating and then sealed. We shake the tube slowly in order to mix AgCl with $CdCl_2$ uniformly and at the same time, in order to avoid adhesion of sample to glass wall and to eliminate bubbles. The molten salt is cooled with a speed of the order of 1°C/min near the melting point of AgCl. The speed at which crystal is cooled to room temperature may be larger than that at the melting point, because the quenching has an effect only at lower temperature than the range of our measurements (100∼400°C).[4] The sample thus obtained, was cut with a silicon carbide cutter and ground to a proper size (its typical dimension is $2\times2\times20\,\mathrm{mm}^3$). In some cases, the ground specimens were immersed in concentrated ammonia for a minute to remove the contaminated layers; in other cases, glass knife was used. There are no significant differences in thermoelectric power for both treatments.

The experimental arrangements are shown in Fig. 1. Four silver foils are wound on the specimen. The conductivity is measured as a function of the temperature making use of the four silver probes. We determine $CdCl_2$ concentrations from such conductivity measurements by refering the published data of Teltow.[6] The results are shown in Table I as c. Here c^* denotes $CdCl_2$ concentrations mixed at the beginning.

Temperature gradient is set up by a movable subheater, the position of which determines the magnitude of the temperature gradient and its sign. (The temperature difference between two ends is chosen to be smaller than 15°C.) In practice, in order to save the time necessary for steady state to attain, the main- and sub-heater was fixed and the sample was moved: in this way, the sign of the gradient could be reversed in twenty minutes or shorter than that.

Table I. $CdCl_2$ concentrations.

c^* (Mol-%)	c (Mol-%)	Remark
0.20	0.068	The tube was not shaked
0.20	0.16	
0.026	0.022	The tube was shaked slowly
0.20	0.2_0	
0.010	0.008_0	

§ 3. Result

The result is shown in Fig. 2. For pure samples, the results agree well with Reinhold's one.[5)] In most specimens, if measurements are made in the run of low- high- low temperature, they are not reproducible in low temperature range; that is, the magnitude of the thermoelectric voltage becomes smaller in the second run than in the first run. In the case of the pure samples, this deviation from the theoretical value at low temperature may be explained by an unavoidable contamination during the measurement and may be interpreted by the divalent impurity concentration of about 1×10^3 Mol-% (pure No. 4). But in the case of the doped specimens, it is not possible to give such a simple interpretation.

Now, the thermoelectric power, Q, is given by[2,1)]

$$eQ=-\frac{t_i}{T}(h_F+Q_i{}^*+Q_V{}^*) -k\ln c_v+Q_v/T+\alpha\,, \tag{1}$$

$$\alpha=k\sum\ln\nu_P/\nu_v-(s_P-s_{\mathrm{Ag}}^{\mathrm{Ag}})\,.$$

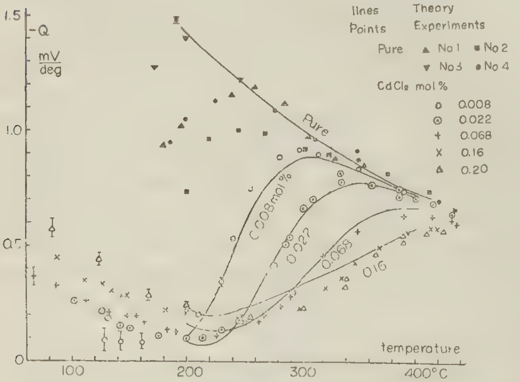


Fig. 2. The thermoelectric power *versus* temperature.

Here, the transport number of Ag interstitial ions, t_i, and the concentration of Ag^+ vacancies, c_v, can be obtained from the conductivity data of Teltow:[5)]

$$t_i=\frac{\varphi}{\varphi+\xi^2},\quad c_v=x_0\xi,\quad z=\frac{\xi+\varphi/\xi}{1+\varphi}\,. \tag{2}$$

One value of $h_F+Q_i{}^*+Q_v{}^*$ is obtained from the difference of Q between a pure sample and an impure sample at each temperature.[1)] Next, the value of $-Q_v{}^*/T-\alpha$ at each temperature is obtained by making use of the mean value of $h_F+Q_i{}^*+Q_v{}^*$ for five impure samples so that Eq. (1) fits experimental value for a pure sample. The values of $h_F+Q_i{}^*+Q_v{}^*$ and $-Q_v{}^*/T-\alpha$ thus obtained are shown in Fig. 3. By making use of these values, the theoretical curves are given in Fig. 2. It is seen from Fig. 2 that the theory fits experiments pretty well. It is seen from Fig. 3 that $h_F+Q_i{}^*+Q_v{}^*$ varies severely with temperature and the value of $-Q_v{}^*$ is larger than the activation energy of the mobility of Ag^+ vacancies.* The simple model of Wirtz[7)] can not explain these results. This theoretical difficulty will be discussed in future.

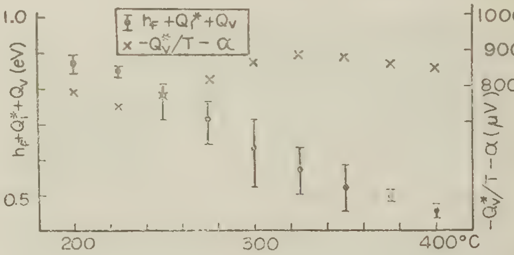

Fig. 3. The values of $h_F+Q_i{}^*+Q_v{}^*$ and $-Q_v{}^*/T-\alpha$.

The writers wish to express their sincere thanks to Dr. Y. Mizuki of Fuji Photo Film Co. for the kind supply of the AgCl samples, and to Mr. T. Ninomiya and Dr. H. Kanzaki of Bussei Laboratory for their kind helps. The writers also are indebted to Dr. A. B. Lidiard and Dr. W. Christy for informing

Internal Friction of KCl Crystals at Low Temperatures

By Taira SUZUKI,* Katsumi SUZUKI and Tomoo KAMIGAKI

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received March 4, 1959)

Ultrasonic attenuation in megacycle range for cold-worked and for quenched KCl crystals has been measured against temperature between 200°K and room temperature. A very broad relaxation band appears below 240°K for cold-worked crystals. The experiments on the anisotropy of attenuation in crystals cold-worked by uniaxial compression demonstrate that the attenuation is caused by the motion of the dislocations. The activation energy is found to be 0.44 eV. Quenched crystals show also a similar band. The following are very unique features: As quenching temperature is raised the attenuation band shifts to higher temperature. This shift is accompanied by the increase of the activation energy. Another significant nature is the ageing effect, which results also a band-shift to higher temperature with increasing ageing time after quenching.

It has been discussed that the effects of vacancies in the dislocation core upon the activation energy for the motion of dislocations and the concurrent motion of vacancies in the cores of oscillating dislocations both give rise to such a broad band as observed.

§ 1. Introduction

Most of the work on low-temperature internal friction has been concerned with metals[1)–5)] and a few with germanium[6),7)] and silicon[8)]. Many interesting features of dislocation dynamics have been revealed so far. However, there are several respects in which ionic crystals such as NaCl are of special significance. First, for the comprehensive understanding of dislocation dynamics in crystalline solids it is naturally desired to extend the investigation to the ionic crystals, since no work has been done so far on such crystals. Besides, theoretical aids seem to be possible in the ionic crystals much more than in metals. Indeed, the energy of dislocation cores has been calculated for the first time for NaCl by Huntington, Dickey and Thomson[9)], and Bassani and Thomson[10)] have discussed the electrical interaction between a dislocation and a vacancy in its core. It overwhelms the elastic field interaction, which is most important in metals.

A second point of interest in connection with the alkali halides relates to a question on the nature of low-temperature relaxation peak: In the discussion of the Bordoni peak in face-centred cubic metals Seeger[11] has stated his opinion that the impurities present in the crystals give no effect on the peak temperature for a fixed frequency. This is the feature really found in most metals such as aluminium and copper. However, it is questionable if we believe the Seeger-Mason mechanism based on the oscillation of a dislocation line in a potential well. This is because even fresh dislocations introduced by cold-working in specimen crystals have a sufficient time to be trapped by the impurities in most experiments before starting the measurements of ultrasonic attenuation and these impurities will modify the activation energy for the oscillatory motion of the dislocations. It is desired to do experiments with respect to the above question. It seems most appropriate for this aim to study the effect of vacancies on low-temperature internal friction of the alkali halides because of their strong interaction with dislocations as mentioned above.

---

* Now at the Institute for Solid State Physics, Tokyo University, Tokyo.

The results obtained by the present experiment have been discussed in connection with the recent proposal on the minimum stress required for the motion of charged dislocations in the alkali halides made by Eshelby, Newey and Pratt[12] and with the experimental results on critical shear stress of KCl studied by Doyama and one of the present authors[13].

§ 2. Experimental Procedure

Measurements were made with the pulsed ultrasonics[14]. The system for the measurement consists of a pulse generator and a receiver to produce and to detect the megacycle-frequency pulses which are impressed on the x-cut quartz crystal. The quartz crystal used is about 1 cm in diameter and the thickness corresponds to the fundamental frequency of 5 Mc/sec. The multiply reflected pulses are received by the quartz crystal and observed by a cathode-ray oscilloscope. The smallest reading of a variable attenuator inserted in series in the circuit was 0.1 db, which corresponds to 0.05 db/cm for a specimen of 1 cm in length.

Prior to mounting the crystal a metal foil of copper of five microns in thickness was cemented carefully to the cleavage surface of a specimen crystal by means of beeze-wax or rosin. This metal foil was connected to the detecting system. It is very important to find out appropriate cementing materials for the test of brittle specimens such as the present crystals, otherwise fine cracks are formed at low temperatures. Since we could not make a success in finding such a material, the temperature range investigated is from 200°K to room temperature. Further studies on acoustic spectra of KCl crystals at sufficiently low temperatures will be done in near future. The transducer crystal was then cemented on the above metal foil by the Bond cement and its opposite face was also cemented to another metal foil serving as the input electrode. A sufficient damping of the transducer was given by means of an ebonite block. The assembly was enclosed in a container made of copper block wound by an insulated resistance wire for heating and inserted into a glass tube. The whole assembly was then evacuated and cooled in the liquid nitrogen bath. Temperature of a specimen was measured by a copper-constantan thermocouple mounted in a very close distance from the specimen.

The attenuation was measured at temperature intervals of 2° to 5° on heating run. The maximum strain amplitude was less than 10^{-7} and the frequencies used were 5 and 15 Mc/sec. Within this strain range the attenuation proved independent of strain. The absolute accuracy of measured attenuations from one run to the next is mainly determined by the mounting conditions and is approximately ± 0.3 db/cm.

Specimen crystals were KCl obtained from the Harshaw Chemical Company, which were annealed normally at 550°C in air for 5 hours and, then, slowly cooled to room temperature in taking care to avoid thermal strain. The specimens were cleaved to about $1.5 \times 1.5 \times 1.5$ cm^3 before the final anneal. Cold work was given by a compression testing machine at room temperature. An appropriate lubricant was used to give a deformation as uniform as possible. Quenching was made by pulling out a thin SB glass tube opened to air containing the specimen from a resistance-furnace at a desired temperature onto a copper plate at room temperature.

§ 3. Experimental Results

1. *General*

Attenuation was measured on specimen crystals which were slowly cooled and then cold-worked by compression. The general features will be seen in Fig. 1. Attenuations for crystals quenched from 550° and 700°C are also plotted in this figure. Since measurements were all made above 200°K, it is not clear whether a sharp peak corresponding to the Bordoni peak such as found in metals appears below this temperature or not. A question arises on the origin of the attenuation band near 240°K. Since there has been no indication of any similar side-peak on the higher temperature side of the Bordoni peak in face-centred cubic metals, it may be possible that the phenomenon is based on some characteristics of the dislocations or other imperfections in ionic crystals of NaCl type.

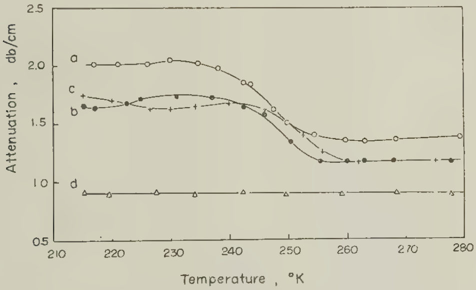

Fig. 1. Attenuations plotted against temperature for cold-worked and for quenched crystals.
(a) Cold-worked by 0.26 precent in compression (specimen No. 29E).
(b) Quenched from 550°C (specimen No. 22A–1).
(c) Quenched from 700°C (specimen No. 27E).
(d) Slowly cooled (specimen No. 9).

The general features of the observed band are:

(1) The band-edge position is independent of strain amplitudes in the range investigated here.

(2) The band-height increases with plastic strain less than 4 percent. For higher strains it does not seem so sensitive to plastic strain as before.

(3) The band-edge shifts to higher temperature with increasing quenching temperature.

(4) The shift of the band-edge also occurs in the case of holding crystals at room temperature after quenching (ageing effect).

(5) The attenuation is sensitive to the frequency of ultrasonics. Curves in Fig. 1 were obtained at 5 Mc/sec. More detailed descriptions for each case will be given in the following.

2. *Anisotropy of attenuation in cold-worked crystals*

When the crystals are compressed in the direction parallel to a cubic axis, the four glide systems, $\{\langle\bar{1}01\rangle/(101)\}$, are equally oriented to the applied stress. It is known that as long as plastic strain is not so large the crystals occasionally deform by the action of a single glide system or double glide systems whose Burgers vectors are perpendicular to each other[15]. If the longitudinal wave excited by the x-cut quartz crystal directs in the direction normal to the Burgers vector of the dislocation concerned, no contribution to the dislocation damping should be expected, since it gives no effective shearing stress acting on it. Therefore, the respective attenuations parallel to three directions normal to each other such as shown in Fig. 2 will constitute an arithmetic relation. A hatching indicated in the inset in the same figure corresponds to the birefringence bands observed by polarizing microscope. We tried to observe the predicted relation on different specimens and obtained

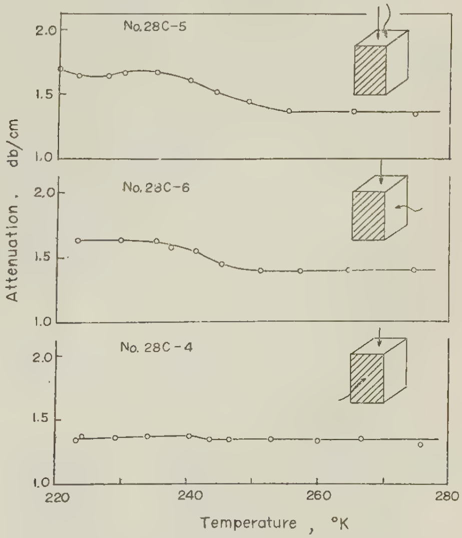

Fig. 2. Orientation dependence of attenuations in cold-worked crystals. A hatching corresponds to the birefringence bands observed by polarizing microscope. Solid arrows indicate the direction of compression and wavy arrows designate the one of incident pulsed waves.

a consistent result in every case as expected. Solid arrows designate the compression axis and wavy arrows correspond to the direction of propagation of longitudinal pulsed waves. The peak attenuation for the specimen No. 28C–5 is approximately equal to the sum of the ones at respective peaks for other two. A very small step can be seen at about 243°K in the case of No. 28C–4. This would be caused either by a small number of the dislocations introduced by cold-working whose Burgers vectors are not normal to the oscillation direction of pulsed waves, or by the possibility that the acoustic waves have a small component of stress parallel to the specimen surface on which the transducer crystal was cemented.

The above observations give doubtlessly an evidence that the attenuation observed is related to the motion of dislocations in crystals. A similar anisotropy of the logarithmic decrement has been observed on zinc single crystals by Read[16], Alers[17], and Waterman[18]. The observations of this sort can offer a most beautiful demonstration of dislocation damping.

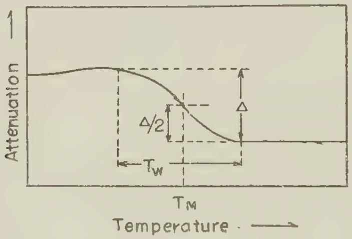

Fig. 3. A schematic illustration for the definition of T_M.

The observed attenuation forms a very broad band showing a spectrum of activation energies. For the sake of brevity, however, we assume the following working hypothesis that the largest activation energy W of the relaxation process is to be determined by using the following equation, i.e.,

$$\frac{W}{R}\left(\frac{1}{T_{M1}}-\frac{1}{T_{M2}}\right)=\log\left(\frac{f_2}{f_1}\right), \qquad (1)$$

for a change in frequency from f_1 to f_2, where R is the gas constant. T_{M1} and T_{M2} are the temperatures for frequencies f_1 and f_2, respectively, corresponding to the half maximum at the band edge. This is schematically illustrated in Fig. 3. Table I sums up all the results of cold-worked crystals in the range of plastic strain 0.2 to 4 percent. The band-edge position is rather independent of ageing time at room temperature after cold work. It must be remembered here that it spent at least one hour for mounting the specimen and lowering temperature before starting measurements. Taking average of T_M shown in Table I, it gives 242°K for 5 Mc/sec and 251°K for 15 Mc/sec. The activation energy thus obtained is 0.44 eV.

3. *Attenuation of quenched crystals*

The attenuation band obtained from crystals quenched from the temperature range of

intrinsic conductivity is very similar to that observed in cold-worked specimens as already shown in Fig. 1. One of the most remarkable features will be the shift of the band edge with increasing quenching temperature. Table II includes all the data on quenched crystals from 550° and 700°C. Another remarkable feature seen in Table II is the shift of the band edge with increasing ageing time at room temperature. The results are illustrated in Fig. 4 for crystals quenched from 700°C. Such effects have not been observed in other materials.

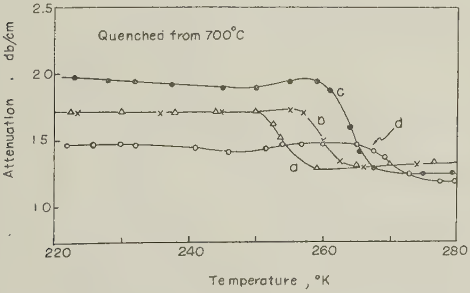

Fig. 4. Frequency dependence of attenuation and its variation with ageing time at room temperature for crystals quenched from 700°C. (a) specimen No. 31 at 5 Mc/sec after 2 hours; (b) specimen No. 30 at 5 Mc/sec after 38 hours; (c) specimen No. 28D-2 at 15 Mc/sec after 6 hours; (d) specimen No. 28D-4 at 15 Mc/sec after 27.5 hours.

In our crystals quenched from 550°C, T_M is 248°K for 5 Mc/sec after about one hour from quenching and it shifts to 250°K after one day at room temperature. For crystals quenched from 700°C, the temperature shifts from 252° to 262°K for 5 Mc/sec with increasing ageing time. This phenomenon is accompanied by a remarkable increase of the activation energy. The following Table III will show such a variation of the activation energy. An increase in the activation energy also occurs when quenching temperature is raised as seen in the same table. The frequency ν_0 in Table III is obtained from the relation $\nu=\nu_0 \exp(-W/kT_M)$, where ν is taken to be the frequency of applied ultrasonics.

Quenching from the temperature range of

intrinsic conductivity will introduce dislocations and vacancies into the crystal. The above effects are hardly explained by a separate action either of the dislocations or of the vacancies. The activation energy for the motion of paired vacancies in KCl is 0.38 eV according to Dienes' calculation[19] and it does not seem to depend upon quenching temperature. Therefore, the motion of paised vacancies is hardly responsible for the observed relaxation. It will be necessary to take account of some correlation characteristic of the ionic crystals between the dislocations and the vacancies for the explanation of the observed phenomena.

§ 4. Discussions

1. *The Bordoni peak*

It has been shown in most experiments concerning the Bordoni peak in metals that the peak temperature for a fixed frequency is independent of the concentration and the nature of the impurities present. Seeger[11] has thus developed his theory of the Bordoni peak in face-centred cubic metals without taking account of the influence of impurities present. It seems to be quite questionable, however, that the impurities attached to the dislocations do not give any influence on the oscillatory motion of dislocations which causes the relaxation to be considered. In fact, the following discussion will lead us to conclude that the low-temperature internal friction peak should generally depend on the point defects present. The degree of the dependence is determined by the nature and the magnitude of interaction between the defects and the dislocation, however.

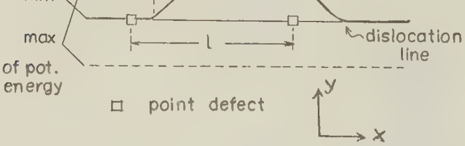

Fig. 5. Transition state in the formation of a kink pair according to Seeger. The effect of point defects attached to the dislocation line is described in the present paper.

Following Seeger and Mason[20] we consider the relaxation process due to the oscillation of a dislocation lying along its potential minimum. The activation energy is given by the formation energy of a half-kink pair. Fig. 5 illustrates the transition state corresponding to the position of maximum energy through which a dislocation segment is thrown to the neighbouring potential minimum. For practical purpose the potential energy of the dislocation line may be given by

$$E(y)=E_0-\alpha\cos\frac{2\pi y}{a}\,, \tag{2}$$

where 2α is the amplitude of the potential and a is the lattice constant. Using this one obtains the activation energy as

$$W=W_k+2\alpha d\,, \tag{3}$$

where W_k is the energy of a kink of width w and d is the optimum length of the dislocation segment at the transition state. Both are given by Seeger as increasing functions of α.

To examine the effect of point defects attached to the dislocation line we will begin with the case where the point defects are elastically bound to an edge dislocation. The interaction potential is given by Bilby (see Cottrell)[21] as

$$U=-A(\sin\theta)/|\boldsymbol{r}|\,, \tag{4}$$

where $|\boldsymbol{r}|$ is the magnitude of the radius vector from the dislocation line to the defect, θ is the angle between $\boldsymbol{r}$ and the Burgers vector of the dislocation, and A is a parameter depending on the elastic constants of the crystal, the lattice constant, and the relative degree of misfit of the defect. $|\boldsymbol{r}|$ should be larger than the core-radius r_0 of the dislocation. Suppose the defects pinning the dislocation line at the points separated by l from each other. Taking the displacement of the dislocation to be $\boldsymbol{\delta}$, the change of the potential will be $-\boldsymbol{\delta}\cdot\nabla U(\boldsymbol{r})$ when $|\boldsymbol{r}|>|\boldsymbol{\delta}|$. One easily finds that the increase of the activation energy is at most one tenth of $|U|_{\max}$ when $l\approx(d_0+w)$. The maximum value of $|U|$ in most cases is taken to be 0.2 eV or less, whereas the activation energy W is found experimentally to be 0.1 eV for aluminium and 0.07 eV for copper. Here the suffix 0 denotes the values for the dislocations free from point defects. Since the Bordoni peak is thought to be caused by fresh dislocations introduced by cold-working, the mean separation l between the pinning points should be large as compared to an equilibrium value, which is attained by the diffusion process. l can be estimated as $4a$ for $|U|_{\max}=0.2$ eV and $200a$ for $|U|_{\max}=0.1$ eV for copper of 99.99 percent purity in equilibrium at room temperature. On the other hand, (d_0+w) is found to be about $60a$ in copper for the applied shear stress smaller by one order of magnitude than the Peierls-Nabarro stress.

At any rate, it is doubtless that the activation energy for the motion of edge dislocations is very sensitive to the impurities. Therefore, the main Bordoni peak in such metals should be thought to be caused by the relaxation associated with the motion of screw dislocations which are less sensitive to the impurities. Besides, it is possible that the activation energy W_0 for the screw dislocations are large as compared with that for the dislocations of other orientation in such metals. This makes much simpler the appearance of the Bordoni peak as observed than in the opposite case.*

The situation is probably more complex in the case of ionic crystals. According to Bassani and Thomson[10], the positive-ion vacancy in NaCl is bound to the dislocation core with the binding energy equal to 0.4 eV. The binding energy of the negative-ion vacancy should be at least as large as that of the positive-ion vacancy. Fig. 6 illustrates the configuration of ions and the negative-ion vacancy in the core of a (110) edge dislocation. When the dislocation proceeds a distance of b in the direction [$\bar{1}10$], the ion configuration (a) changes to the one (b), in which the vacancy is left behind. The core-radius of a (110) edge dislocation in NaCl has been estimated to be $0.75b$ by Huntington *et al*[9]. It may be about the same in KCl. When the dislocation proceeds a unit distance b, therefore, the vacancy is left at the edge of the core. If we apply Eq. (4) to this case, the binding energy is found to be negative and equal to -0.06 eV using Bassani-Thomson's estimate of the relative misfit of the *positive-ion vacancy*. Accordingly, the activation energy for the motion of the dislocation increases by at least 0.4 eV as long as $l<(d_0+W)$. It should be noted that Bassani and Thomson have estimated l at room temperature for annealed NaCl of high purity as about $20a$. While, (d_0+W) can be assumed to be of the same order as that for copper, i.e., $60a$.

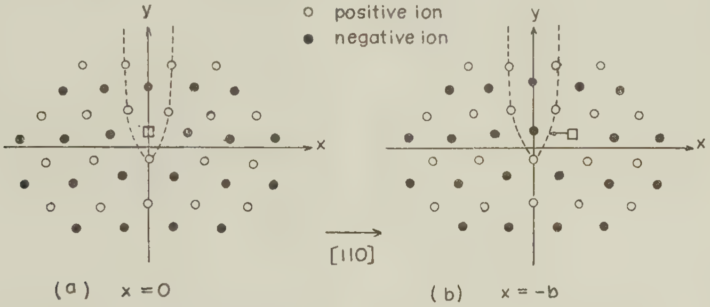

Fig. 6. Ion configuration of a (110) edge dislocation.

(a) illustrates the configuration of the dislocation at $x=0$, and the position of the vacancy in the core according to Bassani and Thomson.

(b) corresponds to the same dislocation proceeded a distance of b to the negative direction of the x-axis. The vacancy left behind tends to follow this motion.

Since the activation energy W_0 is thought to be about 0.1 eV for the crystals concerned, it is quite reasonable to expect a great influence of the vacancies in the dislocation core upon the low-temperature internal friction. It is also natural to expect a spectrum of activation energies depending on various l in cold-worked or quenched crystals, and the ageing effect is also easily understood in taking account of a variation of l with ageing time.

The predicted spectrum of attenuations in KCl is illustrated in Fig. 7(a), whereas the corresponding spectrum for metals of face-centred cubic structure is shown in (b). The main peak in (a) is due to the dislocations free from vacancies. It may happen in cold-worked crystals. The spectrum shown in (b) has been found in copper²⁾,³⁾. It is possible that the impurities elastically bound to the 30°-dislocations is responsible for the subsidiary peak with the activation energy smaller than that of the main peak. Caswell has indeed observed that the subsidiary peak in copper is sensitive to impurities present. A question may be raised in his observation, that is, a slight shift of the main peak to lower temperature with increasing concentration of impurities. A similar observation has also been made by Einspruch and Truell⁴⁾ in aluminium. These facts may be explained by the present prediction as due to the shift of the subsidiary peak to higher temperature.

---

* The above discussion neglected the effects of the separation of a dislocation into two partials.

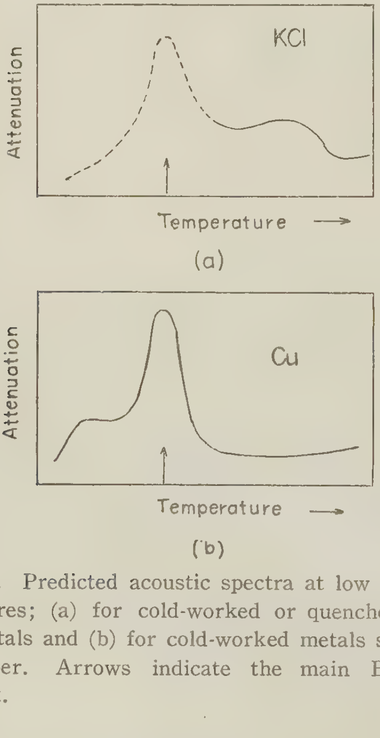

Fig. 7. Predicted acoustic spectra at low temperatures; (a) for cold-worked or quenched KCl crystals and (b) for cold-worked metals such as copper. Arrows indicate the main Bordoni peak.

Although the experimental results on KCl seem to be explained satisfactorily by the above theory, there remains one difficulty, that is, the magnitude of ν_0 corresponding to the value at the attenuation edge as listed in Table III. They are too large to be the frequency with which a rigid dislocation line oscillates in its potential well. The corresponding frequency for copper is calculated as 10^{11} sec^{-1} using Seeger's estimate and 10^{10} sec^{-1} using Mason's estimate. Experimentally, it is obtained as 8×10^{7} sec^{-1} for copper²⁾ and 4×10^{10} sec^{-1} for aluminium⁴⁾. In KCl it will not be much different from these values, even if the strong binding of vacancies to the dislocations is taken into account. It thus appears worth while examining the following possibility to solve the difficulty.

2. *The concurrent motion of vacancies with dislocations*

The possibility to be discussed here is the concurrent motion of vacancies with the dislocation motion. Other possibilities independent of the dislocation motion such as the motion of paired vacancies or vacancy-multivalent impurity pair encounter difficulties in explaining the magnitude of the observed activation energy and its variation with quenching temperature and with ageing time at room temperature.

Kessler⁶⁾ has explained the peak of logarithmic decrement in germanium by the vacancy-drag model following the idea of Cottrell and Jaswon²²⁾. In his theory the vacancies are bound to an edge dislocation by the elastic interaction. The logarithmic decrement is thus predicted to be proportional to the vacancy concentration in the lattice and to the lattice diffusion coefficient of vacancies. These predictions, accordingly, encounter the same difficulties as mentioned above. However, the vacancies in KCl are trapped in the dislocation core and behave quite differently from the above case. It may be possible to alter the general nature of the vacancy-drag process.

When the vacancies are trapped in the dislocation core, the dislocation will be charged either positively or negatively depending upon the effective charge of those vacancies. If crystals such as NaCl are annealed at high temperatures in the range of intrinsic conductivity, the positive-ion vacancies are more easily introduced. Consequently, the dislocations acting as internal sources for vacancies will be oppositely charged to compensate the excess charge introduced. Then the Debye-cloud will be formed around the charged dislocation. This is what Eshelby, Newey and Pratt¹²⁾ have recently discussed as an important origin of critical shear stress of such crystals

Following the above theory, it is expected that as quenching temperature increases the electrostatic potential hill opposing the motion of the vacancies in the dislocation core is raised on account of the increase in the line charge of the dislocation. The motion of dislocation jogs carrying a net charge will also induce a relaxation peak. However, the motion of the jogs with gliding edge dislocation does not need the vacancy diffusion. Accordingly, the potential barrier will be small as compared with that for the above process.

We will discuss following the above interpretation a few points with respect to the activation energy obtained. Although the activation energy for the crystals quenched from 700°C increases appreciably with ageing time at room temperature, the one obtained for the crystals plastically deformed or quenched from 550°C does not seem to alter with ageing time. This will be explained partly because the density of excess vacancies introduced is too low to form the effective Debye-cloud and partly because the ageing process is almost over before starting the measurements. In fact, Fischbach and Nowick[23] have found that the Gyulai-Hartly effect supposed to be caused by the excess free vacancies introduced into NaCl by plastic deformation at room temperature completely dissapeared within about one hour. The number of the vacancies generated by applied stress of 10^7 dynes/cm^2 is estimated to be 10^{15} cm^{-3}. The number of free vacancies in equilibrium at 550°C for KCl is larger only by one order of magnitude than the above value.

According to the above discussions, the activation energy 0.44 eV obtained from cold-worked crystals can be taken to be equal to the one for the motion of the negative-ion vacancy in the dislocation core. This is about one third of the activation energy for the motion of the negative-ion vacancy in the lattice if it is taken to be almost equal to the value in NaCl, which has been directly measured recently[24]. The activation energy to overcome the potential hill due to the Debye-cloud formed at 700°C is thus estimated from Table III as $(0.49-0.44)=0.05$ eV. The increase of the activation energy with ageing time at room temperature after quenching from 700°C, which is equal to (0.12 ± 0.07)eV, may be explained by the increase of the barrier height due to a change in the Debye-radius during the ageing. The phenomenon is then thought to be similar to the one found in additively coloured KCl[13]. The activation energy to overcome the potential barrier is proportional to the inverse root of temperature and other variables are taken to be constant. The increase of the activation energy concerned is thus estimated as

$$0.49\times(\sqrt{700/300}-1)=0.26\,\mathrm{eV}\,.$$

This is not unreasonable as compared with (0.12 ± 0.07) eV as obtained above, if we take into account of the possibility that the crystals are not effectively quenched from 700°C but the number of quenched-in vacancies will correspond to the equilibrium number at lower temperature.

The phenomena are thus qualitatively well explained and the magnitude of the frequency ν_0 is most plausible according to the above mechanism. At present, however, it seems reasonable to conclude that both mechanisms mentioned above in (1) and (2) produce the broad attenuation band in the temperature range investigated.

Finally we would like to remark the effects of the vacancy-drag process upon critical shear stress. They must be known before we discuss the effects of the Debye-Cloud upon critical shear stress. If we take the density of the dislocations ρ and the speed of the dislocations v, then shearing rate is given by

$$\dot{\varepsilon}=b\rho v\,. \tag{5}$$

Since $\dot{\varepsilon}$ is the order of 10^{-3} sec^{-1} under usual conditions and ρ is taken to be the order of 10^6 cm^{-2}, it follows for very small strain as concerned here that

$$v=2.3\times10^{-2}\,\mathrm{cm\cdot sec^{-1}}\,.$$

While, if we consider seriously the present mechanism, it gives from the present measurements as

$$v'=2.2\times10^{-2}\,\mathrm{cm\ sec^{-1}}$$

at about 240°K for the speed of a vacancy in the dislocation core. Accordingly, it will be possible that the vacancies in the dislocation core can follow the motion of the dislocation over some critical distance important for determining critical shear stress. It may be expected, therefore that even in the case where the line charge of dislocations is caused by the vacancies in the cores, not by jogs, critical shear stress of the crystals at relatively high temperatures is influenced by the presence of the Debye-cloud.

Defects in Ionic Crystals,
II. An Analysis of F and V_1 Centers

By Tatsumi KUROSAWA

The Institute for Solid State Physics, University of Tokyo

(Received December 18, 1958)

The deformation of the lattice around F and V_1 (the Seitz' model) centers in alkali halides is determined from the experimental data on the difference between two ionization energies (optical and thermal) of these centers. In the process of the determination, we apply the method which has been developed in the previous paper (J. Phys. Soc. Japan **13** (1958) 153). We find that the lattice deformation is rather small in the case of the F centers, but very large in the case of the V_1 centers.

§ 1. Introduction

Recently, the investigation of the electronic structure of color centers has been developed by many authors. Nevertheless, we know very little about the lattice deformation around the centers. In general, it is very difficult to determine the lattice deformation around a center either experimentally or theoretically. In some cases, however, the following consideration may give a useful information for this purpose, if only the necessary experimental data are available.

As is well-known, the optical ionization energy I_{op} of a center in a crystal is not always equal to its thermal ionization energy I_{th}. This is due to the electron-lattice interaction, and is explained schematically by such a diagram as Fig. 1. Generally, it is very difficult to construct this kind of a diagram with reasonable accuracy. In the cases of F and V_1* centers in alkali halide crystals, however, the construction of the diagram for the ionized state can be performed with reasonable accuracy, because this state is a simple vacancy in an otherwise perfect crystal. Therefore, if the experimental data on the energy difference $(I_{op}-I_{th})$ are available, we can guess the equilibrium configuration of these centers by using the theoretical diagram. Since the problem is to determine the equilibrium configuration in a multi-dimensional space with only one available datum $(I_{op}-I_{th})$, some suitable assumptions are necessary.

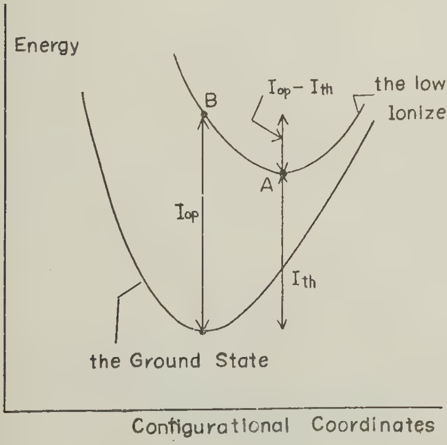

Fig. 1.

In the present paper, the method developed in the previous paper[1)] is applied to compute the energy-configuration diagram of the ionized F and V_1 centers. It is to be noted that the method of Mott and Littleton[2)] is not applicable to the defect which is not in the equilibrium configuration. Using the available data of $(I_{op}-I_{th})$, we determine the ground state configurations of these centers; the deformation of the lattice around the center is small in the case of the F centers, but very large in the case of the V_1 centers.

§ 2. Assumptions and Approximations

In this section we shall summarize assumptions and approximations which we shall adopt throughout this paper.

(1) We calculate the energy-configuration diagrams of the ionized centers by using the method which has been developed in the previous paper. However, since it is difficult to calculate the energy for an arbitrary configuration of the lattice around the center, we adopt an approximate method (see Appendix).

---

* We adopt the model of the V_1 center as suggested by Seitz.

(2) We use the ionic model, where the interionic potentials, the polarizabilities and the short range effect of electronic polarization have been determined in the previous paper.

(3) We assume that the ionic arrangement does not change at the optical transition (the Franck-Condon principle), and that the motion of electrons (for instance, the electronic polarization of the ions around the center) follows any change instantaneously.

(4) We consider only the displacement of the nearest neighbor ions around the center when the F or V_1 center is at the state of the minimum energy. Since these centers are neutral, this assumption may be approximately allowable.

§ 3. *F* Center

As is well-known, an F center consists of a V_- and a trapped electron. Therefore, the state A in Fig. 1 corresponds to the state where a V_- is at its equilibrium configuration and an electron is at the bottom of the conduction band (more precisely, at the lowest polaron state), and in the state B a V_- is surrounded by the ions of the same arrangement as the F center in the equilibrium and an electron is at the bottom of the conduction band (not a polaron state). The energy difference between the state B and A is equal to $(I_{op}-I_{th})$.

Gurney and Mott[3] have calculated the values of I_{th} by using the experimental data of Pohl. Here, we recalculate them by using new data of the formation energy of the Schottky defect. On the other hand, the data of I_{op} are not available except the case of KBr, where the threshold energy $h\nu_{thres}$ of photoconduction due to direct optical ionization of the F center has been measured by Inchauspé.[4]

Now, let us assume that in the state B the nearest neighbour (1, 0, 0) ions are displacing symmetrically around the vacancy, which is situated at the point (0, 0, 0). (This assumption may not be far from truth.) Then, we compute the energy of the V_- of NaCl and KBr crystals in displaced configurations $(1+\xi, 0, 0)$ etc. as a function of the displacement ξ, where the energy is measured from its lowest energy state (Fig. 2). Here we assign the outward displacement positive sign of ξ. As mentioned previously, the displacement of the other ions is assumed to be zero and the electronic polarization is supposed to take its equilibrium value at each displacement ξ.

According to the theory of Lee, Low and Pines,[6] the energy E_p which is necessary to bring an electron from the lowest polaron state to the bottom of the conduction band is given by $\alpha\hbar\omega_l$, where α is the coupling constant between an electron and the polarization field and ω_l is the angular frequency of the longitudinal optical vibration. The numerical values of E_p are shown in Table I, where the effective mass of the conduction band is assumed to be equal to the free electron mass. From these values we may expect that E_p is rather small as compared with the amount of uncertainty of the other quantities, so that we disregard it.

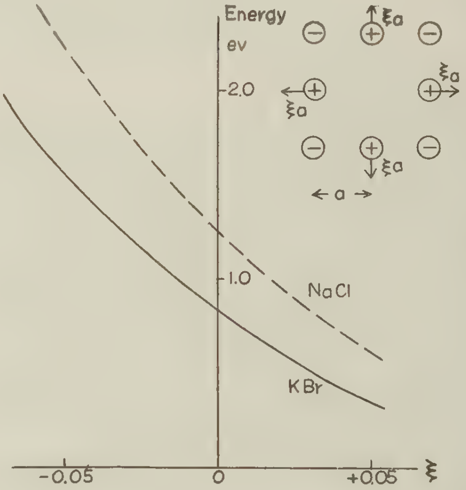

Fig. 2. Energy of a V_- as a function of the displacement of the nearest neighbour ions.

Table I. Energies in eV (F center)

	I_{th}	$h\nu_F$	$h\nu_{thres}$	E_p
NaCl	1,97	2,74		0,18
KCl	2,13	2,31		0,15
KBr	1,88	2,07	3,6	0,12

If we neglect the energy E_p, the energy illustrated in Fig. 2 is to be equal to $(I_{op}-I_{th})$ when ξ takes the value corresponding to the state B. By using the observed data of KBr we estimate: $I_{op}-I_{th}\simeq 1{,}7$ eV and $\xi\simeq -0.06$. We see that the nearest neighbor ions displace inwards in some extent. This result is qualitatively in agreement with the theoretical calculation by Kojima[6] concerning the structure of the F center in LiF; according to his calculation $\xi=-0{,}074$. In the case of NaCl the value of I_{op} is not available. However, it is almost certain that the energy I_{op} is larger than the F band absorption energy $h\nu_F$. That is, $I_{op}-I_{th}>h\nu_F-I_{th}\simeq 0.77$ eV and $\xi<0.04$. At any rate, we find that the deformation of the lattice around the F center seems to be small*.

§ 4. V_1 Center

We assign the Seitz' model to the observed V_1 band,[7] although there are some ambiguities in this assignment. The V_1 center is a peculiar center in the sense that optically it has a deeper level than the F center, but thermally it seems to be very shallow. It is bleached thermally at 128°K in KCl and at 115°K in KBr.[8] Here we shall follow the usual interpretation that the V_1 center is so shallow that the trapped hole is released thermally at such low temperatures, although this interpretation is not unique at present. It is also probable that an electron released from a certain shallow trap annihilates the hole of the V_1 center.[9]

According to the estimation by Dutton and Maurer,[8] the thermal depth of the V_1 center is 0,26 eV in KCl and 0,23 eV in KBr. We assume that these depths correspond to I_{th}, i.e., the energy necessary to decompose a V_1 center into a V_+ in its equilibrium configuration and a hole at the lowest polaron type state.** There remains another possibility, however, that the above-mentioned depth is the barrier height between the lowest state of the V_1 center and the decomposed state. In this case, the values of I_{th} are still more diminished. The energy I_{op} may be larger than the photon energy of the V_1 band absorption $h\nu_V$.

Table II. Energies in eV (V_1 center)

	I_{th}	$h\nu_V$
KCl	0,26	3,48
KBr	0,23	3,02

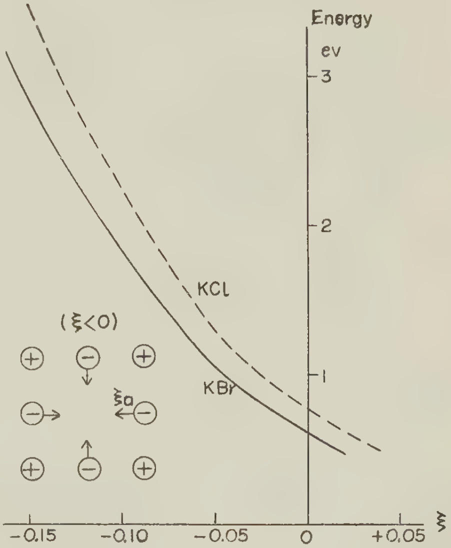

Fig. 3. Energy of a V_+ as a function of the displacement of the nearest neighbour ions (the first model).

In the same way as the case of the F center, we calculate the energy of a V_+ as a function of the displacement of the nearest neighbour ions (Fig. 3). If we take the values, $I_{op}-I_{th}\simeq h\nu_V-I_{th}\simeq 3{,}22$ eV (KCl) and 2,79 eV (KBr), the displacement becomes $-0{,}15a$ and $-0{,}14a$, respectively. We see that the deformation around the V_1 center is quite large as compared with that of the F center.

On the other hand, we think that the

---

* So far we have neglected the displacement of the ions except the nearest neighbor ions. However, the displacement of the other ions may be quite small, because the F center is a neutral one and the orbit of its electron is well localized. Therefore, it would be sufficient to consider the displacement of the second neighbour ions in addition to the nearest neighbours. If the second neighbour ions displace outwards, the energy curve in Fig. 2 goes upwards and the value of ξ where the energy is equal to the observed $(I_{op}-I_{th})$ becomes algebraically larger, and vice versa. In KBr, the displacement of the second neighbour ions around the V_- is estimated to be about $-0.02a$. It is not probable that the displacement would be much larger than this value in the case of the F center. From these considerations we estimate the error in the calculated value of the ξ due to the neglection of the displacement of the other ions as about $0{,}01a$, at most $0{,}02a$.

** Dutton and Maurer have observed a current burst at the thermal bleaching, so that the released hole may not be in such a state as the immobile Känzig's center.

earlier model of Känzig center[10] which was a (halogen$_2$)$^-$ molecular ion accompanied with a V_+, is also possible for the model of the V_1 center. In Fig. 4, the energy contours of a V_+ in KCl are illustrated as a function of the displacement of the two nearest neighbour ions, where all the other ions are fixed at their original sites of the undeformed lattice. In this case, the displacement is about 0,3a. In KBr the situation is nearly the same.

Several points must be mentioned about the reliability of the above results.

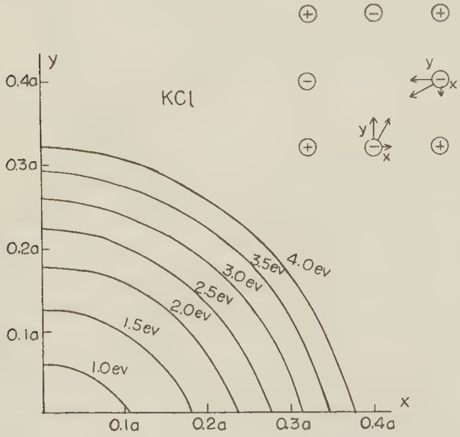

Fig. 4. Energy of a V_+ as a function of the displacement of the two nearest neighbour ions (the second model).

First, the deformation is very large, so that the interionic potentials which have been determined from the data of perfect crystals, may be doubtful. For instance, the short range interaction energy between halogen ions is neglected in our calculations, but it should not be neglected, especially in the case of the second model, because the distance between the relevant halogen ions is very small (about 2,7A in KCl and 2,8A in KBr). However, the determination of the short range energy between two halogen ions with a reliable accuracy is very difficult.

Secondly, the accuracy of our energy form, which is explained in the Appendix, is reduced when the deformation is large. Moreover, we have introduced several simplifying assumptions in the case of the second model so as to avoid cumbersome calculations due to its low symmetry.

Thirdly, the displacement of the other ions may not be small in the case of such a large deformation.

However, all these things get into trouble only when the deformation is large. Therefore, it is certain that the lattice deformation around the V_1 center is large, even if the inaccuracy of the theory affects the detailed results mentioned previously.

Here, we neglect the energy E_p of the hole, which will be larger than that of the electron, because the effective mass of the valence band is heavier than that of the conduction band. But the upper limit of this energy may be of the order of $(1/2)\{1/\mathcal{E}_0)-(1/\mathcal{E})\}(e^2/a)\simeq 0.5$ eV. This does not modify our results considerably.

It is hard to interpret the reason why the lattice deformation around the V_1 center is so large. Although it is out of the scope of our paper to discuss this problem, we shall point out some possibilities.

The first possibility is that the Seitz' model or the interpretation of Dutton and Maurer is incorrect*. In this case, our calculation is meaningless.

Table III. V_1 band absorption (eV).

NaCl	3,59		
KCl	3,48	KBr	3,02
RbCl	3,45	RbBr	2,95

On the other hand, if the Seitz' model and the interpretation of Dutton and Maurer are correct, we are forced to accept the result that the lattice deformation around the V_1 center is large. In the latter case, however, the second model seems to be more favorable than the first to interpret the large deformation. If the model of the Känzig center is true, the existence of the (halogen$_2$)$^-$ molecular ion accompanied with a V_+ is not unreasonable. The second model is also favorable to interpret the fact that $h\nu_V$ depends only on the kind of halogen ions and hardly on alkali ions[11] (Table III). Lambe and West[12] have failed to detect dichroism of the V_1 band. However, if the transition time to convert a V_1 center from a (halogen$_2$)$^-$ configuration to the other (halogen$_2$)$^-$ configuration around the V_+ is sufficiently short*, the dichroism can not be detected. As the transition time depends quite sensitively on the height of the potential barrier to be surmounted, it is possible that the (halogen$_2$)$^-$ state is mobile in the case of the V_1 center but not in the case of the Känzig center.

---

* Delbecq and others[13] have found that the V_1 band is bleached at lower temperature than the Känzig center. If the V_1 center is bleached by the electrons released from the other centers, it is strange that the Känzig center is not bleached at the same time.

We are greatly indebted to Professor J. Yamashita for his helpful discussions.

Appendix

According to the discussion in the previous paper, the energy of a defect is formally given by

$$W(X,\ P,\ x,\ p)=\frac{1}{2}\sum_{\kappa,\lambda} a_{\kappa\lambda}p_\kappa p_\lambda+\sum_{\kappa,\mu} b_{\kappa\mu}p_\kappa x_\mu+\frac{1}{2}\sum_{\mu,\nu} c_{\mu\nu}x_\mu x_\nu+\sum_\kappa f_\kappa(X,\ P)p_\kappa$$
$$+\sum_\mu g_\mu(X,\ P)x_\mu+A(X,\ P)+\phi_0+\sum_\kappa \phi_\kappa{}^p p_\kappa+\sum_\mu \phi_\mu{}^d x_\mu+\Phi(X,\ P)\,, \qquad (\mathrm{A}\cdot 1)$$

where $P\ (\equiv P_1,\ P_2,\ \cdots,\ P_k,\ \cdots)$ and $X\ (\equiv X_1,\ X_2,\ \cdots,\ X_m,\ \cdots)$ represent the electronic polarizations and displacements of the ions in the region near the defect, and $p\ (\equiv p_1,\ \cdots,\ p_\kappa,\cdots)$ and $x\ (\equiv x_1,\ \cdots,\ x_\mu,\ \cdots)$ represent those of the ions in the outer region. In our case, we take the former ions to be the nearest neighbor ions and the latters to be the other ions. The first six terms are the energy necessary to deform the lattice and ions up to a state $(x,\ p,\ X,\ P)$ without the defect, and the last four terms represent the energy necessary to remove the central ion from the lattice to infinity with the fixed state $(x,\ p,\ X,\ P)$.

According to the assumptions in § 2,

$$x_\mu=0 \qquad \text{for all } \mu, \qquad (\mathrm{A}\cdot 2)$$

and the electronic polarizations take their equilibrium values $p_\kappa(X)$'s and $P_k(X)$'s for a given X, that is,

$$\left(\frac{\partial W}{\partial p_\kappa}\right)_{p=p(X),P=P(X)}=0\,, \qquad (\mathrm{A}\cdot 3)$$

or

$$\sum_\lambda a_{\kappa\lambda}p_\lambda(X)+f_\kappa(X,\ P(X))+\phi_\kappa{}^p=0 \qquad \text{for all } \kappa, \qquad (\mathrm{A}\cdot 4)$$

and

$$\left(\frac{\partial W}{\partial P_k}\right)_{p=p(X),P=P(X)}=0 \qquad \text{for all } k. \qquad (\mathrm{A}\cdot 5)$$

If we insert the above x, $p(X)$ and $P(X)$ into $W(x,\ p,\ X,\ P)$, it becomes as follows,

$$W(0,\ p(X),\ X,\ P(X))=\frac{1}{2}\sum_\kappa \{f_\kappa(X,\ P(X))+\phi_\kappa{}^p\}p_\kappa(X)$$
$$+\phi_0+A(X,\ P(X))+\Phi(X,\ P(X))\,. \qquad (\mathrm{A}\cdot 6)$$

It is difficult to solve $p_\kappa(X)$'s for a given value of X. However, when the displacement of the nearest neighbor ions is zero (i.e., no lattice deformation), we can solve $p_\kappa(X)$'s at least approximately. According to the first approximation by Mott and Littleton, $p_\kappa(0)$'s are given by

$$p_\kappa(0)=\frac{ea^3}{2\pi r_\kappa{}^2}\left(1-\frac{1}{\varepsilon_0}\right)\frac{\alpha_\kappa}{\alpha_+ +\alpha_-}\,, \qquad (\mathrm{A}\cdot 7)$$

where r_κ is the distance of the κth ion from the origin, α_κ, α_+ and α_- is the polarizability of the κth, positive and negative ion respectively. Inserting these $p_\kappa(0)$'s into the Eq. (A·6), we can calculate $W(0,\ p(0),\ 0,\ P(0))$. When $X \neq 0$, we avoid the above-mentioned difficulty in the following ways.

---

* If this is true, the strong electric field along the (110) direction may cause a sort of dichroism.

1) In general,

$$|\phi_\kappa{}^p| \gg |f_\kappa(X,\ P(X)) - f_\kappa(0,\ P(0))|\ , \tag{A·8}$$

at least when X is not so large. Therefore we put

$$p_\kappa(X) \simeq p_\kappa(0) \tag{A·9}$$

and then

$$\begin{aligned} W(0,\ p(X),\ X,\ P(X)) &\simeq W(0,\ p(0),\ X,\ P^*(X)) \\ &= \frac{1}{2}\sum_\kappa \{f_\kappa(X,\ P^*(X)) + \phi_\kappa{}^p\} p_\kappa(0) + \phi_0 + A(X,\ P^*(X)) + \Phi(X,\ P^*(X))\ , \end{aligned} \tag{A·10}$$

where $P^*(X)$ are given by

$$\left(\frac{\partial W}{\partial P_k}\right)_{p=p(0),P=P^*(X),x=0} = 0\ . \tag{A·11}$$

2) From Eq. (A·4), we see that

$$\frac{1}{2}\sum_{\kappa,\lambda} a_{\kappa\lambda} p_\kappa(X) p_\lambda(X) = -\frac{1}{2}\sum_\kappa \{f_\kappa(X,\ P(X)) + \phi_\kappa{}^p\} p_\kappa(X)\ . \tag{A·12}$$

Putting $X=0$ in the above equation, we obtain

$$\begin{aligned} W(0,\ p(0),\ X,\ P) = \sum_\kappa p_\kappa(0)\left[\frac{1}{2}\phi_\kappa{}^p + f_\kappa(X,\ P) - \frac{1}{2} f_\kappa(0,\ P(0))\right] \\ + A(X,\ P) + \phi_0 + \Phi(X,\ P) > W(0,\ p(X),\ X,\ P(X))\ . \end{aligned} \tag{A·13}$$

In virtue of this inequality, we can compute the upper bound of the energy. The difference between the above two energy forms (A·10) and (A·13) is very small.

A Semi-empirical Theory of the Conjugated Systems, III. Bond Alternation and Electron Fixation

By Yuzuru OOSHIKA*

Polytechnic Institute of Brooklyn, Broolyn, New York

(Received December 15, 1958)

Extending the previous treatment of the author on the bond alternation in infinite conjugated systems to finite systems, it is investigated why the wave-lengths of some homologous series appear to tend to infinity while those of others to finite limits when the number of carbon atoms increases. It is concluded that the bond alternation does not occur in shorter symmetrical or slightly unsymmetrical chains, while, in strongly unsymmetrical chains, the bond alternation always occurs and that it always occurs in longer chains according to the result in the previous paper.

In the previous paper[1)], the author showed by using his semi-empirical s.c.f. method that the bond alternation in the conjugated polyene chain can actually occur by a bulk effect, not by an end effect as considered earlier. But the treatment there applies only to an infinitely long conjugated chain, and cannot distinguish the difference in the light absorption of symmetrical and unsymmetrical cyanine dyes. Labhart[2)], almost simultaneously with the author, discussed the same problem using the free electron model. His method applies also to chains of finite length, and he showed that, in symmetrical cyanines, the bond alternation does not occur up to about 30 carbon-atom chains. Huzinaga and Hasino[3)], too, discussed the absorption spectra and the bond alternation in conjugated chains by their "bond-orbital" method and obtained agreement between many experimental data and the results calculated from their theoretical formula by adjusting two parameters. In the latter two papers, however, the consideration of the electronic interaction is not very well-formulated. In this note, the author should like to extend his treatment to conjugated chains with finite length and to show the difference between the symmetrical cyanines on one hand and the unsymmetrical cyanines, merocyanines and polyenes on the other.

Consider, at first, an even-membered polyene chain with $2n$ carbon atoms and $2n$ π-electrons. Let the interaction integrals $\left(\beta-\frac{p}{2}\frac{e^2}{R}\right)^{4)}$ be $-\gamma_1, -\gamma_2, -\gamma_1, -\gamma_2, \cdots, -\gamma_1$ $(\gamma_1>\gamma_2>0)$ from the left and alternately. The bond orders are to be different from bond to bond in this case, because all the bonds are not equivalent to each other as contrast to the conjugated ring. But, for simplicity, we shall calculate only the average bond orders for the alternate double (short) and single (long) bonds, respectively. The (average) partial π-bond order for the short and long bonds due to a single molecular orbital

$$p_d(k)=\frac{\sqrt{1+z^2+2z\cos 2k}}{n}\,\frac{(2n+2)+2nz\cos 2k}{(2n+2)+2nz^2+2(2n+1)\cos 2k} \qquad (1)$$

$$p_s(k)=\frac{\sqrt{1+z^2+2z\cos 2k}}{n-1}\,\frac{(2n+z)\cos 2k+2nz}{(2n+2)+2nz^2+2(2n+1)z\cos 2k} \qquad (2)$$

$$z=\gamma_2/\gamma_1\ ,$$

respectively, where k, the value characterizing the molecular orbital, is given by the following simultaneous equations

$$(2n+1)k+2\theta=m\pi\ , \qquad m=1,\cdots,2n \qquad (3)$$

$$\tan 2\theta=\frac{1-z}{1+z}\tan k\ . \qquad (4)$$

The total π-bond orders, P_d and P_s, are calculated by summing up $p_d(k)$ and $p_s(k)$ over filled orbitals, respectively. Then we can obtain approximate s.c.f. orbitals (approximate because of the non-equivalence of different bonds) by the same way as in the previous paper, i.e. calculating p_d and p_s for any given $z(<1)$, deducing z again from the calculated p_d and p_s, and repeating such procedures till s.c.f. orbitals are attained. It may be interesting to calculate the bond order and, hence, the bond length of the particular polyenes and to compare the results with available experimental data. But, here, we need not actually carry out the above procedure, because that the bond alternation occurs in such even-membered polyene chains is self-evident from the result in the previous paper[1]. We shall not discuss these even-membered polyene chain further.

---

* On leave from Kobayashi Institute of Physical Research.

Now we shall consider how the situation is different in odd-membered ($2n+1$-carbon) chain. Let the interaction integrals be $-\gamma_1$, $-\gamma_2, -\gamma_1, \cdots, -\gamma_2$, alternately from the left end of the chain ($\gamma_1>\gamma_2>0$). The molecular orbitals are

$$\psi_k=\frac{1}{n+1}\left[\sum_{s=1}^{n+1}\sin\{(2s-1)k+2\theta\}\psi_{2s-1}\right]$$
$$+\sum_{s=1}^{n}\sin 2sk\psi_{2s} \qquad (5)$$

where ψ_{2s-1} is the atomic orbital on the $2n-1$-th carbon atom, $\tan 2\theta$ is as in Eq. (4), and

$$k=\frac{m}{n+1}\frac{\pi}{2} \qquad m=1, \cdots, n, n+2, \cdots, 2n+1\,. \qquad (6)$$

In addition to the $2n$ molecular orbitals above, we obtain a "surface" (or end) orbital,

$$\psi_0=\frac{1}{\sigma}\left\{\sum_{s=1}^{n+1}\left(-\frac{\gamma_2}{\gamma_1}\right)^{n+1-s}\psi_{2s-1}\right\}\,. \qquad (7)$$

This end orbital is of non-bonding character, and the electron in that orbital is almost localized in one end, which may be called the electron fixation, to distinguish from the electron localization used in the electronic theory of organic reactions. It does not occur in the ordinary treatment of allyl radicals where $\gamma_1=\gamma_2$. The average partial bond orders by orbital k are very simply

$$\left.\begin{aligned} p_d(k)&=\frac{1}{n}\cos(k-2\theta)\\ p_s(k)&=\frac{1}{n}\cos(k+2\theta)\end{aligned}\right\} \qquad (8)$$

for the double and single bonds, respectively.

Then we can calculate bond orders by summing up $p_d(k)$'s and $p_s(k)$'s, respectively. If we neglect the effect of the net charge, the number of electrons in the non-bonding end orbitals does not matter, and the bond orders are the same for $2n$, $2n+1$, and $2n+2$ electrons, i.e. for the cation, the radical and the anion. The actual numerical calculations were carried out by using the values of parameters and the method in the previous paper[4], and it is found that for $n=2$ or 3, i.e., for 5 or 7-membered chain, $z=1$ is the only solution and the bond alternation and the resulting electron fixation cannot occur, and for $n=3$ or 4 it actually occurs. The precision of our numerical calculation prevents our predicting exactly the chain length at which the bond alternation actually begins. In addition, it is sensitive to the values of the parameters. But, in any case, it may be concluded that the bond alternation and the electron fixation do not occur for the shorter chain with carbon atoms less than 7 or 9. The electron fixation and the bond alternation in odd-membered chain are closely related to each other, and if one of them occurs, the other also occurs if we remove one π-orbital and one π-electron from the allyl radical, the remainder is similar to the polyene chain. Then if we can make the electron fixation to occur by a certain method and the remaining system to be polyene-like, the bond alternation may occur for short chains. The electron fixation has previously been pointed out by Nikitiné[5] in his free electron treatment of cyanine dyes, but its connection with the bond alternation was not clear.

Now, the cyanine dye cations have nitrogen-containing nuclei at both ends, where the potential is deeper than at the intermediate portion of the chain. If the coulomb integral (in the sense of the s.c.f. method) at one end is sufficiently more negative than those in the intermediate portion, it may be expected that the two electrons are fixed at the end and that the remaining $2n$ centers and $2n$ electrons constitute a system just like the polyene chain, and then the bond alternation may occur in rather short chains. This is shown as follows.

Let the coulomb integral of the left end atom be α'; those of other atoms be α ($\alpha'<\alpha<0$), and the interaction integrals be $-\gamma$ for all bonds. The simultaneous linear equations for determining the molecular orbitals are now

$$\left.\begin{aligned}&(\alpha'-\mathcal{E})c_1-\gamma c_2=0\\&-\gamma c_1+(\alpha-\mathcal{E})c_2-\gamma c_3=0\\&-\gamma c_2+(\alpha-\mathcal{E})c_3-\gamma c_4=0\\&\cdots\cdots\cdots\cdots\end{aligned}\right\}\qquad(9)$$

If these equations have a solution which damps out towards the right of the chain, i.e.,

$$\left.\begin{aligned}&c_1=1\,,\quad c_2=e^{-k}\,,\quad c_3=e^{-2k}\,,\\&Re(k)>0\end{aligned}\right\}\qquad(10)$$

for a half-infinite chain, e^k is to be equal to $(\alpha-\alpha')/\gamma$. Then, if $\alpha-\alpha'>\gamma$, there exists an end orbital even when the bond alternation does not occur, and the energy of the end orbital is the lowest of all the molecular orbitals. By a similar method, for a symmetrical finite odd-membered chain ($2n+1$-centers, and equal coulomb integrals for both end atoms), it is shown that

$$\frac{\cosh(n+1)k}{\cosh nk}=\frac{\alpha-\alpha'}{\gamma}\qquad(11)$$

or

$$\frac{\sinh(n+1)k}{\sinh nk}=\frac{\alpha-\alpha'}{\gamma}\,.\qquad(12)$$

Then, in the case also, we may consider that the electron fixation occurs if the equations above have solutions with real values of k though the end orbital is not non-bonding. With increasing ratio of $\alpha-\alpha'$ to γ, we, at first, obtain a solution of a real k value by Eq. (11) when the ratio exceeds unity, and then another one by Eq. (12) for a slightly higher value of $(\alpha-\alpha')/\gamma$. Thus, whether the electron fixation does occur or not depends upon the value of $(\alpha-\alpha')/\gamma$. For unsymmetrical odd-membered chains, where the coulomb integrals are α' and α'' for the left and right end atoms, respectively, we cannot carry out such an exact calculation as above, but we may expect that $(\alpha-\alpha')/\gamma$ (or $(\alpha-\alpha'')/\gamma$) is a measure of whether the electrod fixation occurs or not at the left (or right) end. From these discussions, the conclusions below may be deduced:

1. If $(\alpha-\alpha')/\gamma>1$ and $(\alpha-\alpha'')/\gamma>1$, the electron fixation occurs at both ends. The remaining system is of $2n-1$-center and $2n-2$-electron, and just like to an allyl cation with a shorter chain-length than that of the parent cyanine cations. The bond alternation does not occur up to $n=4$ or 5 as shown in the preceding paragraph, and, hence, the absorption wave length seems to increase linearly with the number of carbon atoms.

2. If $(\alpha-\alpha')/\gamma<1$ and $(\alpha-\alpha'')/\gamma<1$, the electron fixation does not occur at both ends, and the system is in itself like to an allyl anion of $2n+1$-center and $2n+2$-electron. The bond alternation does not occur up to $n=3$ or 4, and the absorption wave length is somewhat longer than that in case 1, because the effective chain length is larger by one C–C bond.

The two cases above correspond to symmetrical or slightly unsymmetrical dyes.

3. If $(\alpha-\alpha')/\gamma>1$ and $(\alpha-\alpha'')/\gamma<1$ (or $(\alpha-\alpha')\gamma<1$ and $(\alpha-\alpha'')/\gamma>1$), the electron fixation occurs at the left (or right) end only, and the remaining system is of $2n$-center and $2n$-electron, just like to polyene chains. Hence, the bond alternation does occur even for the shortest chain. This behavior corresponds to that of the strongly unsymmetrical cyanine dyes.

It is now clear from the above conclusion why the absorption wave length of strongly unsymmetrical dyes appears to be convergent while those of symmetrical and slightly unsymmetrical dyes appear to be non-convergent. It depends wholly on the electron fixation and the resulting bond alternation. Using the discussions in this note and the previous one, we need no longer introduce the shady concept that an end effect survives even in an infinitely long chain. The end effect works only at shorter chains.

Galvano- and Thermomagnetic Effects in α-Ag_2Te

By Shin-ya MIYATANI and Isaaki YOKOTA

Department of Physics, Faculty of Science, Niigata University

(Received December 20, 1958)

Nernst coefficient, magnetoresistance, and magnetothermoelectric power together with electrical conductivity, Hall coefficient, and thermoelectric power of α-Ag_2Te are measured as functions of the e.m.f., E of the galvanic cell Ag|AgI|Ag_2Te|Pt, where E may be considered to represent the relative position of the Fermi level in the Ag_2Te specimen. The experimental results exhibit consistent agreement with the Lorentz-Sommerfeld theory for degenerate two-band semiconductors with energy independent mean free paths of carriers. Relative thermal conductivity is also measured, showing minimum at a E value expected from the theory.

§1. Introduction

In the recent work[1] on semiconducting properties of α-Ag_2Te by one of the present authors, it has been shown that electrical conductivity, Hall coefficient, thermoelectric power, and the amount of silver removed from (or supplied to) Ag_2Te specimen across the galvanic cell Ag|AgI|Ag_2Te|Pt as functions of the e.m.f., E, of the cell, while temperature is kept constant, can be consistently interpleted in terms of the Lorentz-Sommerfeld theory, the e.m.f. of the cell being assumed to represent the relative position of the Fermi level in the Ag_2Te specimen. As pointed out there, there has remained some indefiniteness on the energy dependence of the mean free path, l, of carriers. Namely, assuming $l=l_0x^r$ where x is the reduced carrier energy, the two assumed values, $r=0$ (energy independent mean free path) and $r=1/2$ (energy independent relaxation time), have been as well able to account for the experimental results.

In the present work, Nernst coefficient, magnetoresistance, and magnetothermoelectric power of α-Ag_2Te have been measured also as functions of the e.m.f. of the cell, E, for the purpose to determine more accurately the energy dependence of mean free paths of carriers, since these quantities are rather sensitive to the scattering mechanism. As will be seen later, the assumption of energy independent free path length ($r=0$) yields better agreement between theory and experiment for these quantities than that of energy independent relaxation time ($r=1/2$).

By the way, in the β-form of Ag_2Te (stable below ~140°C) there exsist rather complicated situations, that is, the e.m.f. of the galvanic cell seems not to represent the relative position of the Fermi level in the Ag_2Te specimen, indicating that the chemical potential of Ag ion in β-Ag_2Te depends rather sensitively on the composition, and, moreover, the experimental results cannot be accounted for by energy independent mean free paths even when appropriate corrections to the e.m.f. of the cell is made so as to deduce the relative position of the Fermi level. The details will be reported elsewhere.

§2. Theoretical

Here, we summarize the theoretical formulae for the transport coefficients in two-band semiconductors which can be obtained from the Boltzmann equation[2~8]. In the present case of Ag_2Te, the energy gap is so narrow as several kT and effective mass of conduction electrons is so small as $0.1\,m$ (see Table I) that one must take into account the degeneracies of both electrons and holes. The assumptions made are as follows:

(i) The energy momentum relations are of standard form for both electrons and holes $\mathcal{E}=\hbar^2k^2/2m^*$[5].

(ii) There exists the time of relaxation for carriers, τ, which is a function of carrier energy only.

(iii) The mean free path, l, of carriers defined as $l=\tau v$, where v is the carrier velocity, depends on carrier energy as $l=l_0(\mathcal{E}/kT)^r$.

In this paragraph we confine ourselves to the effects which have been measured in the present work. As for other related effects such as Ettinghausen effect and Righi-Leduc effect see the Appendix I.

For convenience of description we first summarize the formulae for single carrier semiconductors²⁾.

(A_1) The electrical conductivity, σ:

$$\sigma=e\mu N\frac{4}{3\sqrt{\pi}}(r+1)F_r(\eta)\,. \tag{1}$$

(B_1) The thermoelectric power, Θ:

$$\Theta=\mp\frac{k}{e}(\beta-\eta)\,. \tag{2}$$

(C_1) The Hall coefficient, R:

$$R\sigma=\mp\mu\alpha\,. \tag{3}$$

(D_1) The Nernst coefficient, Q:

$$Q=\frac{k}{e}\mu(\alpha\beta-\gamma)\,. \tag{4}$$

(E_1) The thermal conductivity, κ.

$$\kappa=\left(\frac{k}{e}\right)^2 T\sigma(\delta-\beta^2)+\kappa_{ph}\equiv\kappa_e+\kappa_{ph}\,. \tag{5}$$

where κ_e is the electronic thermal conductivity and κ_{ph} is the phonon term.

(F_1) The magnetoresistance, B:

$$B=\frac{\Delta\rho}{\rho H^2}=\mu^2(\varphi-\alpha^2)\,. \tag{6}$$

(G_1) The magneto-thermoelectric power, W:

$$W=\frac{\Delta\Theta}{H^2}=\mp\frac{k}{e}\mu^2\{\beta(\varphi-\alpha^2)+\alpha\gamma-\psi\}\,. \tag{7}$$

In Eqs. (2), (3) and (7) the upper sign applies to n-type material and the lower to p-type material. The meenings of the notations above used are as follow:

$$\mu=\frac{el_0}{\sqrt{2m^*kT}} \tag{8}$$

which differs from the ordinary mobility in the classical limit by the factor $3\sqrt{\pi}/4\Gamma(r+2)$.

$$N=2(2\pi m^*kT)^{3/2}h^{-3}\,. \tag{9}$$

η is the reduced Fermi level measured from the edge of the band, i.e. ζ/kT for n-type materials and $(-\zeta-E_g)/kT$ for p-type materials where ζ is the Fermi level measured from the bottom of the conduction band and E_g is the energy gap. $F_r(\eta)$ is Fermi-Dirac function of order r: $F_r(\eta)=\int_0^\infty x^r\,dx/(e^{x-\eta}+1)$. α, β, γ, δ, φ and ψ are functions of η and are defined as ratios of two Fermi-Dirac functions:

$$\left.\begin{array}{lll}\alpha=\dfrac{(2r+\frac{1}{2})F_{2r-(1/2)}}{(r+1)F_r}\,, & \beta=\dfrac{(r+2)F_{r+1}}{(r+1)F_r}\,, & \gamma=\dfrac{(2r+\frac{3}{2})F_{2r+(1/2)}}{(r+1)F_r}\,,\\[2ex] \delta=\dfrac{(r+3)F_{r+2}}{(r+1)F_r}\,, & \varphi=\dfrac{3rF_{3r-1}}{(r+1)F_r}\,, & \psi=\dfrac{(3r+1)F_{3r}}{(r+1)F_r}\,,\end{array}\right\} \tag{10}$$

(Remark: $(s+1)F_s(\eta)$ with $s=-1$ means $(1+e^{-\eta})^{-1}$).

It is straightforward but in some cases rather tedius to generalize above formulae to two-band semiconductors. In doing with the non-isothermal effects, the temperature dependence of the energy gap has been taken into consideration⁷⁾, though it does not explicitly enter into the final expressions. In the followings the suffices 1 and 2 refer to electrons and holes respectively. Especially

$$t_1=\frac{\sigma_1}{\sigma_1+\sigma_2}\,,\qquad t_2=\frac{\sigma_2}{\sigma_1+\sigma_2} \tag{11}$$

are the transport numbers of electrons and holes respectively. We have

(A_2) The electrical conductivity, σ:

$$\sigma=\sigma_1+\sigma_2\,. \tag{12}$$

(B_2) The thermoelectric power, Θ:

$$\Theta=t_1\Theta_1+t_2\Theta_2\,. \tag{13}$$

(C_2) The Hall coefficient, R:

$$R\sigma=t_1(R\sigma)_1+t_2(R\sigma)_2\,. \tag{14}$$

(D_2) The Nernst coefficient, Q:

$$Q=t_1Q_1+t_2Q_2-t_1t_2\frac{k}{e}(\beta_1+\beta_2+g)(\mu_1\alpha_1+\mu_2\alpha_2)\,, \tag{15}$$

where g is the reduced energy gap: $g=E_g/kT$.

(E$_2$) The electronic thermal conductivity, κ_e:

$$\kappa_e=\kappa_{e,1}+\kappa_{e,2}+t_1t_2\left(\frac{k}{e}\right)^2 T\sigma(\beta_1+\beta_2+g)^2\ . \tag{16}$$

(F$_2$) The magnetoresistance, B:

$$B=t_1B_1+t_2B_2+t_1t_2(\mu_1\alpha_1+\mu_2\alpha_2)^2\ . \tag{17}$$

(G$_2$) The magneto-thermoelectric power, W:

$$W=t_1W_1+t_2W_2+t_1t_2\frac{k}{e}\{(\beta_1+\beta_2+g)(\mu_1{}^2\varphi_1-\mu_2{}^2\varphi_2)$$
$$-(\mu_1\alpha_1+\mu_2\alpha_2)[(t_1\mu_1\alpha_1-t_2\mu_2\alpha_2)(\beta_1+\beta_2+g)+\mu_1(\alpha_1\beta_1-\gamma_1)-\mu_2(\alpha_2\beta_2-\gamma_2)]\}\ . \tag{18}$$

In the above, σ_1 and σ_2 are given by Eq. (1) with appropriate respective parameters, and so on. It is easy to see that these agree with those derived by Putley[3] in the limit of Boltzmann statistics with energy independent mean free path of carriers except Eq. (18) to which the corresponding equation is missing in his paper.

We notice that for $r=1/2$ (energy independent relation time) $\alpha=\varphi=1$ and $\beta=\gamma=\psi$, and hence Nernst coefficient, magnetoresistance and magnetothermoelectric power vanish except for the mixed conduction region where both electrons and holes contribute to the conduction.

§ 3. Comparison with Experiment

The experimental arrangements are same as previously reported[1]. In α-Ag$_2$Te the electron mobility is far larger than the hole mobility ($\mu_1\sim 80\mu_2$, see Table I) and hence we are allowed to neglect all terms involving μ_2 in Eqs. (14) to (18). We then rewrite Eqs. (13) to (18) in the forms which will be convenient for comparing with experiment in the present work. We have:

(B$_2$) Thermoelectric power:

$$\theta\equiv\Theta\frac{e}{k}=-(\beta_1-\eta_1)+t_2(\beta_1+\beta_2+g)\ . \tag{13a}$$

(C$_2$) Hall coefficient:

$$R\sigma=t_1\mu_1\alpha_1\ . \tag{14a}$$

(D$_2$) Nernst coefficient:

$$q\equiv Q\frac{e}{k\mu_1}=t_1\{(\eta_1-\theta)\alpha_1-\gamma_1\}\ . \tag{15a}$$

(E$_2$) Electronic thermal conductivity:

$$\bar{\kappa}_e\equiv\kappa_e\left(\frac{e}{k}\right)^2\frac{1}{T}$$
$$=\bar{\kappa}_{e,1}+\bar{\kappa}_{e,2}+t_1t_2\sigma(\beta_1+\beta_2+g)^2\ . \tag{16a}$$

(F$_2$) Magnetoresistance

$$b\equiv\frac{B}{\mu_1{}^2}=t_1(\varphi_1-t_1\alpha_1{}^2)\ . \tag{17a}$$

(G$_2$) Magneto-thermoelectric power

$$w=\frac{We}{k\mu_1{}^2}=-t_1\{(\eta_1-\theta)(\varphi_1-t_1\alpha_1{}^2)$$
$$+\alpha_1\gamma_1t_1-\psi_1\}\ . \tag{18a}$$

Fig. 1 shows σ/μ_1, t_1, $R\sigma/\mu_1$ and θ vs eE/kT

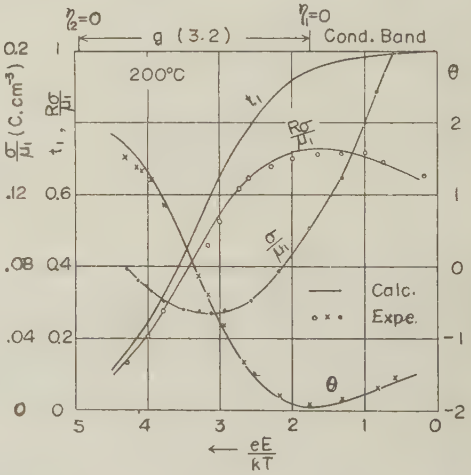

Fig. 1. σ/μ_1, t_1, $R\sigma/\mu_1$ and θ vs eE/kT at 200°C. $\mu_1=1700$ cm^2 sec^{-1} volt^{-1}.

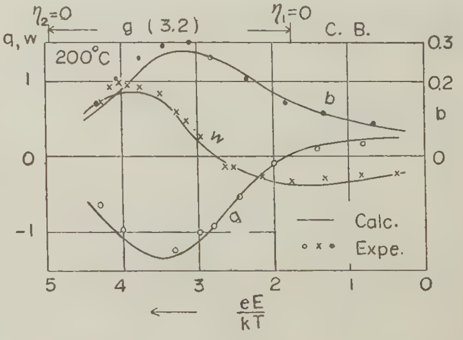

Fig. 2. q, b, and w vs eE/kT at 200°C.

plots at 200°C (see also Figs. 3, 10 and 12 in the reference (1)), and Fig. 2 shows q, b and w vs eE/kT plots at the same temperature where E is the e.m.f. of the galvanic cell Ag|AgI|Ag_2Te|Pt. As noted at the end of the preceding paragraph, if $r=1/2$ is valid then q, b and w should vanish in the limit of $t_1=1$ (at the right-hand parts of the plots). As seen in Fig. 2, this is not the case, indicating that $r=1/2$ is not valid. Therefore, we construct the theoretical curves assuming $r=0$ in the following way. At first, comparing log σ vs eE/kT plot with log F_0 vs η curve we determine the position of the bottom level of the conduction band (eE/kT value corresponding to $\eta_1=0$) and $\mu_1 N_1$ so as to give the best fit at the right-hand part of the plot where electron conduction is far predominant. Thus we determine the electron conductivity σ_1 and accordingly the transport number, t_1, of electrons as functions of η_1.

Next, E_g/kT and accordingly the top level of the valence band are determined from the eE/kT value (η_1 value) at the reversal of experimental Θ by making use of Eq. (13a). Further μ_1 is determined from $R\sigma$ by making use of Eq. (14a). Then we have all parameters necessary for calculating θ, $R\sigma/\mu_1$, q, b and w. The numerical values of α, β, γ, δ and φ, as functions of η for $r=0$ are tabulated in the Appendix (II). Calculated curves are shown in the figures in full lines. As seen in the figures, the agreement between the experimental plots and the calculated curves is satisfactorily good, indicating that $r=0$ (energy independent mean free paths of carriers) is valid for α-Ag_2Te.

Table I.

Temperature (°C)	$\frac{4\mu_1}{3\sqrt{\pi}}$ (cm² s⁻¹v⁻¹)	m_1^*/m	$\frac{4}{3\sqrt{\pi}}\mu_2$	m_2^*/m	E_g (mv)
165	1.5×10^3	0.077	18	1.5	95
220	1.1 〃	0.093	16	1.7	140
300	0.76 〃	0.11	13	1.7	180

The effective mass of electron can be obtained from μ_1 and $\mu_1 N$ above determined. As for the effective mass and μ_2 of holes, we can determine them from the analysis of the amount of silver removed from Ag_2Te specimen across AgI vs eE/kT plot and conductivity vs eE/kT plot; the former should represent $n_2-n_1=2/\sqrt{\pi}\cdot(N_2F_{1/2}(\eta_2)-N_1F_{1/2}(\eta_1))$ vs η_1 apart from an additive constant. For the details, refer to the reference (1). In Table I, being the revision of the table in the reference (1) where $r=1/2$ is assumed, the effective masses and the mobilities of carriers thus determined are tabulated together with energy gap for three temperatures in the α-range.

We have measured also the relative value of the thermal conductivity which may be determined from the ratio of the temperature drops across the two specimens, one to be measured and the other to be refered (see Fig. 3). The measured relative thermal conductivity shows a minimum at eE/kT value just expected from the theoretical expression for electronic thermal conductivity, Eq. (16a).

This work was supported by the research grant of the Ministry of Education.

JOURNAL OF TEH PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 6, JUNE, 1959

On the X-Ray Diffuse Scattering by 1-3-5-Triphenylbenzene

By M. Shehata FARAG

National Research Centre, Dokki, Cairo-Egypt

(Received May 6, 1958)

In crystalline 1-3-5-triphenylbenzene every four molecules form a pseudo-hexagonal *orthorhombic* unit cell with the [100] as the pseudo-hexagonal axis. The deviation from hexagonal symmetry which is only 0° 19′ is discussed in terms of both the crystal structure and the diffuse scattering reflections shown by a Laue photograph taken with the X-ray beam parallel to the [100] axis. Two other Laue photographs with the X-ray beam parallel to the [010] and [001] axes are given. All the diffuse scattering reflections in the three photographs are indexed and the types of elastic waves (of thermal origin) affecting the crystal lattice are revealed.

§ 1. Introduction

1-3-5-Triphenylbenzene $C_6H_3\ (C_6H_5)_3$ crystallises in the orthorhombic system. It has been crystallographically studied by Knopp and Arzruni; their results have been quoted by Groth[1]. The a-and c-axes given in Groth are now interchanged and the original c-axis is halved. This interchange is necessary, because the crystal, as shown by Lonsdale and Orelkin[2], is polar.

The crystal structure was completely solved by the author by the method of double Fourier series and three dimensional line syntheses. The unit cell dimensions are:

$a=7.47\pm0.02$ Å, $b=19.66\pm0.05$ Å,
$c=11.19\pm0.03$ Å.

The space group is $Pna2_1$, with four molecules per unit cell.

§ 2. Pseudo-Hexagonal Symmetry

From the values of "b" and "c". ($c/b\approx\tan 30°$) it is clear that the crystal is pseudo-hexagonal with "a" as the pseudo-trigonal axis. The deviation from pseudo-hexagonal symmetry is 0° 19′.

Fig. 1 shows, in projection, the orthorhombic unit cell (of sides ob and oc) with its pseudo-hexagonal dimensions. The crystal structure analyses show that the molecules are arranged in two layers apporximately at $x=1/4$, $3/4$ and are nearly parallel to the (200) planes. The fractional coordinates of the centre of the molecules as given by the author[3], are (0.250, 0.169,–0.011). For the sake of the present argument these are approximately (1/4, 1/6, 0). This approximation will not upset the final conclusion. According to the space group symmetry the coordinates of the centres of the molecules in the two layers are approximately:

First layer: (1/4, 1/6, 0); (1/4, 4/6, 1/2)
Second layer: (3/4, 2/6, 0); (3/4, 5/6, 1/2)

If these coordinates are referred to a hexagonal unit cell, they show clearly the presence of a trigonal axis perpendicular to each layer as can be seen in Fig. 1. These axes, although parallel to the a-axis of the orthorhombic unit cell, are not coincident, the lateral shift being $b/6=3.28$ Å as we go from layer to layer. Had there been no shift, the unit cell would have been a true hexagonal one. This difference being 3.28 Å is quite considerable, and is presumably associated with the absence of a true trigonal axis in both the crystal and molecule.

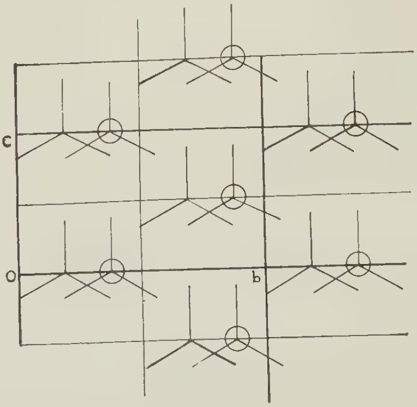

Fig. 1.

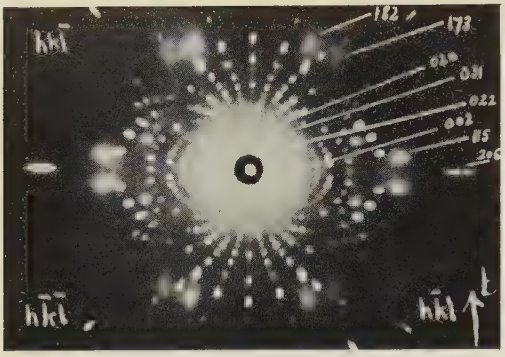

Fig. 2-a. The beam is along [100], the [010] is vertical.

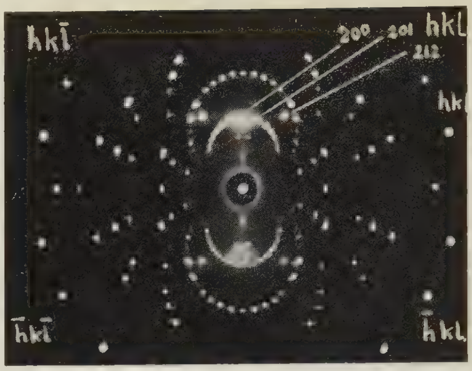

Fig. 3. The beam is along [010], the [100] is vertical.

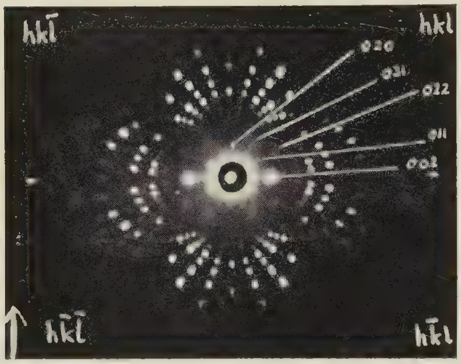

Fig. 2-b.

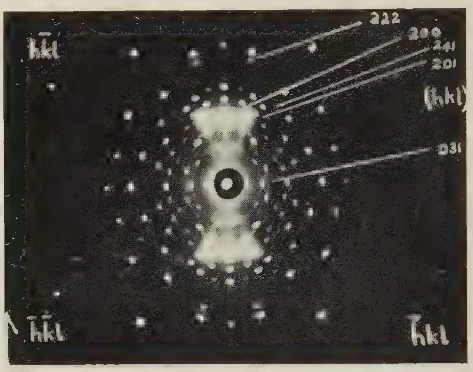

Fig. 4. The beam is along the [001], the [100] is vertical.

Table I.

Direction of X-ray beam	Diffuse reflection observed		
	Index	Shape	Intensity
[100]	(020)	very small, circular	weak
	(002)	small, circular	very strong
[010]	(200)	large, elliptical	very strong
	(002)	absent	absent
[001]	(200)	large, elliptical	very strong
	(020)	absent	absent

Figs. 2-a and -b, 3 and 4 show three Laue photographs taken with the X-ray beam parallel to [100], [010], and [001] axes respectively. The Laue spots in them show that the crystal has an mmm symmetry, while the extra spots, i.e., the diffuse scattering reflections in photograph Fig. 2 show a well marked pseudo-hexagonal symmetry.

The diffuse scattering reflections in each photograph were indexed by comparing the Laue photographs with 10° oscillation photographs taken on flat films at the same crystal-film distance (3 cm.) and with the Laue positions as centres of oscillations, Bernal[4)], Lonsdale and Smith[5)]. The indices of the Bragg reflections corresponding to the diffuse scattering reflections are shown on the photographs.

The striking similarity between Fig. 2-a and Fig. 1 is evident. The signs of pseudo-hexagonal symmetry exhibited in photograph Fig. 2 are shown by the following groups of diffuse reflections:

(a) The diffuse scattering pattern of (182), $(18\bar{2})$, $(1\bar{8}\bar{2})$, $(1\bar{8}2)$, (173), $(17\bar{3})$, $(1\bar{7}\bar{3})$, $(1\bar{7}3)$ and

(115), (11$\bar{5}$), ($\bar{1}\bar{1}$5), (1$\bar{1}$5) shows a well marked hexagonal symmetry. It is of interest to consider the (0kl) planes which pass through the intersections of the previous planes and the (100), i.e. the (082), (08$\bar{2}$), (0$\bar{8}\bar{2}$), (0$\bar{8}$2), (073), ···; and (015), ···. These planes have nearly the same spacings, lie at 60° approximately to each other if taken in a cyclic order (as will be shown) and the reflections from them are relatively of large amplitudes as can be seen from the following data:

Plane:	(082)	(073)	(015)	
Spacing:	2.28	3.25	2.22 Å	
$\lvert F(\text{obs})\rvert$:	42	71	70,	on the absolute scale, cf. F (000)=648

The angle between (082) and (073)=60° 20′ and
The angle between (073) and (015)=59° 41′

(b) The diffuse reflections of (011), (01$\bar{1}$), (0$\bar{1}\bar{1}$), (0$\bar{1}$1) and (020), (0$\bar{2}$0) show also signs of hexagonal symmetry, which could be seen in Fig. 2-a and not in Fig. 2-b. This is due to the central halo in the latter. The spacings and $\lvert F(\text{obs})\rvert$'s of the corresponding Bragg reflections are:

Plane:	(011)	(020)	
Spacing:	9.74	9.83 Å	
$\lvert F(\text{obs})\rvert$:	46	48,	on the absolute scale.

The angle between (011) and (020)=60° 19′

(c) There are diffuse reflections for the (002), (022), ··· and none at all for their pseudo-hexagonal repetitions, i.e. for the (040) and (0$\bar{4}$0); but the Bragg reflections have nearly the same structure amplitudes as shown by the following data:

Plane:	(022)	(040).	
Spacing:	4.87	4.92 Å	
$\lvert F(\text{obs})\rvert$:	41	44,	on the absolute scale.

The angle between (022) and (040)=60° 19′

(d) The diffuse reflections of the (002), (00$\bar{2}$) and their pseudo-hexagonal repetitions, the (031), (03$\bar{1}$), ··· form another group, but the diffuse scattering reflection of the (002) *is much stronger* than that of the (031). This corresponds to the amplitudes of the Bragg reflections which are of very different values. The spacing and $\lvert F(\text{obs})\rvert$'s of these planes are:

Plane:	(002)	(031)	
Spacing:	5.60	5.70 Å	
$\lvert F(\text{obs})\rvert$:	140	8,	on the absolute scale.

The angle between (002) and (031)=59° 40′

§ 3. Types of Diffuse Reflections

a) *Large elliptical or circular diffuse reflections*

In photographs Figs. 3 and 4, there are large elliptical and circular diffuse spots associated with the (200) and (201). They indicate that the structure is of a layer type (Lonsdale and Smith⁵⁾), the (200) being the molecular plane rather than the (201). This is the case as shown by the author³⁾.

b) *Diffuse streaks*

Diffuse streaks characteristic of chain structures, can be seen in photograph Fig. 3, associated with the Bragg reflections (135), (13$\bar{5}$), ($\bar{1}$3$\bar{5}$) and ($\bar{1}$35). This indicates that the atoms form a chain-like-arrangement in planes perpendicular to the previous planes. There are other chains in the structure which should produce similar diffuse streaks on Laue photographs if the crystal has the proper orientation to show them. To reveal all such chains, a series of increasingly mis-set Laue photographs would be necessary.

c) *Small circular diffuse reflections* (*anisotropic*)

It may be seen that although the diffuse scattering reflection of the (002) is very strong in photograph Fig. 2, where the X-ray beam is parallel to the [100] axis, no traces of any diffuse scattering for it are present in photograph Fig. 3 where the X-ray beam is parallel to the [010] axis. The fact is noticeable since in reciprocal space the point corresponding to the (002) lies symmetrically to both the a^*- and b^*-axes. Had the distribution of the diffuse reflecting power about the 002 reciprocal lattice point been spherical or nearly so, one would expect a diffuse reflection corresponding to it to appear in both photographs, Figs. 2 and 3.

These two photographs show that the reflecting power of that plane is extended considerably in the "a^*" direction only in the (a^*–c^*) plane but not in the "b^*" nor in the "c^*" directions in the (b^*–c^*) plane. One concludes from the photographs that the diffuse reflecting power about the 002 reciprocal lattice point is of *a needle* shape whose length is parallel to the a^*-axis and its cross section is circular. In terms of the crystal structure, and according to Born⁶⁾ and Lonsdale⁷⁾

this implies that there are elastic waves of large amplitude affecting the (001) planes and travelling only along the [100] axis.

It should be mentioned here that it is a general rule that elastic waves propagated along a given direction in the crystal cause an extension of the reflecting power of each reciprocal lattice point along the direction of propagation. The diffuse reflections of (011), (022), (031), ⋯ are also such that the diffuse reflecting powers of the points corresponding to these planes in reciprocal space are extended along the [100] axis only.

§ 4. Atomic Movements

To picture the kind of elastic waves, of thermal origin, that affect the crystal lattice, we have to consider the diffuse reflections corresponding to the axial planes. These are sufficient since in the orthorhombic system, the axes of the triaxial ellipsoid representing the physical properties coincide with the crystallographic axes. These are given in Table I. These diffuse reflections show that:

(i) There are *transverse* elastic waves of large amplitude travelling along the crystal [100]-axis such that the (001) planes are strongly affected and the arrangement of the atoms in these planes along the [010] direction is relatively unaffected. Such waves give a strong diffuse reflection for the (002) when the X-ray beam is parallel to the [100]-axis and none for that plane if the X-ray beam is parallel to the [010]-axis.

(ii) Since the (200) gives large elliptical diffuse reflections when the beam is parallel to the [010] and [001] axes, then it implies the presence of waves strongly affecting those planes and travelling in all directions in the crystal. These waves include *transverse*, *longitudinal* and other combinations of them.

(iii) Waves travelling along the [100]-axis such that the (010) planes are affected are highly damped.

(iv) Waves causing oscillational vibrations of the molecules in the (100) planes are forbidden. Such waves, if exist, would affect the relative arrangement of the atoms along the [010]-axis, and would produce a diffuse reflection for the (002) when the beam is along the [010] axis.

All such waves are of thermal origin, and it would be interesting to study the thermal conductivities of the crystal along its three crystallographic axes.

In conclusion the author wishes to record his sincere thanks to Professor Dame Kathleen Lonsdale F.R.S., D.B.E. for her help, criticism and encouragement while this work was in progress.

Metamagnetism of Methylamine Chrome Alum

By Kazuo MOTIZUKI

Department of Physics, Osaka University, Japan

(Received February 18, 1959)

Methylamine chrome alum shows an antiferromagnetic ordering below 0.015°K–0.02°K and it is known that this ordering results from the magnetic dipole-dipole interaction among the chromic ions. The present paper investigates, on the basis of the molecular field approximation, the phenomenon of transition below the Néel point from the antiferromagnetic state to the paramagnetic state caused by an applied field, at constant temperature or at constant entropy. Depending on the direction of the applied field relative to the crystalline axes and also on the shape of sample, different behaviours of the transition are obtained. For a spherical sample three are studied, namely, the cases of $\boldsymbol{H}//[111]$, $\boldsymbol{H}//[100]$ and $\boldsymbol{H}//[10\bar{1}]$, and for an infinitely long sample two cases, i.e., the axis of the sample and $\boldsymbol{H}$ are both parallel to either [111] or [100]. In Appendix is given a summary of the previous theoretical study by Kanamori, Motizuki and Yosida of the same kind of antiferro-paramagnetic transition in two-sublattice antiferromagnet, in relation to the present investigation.

§ 1. Introduction

Methylamine chrome alum is a well-known substance used for adiabatic demagnetization.[1] The magnetic and thermal properties of this salt below 1°K have been studied by several authors, with powder samples[2),3] or with single crystals,[4)-8] and an antiferromagnetic transition has been discovered at about 0.015°K–0.02°K.[4),7] Van Vleck[9] and Hebb and Purcell[10] investigated theoretically the paramagnetic properties of this substance at relatively high temperatures, by the moment expansion method, and O'Brien[11] extended their studies to the antiferromagnetically ordered state, using the molecular field approximation, and has shown that the antiferromagnetic ordering results mainly from the magnetic dipole-dipole interaction among the chromic ions.

In this alum, the chromic ions are situated on the face-centred cubic lattice and the symmetry of the crystalline field at each chromic ion is trigonal, with its trigonal axis pointing along one of the body diagonals. In this crystalline field, the electronic state of the free chromic ion, ^4F, is split in such a way that the ground orbital state is non-degenerate and the two Kramers doublets belonging to it have spin components ±3/2 and ±1/2 along the trigonal axis, the ±3/2 doublet lying lower. The energy difference between these two doublets, δ, has been estimated to be about 0.25°K[12] (in temperature scale), which is about ten times as large as the antiferromagnetic transition temperature, T_N. Therefore, near or T_N, only the lower Kramers doublet should be populated and the spin is to be tightly bound along the trigonal axis. We shall confine ourselves to this temperature range.

The face-centred cubic lattice of the chromic ions can be divided into four simple cubic sublattices whose crystalline fields have their trigonal axes pointing along [111], $[1\bar{1}\bar{1}]$, $[\bar{1}1\bar{1}]$ and $[\bar{1}\bar{1}1]$. We shall denote their magnetizations by J, K, L and M respectively. For a spherical sample, the interaction energy between these four sublattices can be written, according to O'Brien, as

$$\mathscr{H}=-\mu(JK+JL+JM+KL+KM+LM) \quad (1)$$

where μ is the interaction constant and we understand by J, K, L and M the thermal average values of the atomic magnetic moments of the sublattices, measured respectively along their unique axes. The interaction is mainly of the magnetic dipole character and μ is therefore positive according to O'Brien, so that the state with $J=K=L=3\mu_B$ or $-3\mu_B$ is the most stable state at absolute zero in the absence of any external field. The corresponding ordering of the spins is antiferromagnetic in the sense that the total magnetic moment is zero, although the four spin directions are not antiparallel to one another.

The purpose of the present paper is to investigate, on the basis of the interaction energy (1) and the approximation of the molecular field, the phenomenon of the transition from antiferromagnetic state to paramagnetic state due to applied field. Depending on the direction of the applied field relative to the crystalline axes, different behaviours of the transition will be predicted. We shall treat particularly the cases in which the external field is applied parallel to [111], [100] and [10$\bar{1}$].

The antiferro-paramagnetic transition by application of a magnetic field has been studied by several authors for the ordinary two-sublattices antiferromagnet. Garrett[13] has studied this phenomenon for the case where the exchange interaction acts only between different sublattices and has shown that the transition is always of the second kind. The present author, in collaboration with Kanamori and Yosida,[14] has extended Garrett's theory to the case where there exist exchange interactions not only between different sublattices but also within the same sublattice. The exchange interactions have been assumed to be anisotropic. It was found, for instance, that the antiferro-paramagnetic transition for a field applied along the easy axis of magnetization is not always of the second kind; if antiferromagnetic interaction acts not only between different sublattices but also in the same sublattice, the type of the transition changes from the second kind to the first kind with lowering temperature. Gorter and Van Peski-Tinbergen[16] studied independently the same problem and arrived at the same results. Since, however, our study was published in Japanese and treats the problem a little more in detail than Gorter et al. do, we shall summarize in Appendix the most essential part of it which is intimately connected with the present problem.

§ 2. Change of Magnetization due to Application of a Magnetic Field

In the presence of an external magnetic field, $\boldsymbol{H}$, the effective magnetic field acting on each ion of sublattice J is given, corresponding to (1), by

$$H_{J,eff}=\mu(K+L+M)+H\cos\theta_J \tag{2}$$

where θ_J is the angle between the external magnetic field and the trigonal axis of this sublattice. Similar expressions are given for sublattices K, L and M. In (2), the demagnetizing field is included in $\mu(K+L+M)$, assuming the sample to be spherical. Later in § 3 we shall consider the case of an infinitely long sample, in which case $\mu(K+L+M)$ must be corrected for different demagnetizing field.

In the effective field (2), the chromic ion takes energy values $-3\beta H_{J,eff}$ and $+3\beta H_{J,eff}$, where β is the Bohr magneton. Therefore the molecular field theory gives the equation

$$\tanh\frac{3\beta}{kT}\left[\mu(K+L+M)+H\cos\theta_J\right]=\frac{J}{3\beta}. \tag{3}$$

For the sake of simplicity, we shall use the following reduced quantities:

$$\begin{aligned}&a=J/3\beta,\ b=K/3\beta,\ c=L/3\beta,\ d=M/3\beta;\\&x=9\beta^2\mu/kT=T_N/3T;\\&h=H/3\beta\mu,\ h_J=h\cos\theta_J,\quad\text{etc.}\end{aligned} \tag{4}$$

Here $T_N=27\beta^2\mu/k$ is the Néel temperature when there is no external field. Then, Eq. (3) and the corresponding equations for K, L and M can be written

$$\begin{aligned}x(b+c+d+h_J)&=\tanh^{-1}a,\\x(a+c+d+h_K)&=\tanh^{-1}b,\\x(a+b+d+h_L)&=\tanh^{-1}c,\\x(a+b+c+h_M)&=\tanh^{-1}d.\end{aligned} \tag{5}$$

We shall solve these equations for the following three special cases.

a) The external field is parallel to [111].

In this case Eqs. (5) become

$$\begin{aligned}x(b+c+d+h)&=\tanh^{-1}a,\\x(a+c+d-h/3)&=\tanh^{-1}b,\\x(a+b+d-h/3)&=\tanh^{-1}c,\\x(a+b+c-h/3)&=\tanh^{-1}d.\end{aligned} \tag{6}$$

From these equations it follows that $b=c=d$, since b, c and d are uniquely determined from these equations by giving a, x and h, as one can verify easily, and $b=c=d$ is compatible with these equations. Thus Eqs. (6) reduce to

$$\begin{aligned}x(3b+h)&=\tanh^{-1}a\,,\\x(a+2b-h/3)&=\tanh^{-1}b\,.\end{aligned} \tag{7}$$

These equations can be solved easily at absolute zero and the result for the total magnetization, a–b, is plotted against h in Fig. 1.

At an arbitrary temperature, it is convenient to use a graphical method to solve Eqs. (7). Curves of constant temperature, x, and curves of constant field, h, are drawn in the a, b-plane, and the intersecting points are looked for. These curves are given in Fig. 2 and Fig. 3. The total magnetization, a–b, as a function of h, at two temperatures $T=(2/3)T_N$ and $T=T_N$, is given in Fig. 4. It is seen that there are three different solutions, (A), (B), (C), on the lower field side. Two of them, (B) and (C), join smoothly with each other at a certain field, above which they cease to exist. This field is $h=9$ at 0°K; since the unit of the field is $3\beta\mu=34.0$ oe., $h=9$ corresponds to 306 oe.. When the temperature is raised, it shifts towards the lower field side and the area enclosed by (B) and (C) decreases. At $T=T_N$ the area vanishes and (A) becomes a broken curve shown in Fig. 4. Fig. 5 shows schematically the vari-

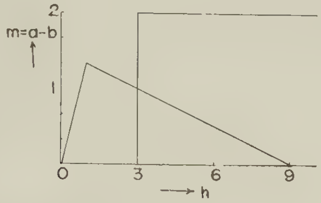

Fig. 1. Magnetization, $m=a-b$, versus applied field along [111] at 0°K.

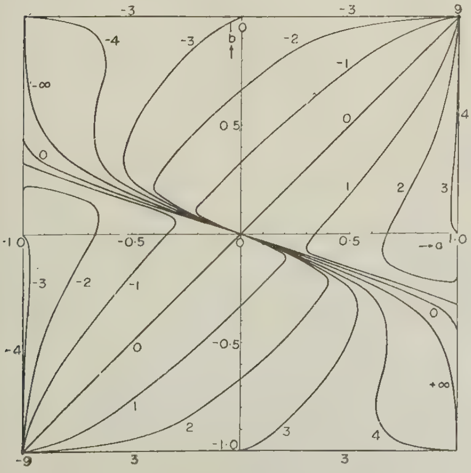

Fig. 3. Curves of constant field in the a, b-plane. $\boldsymbol{H}$//[111].

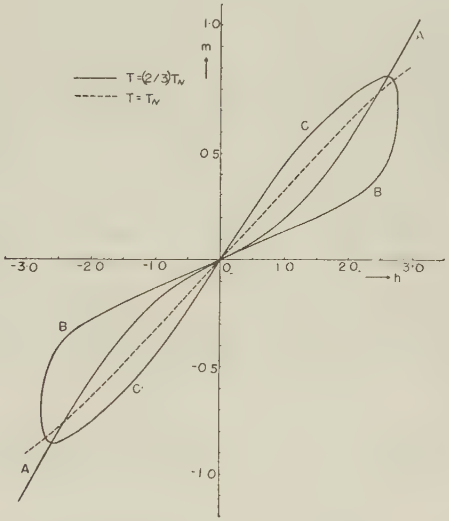

Fig. 4. Magnetization, $m=a-b$, versus applied field along [111] at $T=(2/3)T_N$ and $T=T_N$.

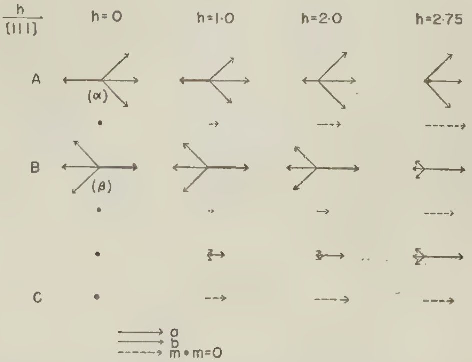

Fig. 5. Behaviours of a, b and $m=a-b$ with applied field.
Three cases A, B and C correspond, respectively, to the solutions (A), (B) and (C) given in Fig. 4.

ations of a, b and $m=a-b$ with varying external field, corresponding to the three solutions. If the field is reversed, the signs of a and b are reversed.

At $T=0$, a and b are zero for the solution (C). Therefore this solution corresponds to the paramagnetic state which must be unstable. Corresponding to (A) and (B), there are two states which are degenerate at $h=0$. In one of them, the spin directions of the four sublattices are $[111]$, $[1\bar{1}\bar{1}]$, $[\bar{1}1\bar{1}]$, $[\bar{1}\bar{1}1]$, as shown in Fig. 5, (β), and in the other all the spin directions are reversed, (α). The crystal may consist of antiferromagnetic domains of these two states at $h=0$ and $T=0$. However, when the field is applied along [111], the domain structure will vanish and the magnetization will follow the curve (A) starting from (α), as this curve will give a higher magnetization than the curve (B). Decreasing the field and further reversing its direction, one will perhaps observe the following hysteresis effect: the magnetization will first come back along (A), then, after passing through the origin, will follow the curve (B) since the sudden change from (α) to (β) at the origin might not take place easily, and finally at a certain negative field it will change over to the curve (A).

b) The external field is parallel to [100].

Evidently, $a=b$ and $c=d$ in this case. Thus Eqs. (5) become

$$\begin{aligned} x(a+2c+h/\sqrt{3})&=\tanh^{-1} a,\\ x(c+2a-h/\sqrt{3})&=\tanh^{-1} c. \end{aligned} \tag{8}$$

At absolute zero, the relation between h and $a-c$ ($=\sqrt{3}/2$ times the total magnetization in the direction of the external field) is easily obtained and is shown in Fig. 6. Our previous theory[14] of the two-sublattices model can be applied for the present case, taking the molecular field coefficients A and Γ in the ratio 2:1 (A is the coefficient of the molecular field in one sublattice due to the other sublattice and Γ that due to the same sublattice). Then equations determining the sublattice magnetizations of the two-sublattices model become equivalent to Eq. (8). For the details, the reader is referred to Appendix, where different cases are classified according to different values of $\lambda=\Gamma/(A+\Gamma)$, including $\lambda=1/3$. Here we only summarize our results:

1) At temperatures above t_1 (measured in units of T_N), defined in 3) of Appendix, the antiferro-paramagnetic transition due to application of a magnetic field is of the second kind, as predicted by Garrett.[13]

2) At low temperatures below t_2 ($<t_1$), defined also in Appendix, the antiferro-paramagnetic transition is of the first kind.

3) In the temperature range between t_1 and t_2, transition occurs twice. The first transition occurs from an antiferromagnetic state to another antiferromagnetic state and it is of the first kind. A further transition occurs from the latter to the paramagnetic state at a higher field and it is of the second kind.

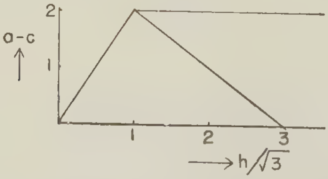

Fig. 6. Magnetization, a-c, versus applied field along [100] at 0°K.

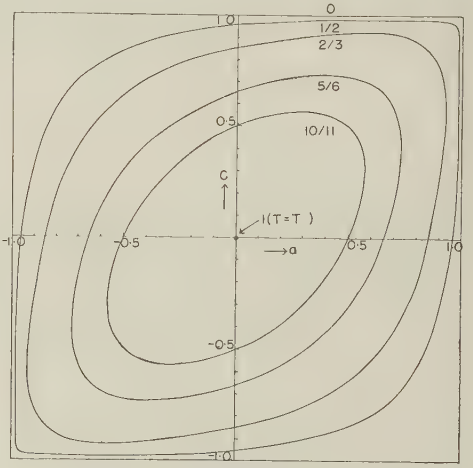

Fig. 7. Curves of constant temperature in the a, c-plane. $\boldsymbol{H}$//[100].

To estimate temperatures t_1 and t_2, a graphical method was used. Curves of constant temperature, x, and curves of constant field, h, corresponding to Eqs. (8) are drawn as given in Fig. 7 and Fig. 8; their intersecting points correspond to antiferromagnetic and paramagnetic solutions. The antiferromagnetic solution coincides with the paramagnetic solutions ($a=-c$) at the following critical curve (see Fig. 9)

$$1/x_c=3(1-a^2)\,,$$
$$h_c/\sqrt{3}=a+3(1-a^2)\tanh^{-}a. \qquad (9)$$

According to our previous theory (given in Appendix), there exists in the temperature range $t>t_1$ ($t=1/3x=T/T_N$) only one antiferromagnetic solution below h_c and none above h_c (Fig. A. 4 (e)). On the other hand, between t_1 and t_2 there exist two or three antiferromagnetic solutions in a certain narrow field range which lies below h_c (Fig. A. 5 (2)).

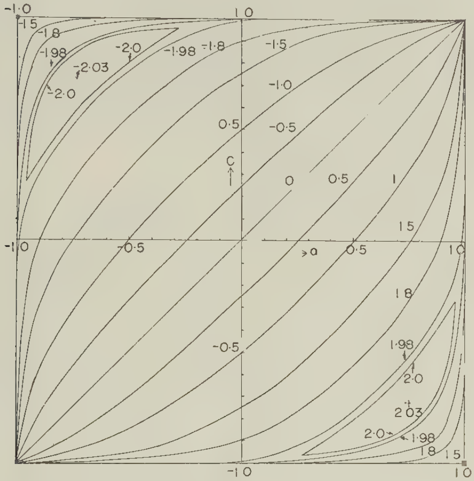

Fig. 8. Curves of constant field in the a, c-plane. $\boldsymbol{H}$//[100].

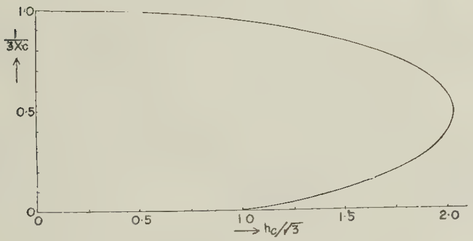

Fig. 9. Critical curve, $1/3x_c$ vs. $h_c/\sqrt{3}$.

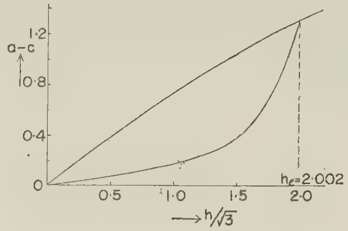
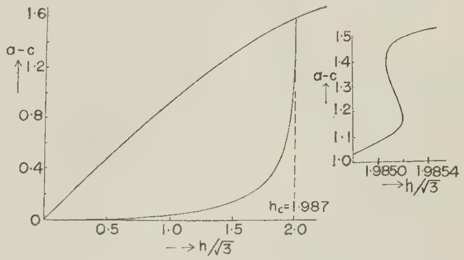
From the intersecting points of curves of Fig. 7 and Fig. 8 above $t=0.467$ (at which h_c attains its maximum) we find only one antiferromagnetic solution for $h\leq h_c$. We see therefore that t_1 is lower than 0.467. As an example the magnetization curve at $t=0.564$ is shown in Fig. 10(a). As another example, we took $t=0.360$ and made a numerical calculation, and found that at this temperature there is only one solution at $h=h_c$ ($=1.9865$) but there are three solutions at $h=h_c-0.0013$. Fig. 10(b) shows the magnetization curve at this temperature. Therefore, t_1 must lie in the range $0.360<t_1<0.467$, and probably very close to 0.360.

Next we estimate t_2. At this temperature, there exist three antiferromagnetic solutions at $h=h_c$, one of which coinciding with the paramagnetic solution; a transition of the first kind must occur at h_c. According to our previous theory, t_2 is greater than $4/3-1/3\lambda$, which is equal to 1/3 in the present case of $\lambda=1/3$. The magnetization curve at $t=0.340$ is shown in Fig. 10(c); it can be seen that at this temperature the antiferro-paramagnetic transition is of the first kind but occurs at a field a little higher than h_c (a little to the right of the vertical broken line, as the two areas enclosed by this line and the curve are unequal). Therefore, t_2 must be between 0.340 and 0.360.

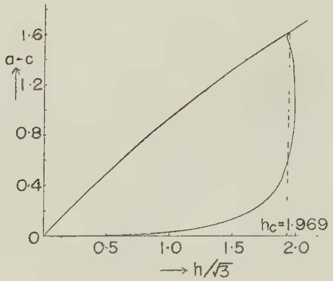
The temperature range between t_1 and t_2 may be too narrow to be of practical interest.



a) $T=0.564T_N$,



b) $T=0.360T_N$



c) $T=0.340T_N$.

Fig. 10. Magnetization, $a-c$, versus applied field along [100] at constant temperature.

c) The external field is parallel to $[10\bar{1}]$.

In this case the external field is perpendicular to a and c, and Eqs. (2) become

$$\begin{aligned} &x(b+c+d)=\tanh^{-1} a, \\ &x(a+c+d+2h/\sqrt{6})=\tanh^{-1} b, \\ &x(a+b+d)=\tanh^{-1} c, \\ &x(a+b+c-2h/\sqrt{6})=\tanh^{-1} d. \end{aligned} \tag{10}$$

Subtracting the third equation from the first one, we obtain $xc+\tanh^{-1} c=xa+\tanh^{-1} a$, so that $a=c$. Therefore Eqs. (10) reduce to

$$\begin{aligned} &x(a+b+d)=\tanh^{-1} a, \\ &x(2a+d+2h/\sqrt{6})=\tanh^{-1} b, \\ &x(2a+b-2h/\sqrt{6})=\tanh^{-1} d. \end{aligned} \tag{11}$$

As a is perpendicular to the external field, the total magnetization in the direction of the external field is $b-d=m$ times $\sqrt{2/3}$. Writting $b+d=m'$, Eqs. (11) can be written as follows:

$$\begin{aligned} &m^2=m'^2+4-4m' \Big/ \tanh\left[\frac{m'+4a}{m'+a}\tanh^{-1} a\right], \\ &x=\frac{\tanh^{-1} a}{m'+a}, \\ &\frac{4}{\sqrt{6}}h=m+(m'+a)\tanh^{-1}\left[\frac{m}{1-(m'^2-m^2)/4}\right] \\ &\qquad \Big/ \tanh^{-1} a. \end{aligned} \tag{12}$$

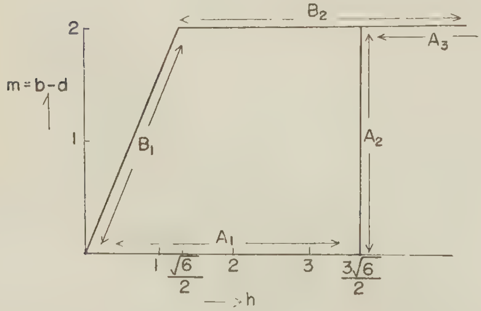


Fig. 11. Magnetization, $m=b-d$, versus applied field along $[10\bar{1}]$ at 0°K.

The relation between h and m at absolute zero is shown in Fig. 11. The portions of this curve denoted by A_1, B_1, etc. correspond to the following states:

A_1: two states, $a=c=1$, $b=1$, $d=1$ and $a=c=-1$, $b=-1$, $d=-1$, of an equal energy.

A_2: two states, $a=c=1$, $b=1$, $-1\leq d\leq 1$ and $a=c=-1$, $-1\leq b\leq 1$, $d=-1$.

A_3: two states, $a=c=1$, $b=1$, $d=-1$ and $a=c=-1$, $b=1$, $d=-1$.

B_1: one state, $a=c=0$, $b=(\sqrt{6}/3)h$, $d=-(\sqrt{6}/3)h$.

B_2: one state, $a=c=0$, $b=1$, $d=-1$.

A_3 and B_2 have an equal total magnetization but the respective values of a and c are different. The energy value is lower in A_3 than in B_2. Therefore the magnetization, m, changes along A_1, A_2 and A_3 with increasing external field.

At an arbitrary temperature the relation between m and h cannot be obtained analytically. However, the paramagnetic solution at finite temperatures which joins B_1 and B_2 at absolute zero can easily be obtained putting $b=-d$ $(m'=0)$. Then the relation between m, h and x becomes

$$h=\frac{\sqrt{6}}{2}\left[\frac{1}{x}\tanh^{-1}\frac{m}{2}+\frac{m}{2}\right]. \tag{13}$$

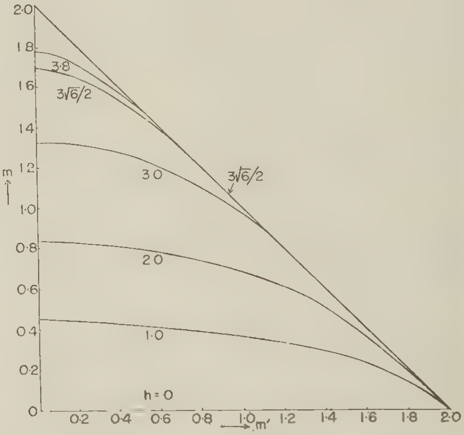

Fig. 12. Curves of constant temperature in the m, m'-plane. $\boldsymbol{H}//[10\bar{1}]$.

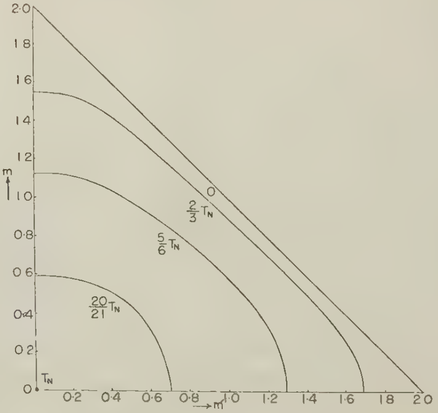

Fig. 13. Curves of constant field in the m, m'-plane. $\boldsymbol{H}//[10\bar{1}]$.

Next, in order to obtain antiferromagnetic solutions ($m'\neq 0$), curves of constant temperature and curves of constant field in the $m\sim m'$ plane were calculated with the use of Eqs. (12) (Fig. 12 and Fig. 13). (In this calculation, a was calculated as a function of m and m' from the first equation of (12) and then x and h were calculated.) At $T=T_N$ the curve of constant x shrinks to the origin and at $T\fallingdotseq 0$ the curve becomes a straight line, $m=2-m'$. The limiting value of m for $m'\to 0$ is given, as a function of x, by

$$m^2=4-\frac{4(1-x)}{x(1+3x)} \qquad \text{for } \frac{1}{3}\leq x\leq 1 \quad \left(\frac{T_N}{3}\leq T\leq T_N\right),$$

$$m=2 \qquad \text{for } 1\leq x \left(T\leq\frac{T_N}{3}\right).$$

In Fig. 13, all curves for $h\leq 3\sqrt{6}/2$ go through a point $m=0$, $m'=2$; at $h=3\sqrt{6}/2$, there are two branches, one of which is a straight line, $m=2-m'$, and the other is a curve bending downwards, both starting from $m=0$, $m'=2$; for $h>3\sqrt{6}/2$, the curve starts at a point $m=2$, $m'=0$, goes down almost along the straight line $m=2-m'$, down to certain point, and then returns in the region enclosed by the two curves for $h=3\sqrt{6}/2$ to a point on the m-axis. In Fig. 13, only the returning part is shown, since the first part is not discriminable from that straight line. At $h=\infty$, the curve becomes a point ($m=2$, $m'=0$).

Looking for the intersecting points of these sets of curves, we obtain the $m\sim h$ relation corresponding to antiferromagnetic solution. In the temperature range $T_N/3\leq T\leq T_N$, there is one antiferromagnetic solution below h_c, at which it coincides with the paramagnetic solution and the transition is of the second kind. As an example, the curve of $m\sim h$ at $T=(2/3)T_N$ is shown in Fig. 14. The transition field h_c is given by

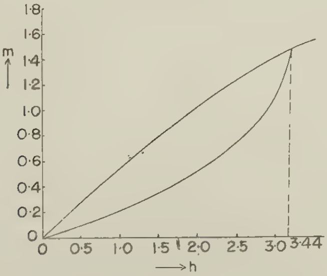

Fig. 14. Magnetization, $m=b-d$, versus applied field along $[10\bar{1}]$ at $T=(2/3)T_N$.

$$\frac{2}{\sqrt{6}}h_c=\left[1-\frac{T(3T-T_N)}{T_N(T+T_N)}\right]^{1/2} +3\frac{T}{T_N}\tanh^{-1}\left[1-\frac{T(3T-T_N)}{T_N(T+T_N)}\right]^{1/2}. \tag{14}$$

When the temperature approaches $T_N/3$, the transition field increases indefinitely. Below $T_N/3$, the antiferromagnetic and paramagnetic solutions do not meet at a finite field strength, so that we have no sharp antiferro-paramagnetic transition.

§ 3. The Case of Infinitely Long Sample

In this section we shall consider the case of an infinitely long sample. The field is assumed as applied parallel to its axis.

If the axis of the sample is parallel to one of the symmetry axes of the crystal, the demagnetizing field is zero. In such a case, the effective field given by Eq. (2) must be corrected as

$$\begin{aligned} H_{J,eff}&=\mu(K+L+M)+H\cos\theta_J \\ &\quad+\frac{4\pi}{3}\left[J-\frac{1}{3}(K+L+M)\right]\times\frac{N}{4} \\ &=\mu[k\{J-(K+L+M)/3\}+(K+L+M)] \\ &\quad+H\cos\theta_J\,, \end{aligned} \tag{15}$$

where $k=\pi N/3\mu=1.71$, if the value of μ given by O'Brien[11] is used. We shall study how the magnetization curve undergoes a change for the present case. Comparing Eq. (15) with Eq. (2), it will be seen that, in the case of $\boldsymbol{H}//[111]$ and $\boldsymbol{H}//[100]$, the correction due to the absence of the demagnetizing field in the present case can be made by altering the scale of the applied fild; namely, one has only to use $h-km$ instead of h for the curves of Fig. 4 and Fig. 10, respectively.

In the case of $\boldsymbol{H}//[111]$, the behavior of the magnetization curve in qualitatively the same as that of Fig. 4. However, in the case of $\boldsymbol{H}//[100]$, for which we have now $\lambda=0.71$ ($\lambda=1/3$ in the spherical case), we are in the region $1/2<\lambda<1$ (see Appendix). Therefore the feature of the transition becomes simpler. Namely, at temperatures below $0.87T_N$ the transition is of the first kind and above $0.87T_N$ it is of the second kind.

§ 4. Magnetization Versus Applied Field at Constant Entropy

At temperatures as low as 0.01°K, experiment at constant temperature may not be practicable. Therefore, we shall calculate the magnetization curve at constant entropy.

In the molecular field approximation, the entropy of system is represented by the sum of the entropy of each spin:

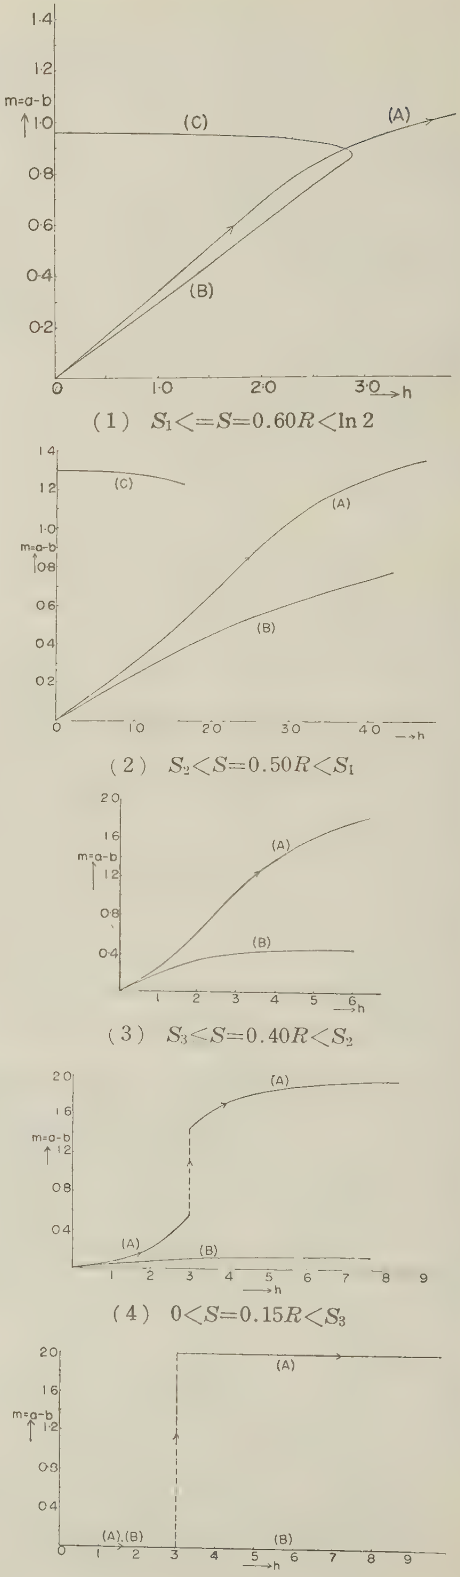
$$\frac{S}{R}=\ln 2-\frac{1}{8}[(1+a)\ln(1+a)+(1-a)\ln(1-a)]$$
$$-\text{similar terms in } b,\ c \text{ and } d, \tag{16}$$

where a, b, c and d are the sublattice magnetizations. We shall consider the case of spherical sample and treat the cases of $\boldsymbol{H}//[111]$ and $\boldsymbol{H}//[100]$, but not the case of $\boldsymbol{H}//[10\bar{1}]$ which requires a more laborious calculation. We look for the intersecting points of curves of constant entropy and curves of constant field, the latter being given in Fig. 2 and Fig. 8.

a) $\boldsymbol{H}//[111]$

Curves of total magnetization, $m=a-b$, at different entropy values are shown in Fig. 15. There are three critical entropy values, $S_1>S_2>S_3$, which are calculated to be $0.52R$, $0.44R$ and $0.17R$, respectively. For $S>S_1$, there are three different solutions, (A), (B) and (C), up to a certain field, but only (A) beyond it. (B) and (C) join smoothly with each other (Fig. 15(1)). At maximum value of entropy, $S=\ln 2$, the loop consisting of (B) and (C) shrinks to nothing and (A) coincides with the abscissa. In the entropy range between S_1 and S_2, (B) and (C) do not join (Fig. 15(2)) and with decreasing entropy from S_1 to S_2, (C) diminishes and finally vanishes at $S=S_2$. Between S_2 and S_3 there are two solutions, (A) and (B), (B) ceasing to exist beyond a certain field (Fig. 15(3)). Below S_3, (A) shows a discontinuity at $h=3$ (Fig. 15(4)). At zero entropy, solution (A) jumps from $m=0$ to $m=2$ at $h=3$ (Fig. 15(5)).

These three solutions correspond to those at constant temperature in Fig. 4. Two of them, (A) and (B), have an equal energy at $h=0$ and (C) has a higher energy. It might be noted that, when S and H are taken as independent variables, differential enthalpy $dH=TdS-MdH$ is to be considered, instead of differential Gibbs free energy $dF=-SdT-MdH$, to treat the thermodynamical equilibrium; thus, for $dS=0$ the state of minimum



(1) $S_1<=S=0.60R<\ln 2$

(2) $S_2<S=0.50R<S_1$

(3) $S_3<S=0.40R<S_2$

(4) $0<S=0.15R<S_3$

(5) $S=0$

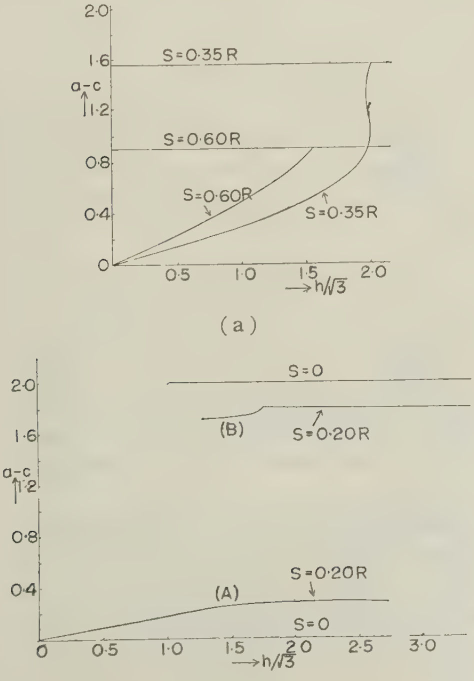
Fig. 15. Magnetization, $m=a-b$, versus applied field along [111] at constant entropy.

magnetization energy $\left(=-\int MdH\right)$ will be realized. So the magnetization will follow the curve (A). The same kind of hysteresis effect as that described in § 2 a) is expected in this case.

b) ***H***//[100]

The intersecting points of curves of constant entropy and curves of constant field give antiferromagnetic solutions ($a \neq -c$) and a paramagnetic solution ($a=-c$). One of these antiferromagnetic solutions coincides with the paramagnetic solution at the critical field h_c given by Eq. (9). For the paramagnetic solution, the magnetization curve at constant entropy is a horizontal line, $a-c=2a=$ constant. The antiferromagnetic solutions behave in the following way.

There are again three critical values of S, $S_1>S_2=0.35R>S_3$. In the entropy range $\ln 2>S>S_1$, there exists only one antiferromagnetic solution below h_c and none above h_c. (At $S=\ln 2$, it disappears.) In the range $S_1>S>S_2$, which is probably very narrow, there exist two or three antiferromagnetic solutions in a certain narrow field range which is below h_c. The magnetization curves for $S=0.60R$ ($>S_1$) and $S=0.35R$ ($=S_2$) are shown in Fig. 16(a).



(a)

(b)

Fig. 16. Magnetization, $a-c=(\sqrt{3}/2)m$, versus applied field along [100] at constant entropy.

Below S_2, the magnetization curve separates into two branches. As an example the magnetization curve at $S=0.20R$ is shown in Fig. 16(b); (A) and (B) represent these two branches. The gap between these two curve may have been caused by our use of the molecular field approximation. If we could calculate the entropy to a better approximation, they might have joined smoothly to each other. For $S=0$, curve (A) coincides with the ordinate for $0 \leq h \leq 3$ and curve (B) becomes one point, $a-c=2$, $h=1$, as shown in Fig. 16(b).

The antiferro-paramagnetic transition is of the second kind at entropies above S_1. In a narrow range between S_1 and S_3, we have two transitions. The first transition occurs from an antiferromagnetic state to another antiferromagnetic state and is of the first kind. A further transition occurs from the latter to the paramagnetic state at a higher field and it is of the second kind. At entropies below S_3, antiferro-paramagnetic transition is of the first kind. These features are similar to those at constant temperature.

§ 5. Conclusion

We have calculated the magnetization curve versus external field at constant temperature and at constant entropy to study the nature of the antiferro-paramagnetic transition.

Interesting results obtained are different behaviors of the transition depending on the direction of the applied field.

The results at constant temperature for spherical sample can be summarized as follows:

a) When the field is parallel to [111], the total magnetization follows the curve (A) in Fig. 4; there is no sharp transition. One expects a hysteresis effect that on reversing the field direction the magnetization will follow curve (B) for a while and then jump over to curve (A).

b) When the field is parallel to [100], there is an antiferro-paramagnetic transition. At temperatures above t_1 (t_1 is between 0.360 and 0.467 and close to 0.360), the transition of the second kind, and below t_2 ($0.340<t_2<0.360$) it is of the first kind. In the temperature range between t_1 and t_2, transition occurs twice. The first transition is from an antiferromagnetic state to another antiferromagnetic state and it is of the first kind. The second transition which occurs at a higher field is from the second antiferromagnetic state to the paramagnetic state and is of the second kind.

c) When the external field is parallel to $[10\bar{1}]$, which is perpendicular to two of the four sublattice spin axes, the antiferro-paramagnetic transition is of the second kind and it occurs only at temperatures above $(1/3)T_N$; there is no transition below $(1/3)T_N$.

Very similar results are predicted for the magnetization at constant entropy.

Calculations at constant temperature have also been made for infinitely long sample to which a field is applied parallel to its axis. In this case we have the following results:

a) When the axis is parallel to [111], the magnetization curve is qualitatively the same as that for spherical sample.

b) When the axis is parallel to [100], the antiferro-paramagnetic transition is of the first kind below $0.87T_N$ but it is of the second kind above $0.87T_N$.

We have assumed that the sublattice spins are tightly bounded along the respective trigonal axes of the crystalline fields (the three-fold axes of the crystal). However, at high field, where the Zeeman energy becomes comparable to or larger than the Kramers doublet separation, δ, there will be a thermal excitation to the upper Kramers doublet and the spin direction will be able to deviate from the trigonal axis. In such a case our conclusion has to be modified.

The writer would like to express her sincere thanks to Professor T. Nagamiya for suggesting this problem and for his help and encouragement. She is also indebted to Dr. J. Kanamori for valuable discussion.

Appendix.

Transition from Antiferromagnetic to Paramagnetic State by an Applied Field

We introduce the following effective field acting on each spin of the positive and negative sublattices:

$$H_{eff}^{\pm}=H-AM^{\mp}+\Gamma M^{\pm}, \qquad \text{(A.1)}$$

where H is the external field applied along the easy axis of the spins, $M^{\pm}$ are the sublattice magnetizations (positive when they are parallel to the applied field, negative when antiparallel) and A and Γ are the molecular field coefficients. $M^{\pm}$ are determined by the equations

$$M^{\pm}=\frac{Ng\beta}{2}B_S\left[\frac{Sg\beta}{kT}(H-AM^{\mp}+\Gamma M^{\pm})\right], \qquad \text{(A.2)}$$

where N is the total number of spins, S the magnitude of each spin and B_S the Brillouin function. The Néel temperature, T_N, is given by

$$T_N=\frac{C}{2}(A+\Gamma)$$

where

$$C=Ng^2\beta^2S(S+1)/3k\,.$$

Using the reduced quantities,

$$M^{\pm}\Big/\frac{N}{2}g\beta S=\sigma^{\pm}\,,$$

$$\frac{T}{T_N}=t\,,$$

$$H\Big/(A+\Gamma)\frac{N}{2}g\beta S=h\,,$$

(A.2) is written

$$\sigma^{\pm}=B_S\left[\frac{3S}{S+1}\frac{h-(1-\lambda)\sigma^{\mp}+\lambda\sigma^{\pm}}{t}\right], \qquad \text{(A.3)}$$

where

$$\lambda=\frac{\Gamma}{A+\Gamma}\,.$$

A is assumed to be positive, Γ either positive or negative and $A+\Gamma>0$, as otherwise the stability of the two-sublattice antiferromagnetism will be invalidated. Therefore $1>\lambda>-\infty$.

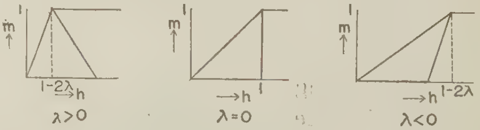


Fig. A1. Magnetization, m, versus applied field at 0°K in the cases of $\lambda>0$, $\lambda=0$ and $\lambda<0$.

At absolute zero, the relation between the external field and the total magnetization, $m=(\sigma^{+}+\sigma^{-})/2$, is as shown in Fig. A.1. In the case of $\lambda\leq0$, the antiferromagnetic state continues up to $h=1$, then a ferromagnetic state starts and at $h=1-2\lambda$ the ferromagnetic state is realized. In the case of $\lambda>0$, the ferromagnetic state is unstable and at $h=1-\lambda$ a transition of the first kind occurs from the antiferromagnetic state to the ferromagnetic state.

To investigate the transition at the arbitrary temperature, we shall confine ourselves to the case of $S=1/2$. Perhaps we may expect similar results for any value of S. For $S=1/2$, Eq. (A.3) reduces to

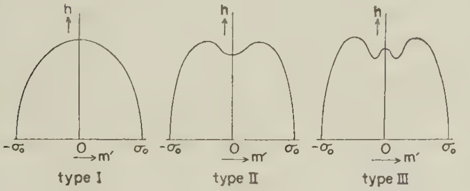
$$\sigma^{\pm}=\tanh\left[\frac{h-(1-\lambda)\sigma^{\mp}+\lambda\sigma^{\pm}}{t}\right]. \qquad \text{(A.4)}$$

If we use $m=(\sigma^{+}+\sigma^{-})/2$ and $m'=(\sigma^{+}-\sigma^{-})/2$ instead of σ^{+} and σ^{-}, Eqs. (A.4) become

$$m^2=1-2m'\coth(2m'/t)+m'^2, \qquad \text{(A.5)}$$

$$h=\frac{t}{2}\tanh^{-1}\left[\frac{\{1-2m'\coth(2m'/t)+m'^2\}^{1/2}}{1-m'\coth(2m'/t)}\right] +(1-2\lambda)\{1-2m'\coth(2m'/t)+m'^2\}^{1/2}. \qquad \text{(A.6)}$$

It can be shown that m is a monotonously decreasing function of $|m'|$ in the allowable range of m', $-\sigma_0<m'<\sigma_0$ (σ_0 represents the magnitude of σ^{+} and σ^{-} of the antiferromagnetic state at $h=0$). The $h\sim m'$ curve representing the antiferromagnetic solution will appear in three types as shown in Fig. A.2, corresponding to different values of t and λ. At the field h_c, which corresponds to $m'=0$, the antiferromagnetic solution joins the paramagnetic solution, which is the vertical line passing through $m'=0$. In order to examine the ranges of λ and t which give rise to these three types, we calculate dh/dm' and expand it in the neighbourhood of $m'=0$. Using another variable $y=2m'/t$, we have



type I type II type III

Fig. A2. Three types of h vs. m' curve.

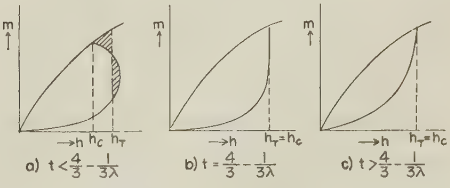
$$\frac{dh}{dy}=\frac{t}{2\{1-ty\coth y+(ty/2)^2\}^{1/2}}\left[\lambda\left(\frac{4}{3}-\frac{1}{3\lambda}-t\right)y +\frac{1}{15}\left(1-\frac{8}{3}\lambda\right)y^3 +\frac{2}{63}\left(-\frac{1}{3}+\frac{4}{5}\lambda\right)y^5+\cdots\right]. \qquad \text{(A.7)}$$

If the coefficient of the linear term of y, $\lambda(4/3-1/3\lambda-t)$, is positive, the $h\sim m'$ curve is of type II, and if it is negative, the curve is either of type I or of type III. The temperature at which the transition from type II to type I or III occurs is determined by $4/3-1/3\lambda-t=0$, i.e., $t=4/3-1/3\lambda$. This t is greater than 1 (higher than the Néel temperature) if $\lambda<0$, in which case we have no finite value of σ_0 and thus Eq. (A.7) has no meaning. In this case, one sublattice magnetization increases and the other decreases monotonically with increasing field below the Néel temperature, as $\Gamma<0$ and $A>-\Gamma$, and we have a $h\sim m'$ curve of type I; thus, a transition of the second kind occurs at $h=h_c$. If $1/4<\lambda<1$, $t=4/3-1/3\lambda$ lies between 0 and 1, and a transition between type II and type I or III occurs below the Néel temperature. We further distinguish between two cases, $1/4<\lambda<3/8$ and $3/8<\lambda<1$, the former corresponding to the positive coefficient of y^3 in Eq. (A.7) and the latter to the negative coefficient. Furtheremore, if $0<\lambda<1/4$, the $h\sim m'$ curve is always of type I or III because the coefficient of y in Eq. (A.7) is negative. We shall investigate these cases separately.

1) $1/2<\lambda<1$

This case is the same as the next case ($3/8\leq\lambda\leq1/2$) except for the existence of a ferromagnetic solution. However, the ferromagnetic Curie point at $h=0$ is $2\lambda-1$ and is lower than the transition point from type II to type I or III, therefore the ferromagnetic solution will not be realized.

2) $3/8\leq\lambda\leq1/2$

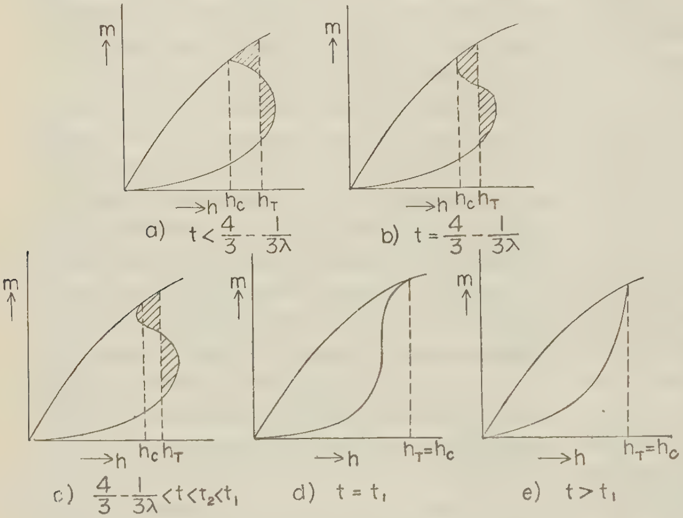


a) $t<\frac{4}{3}-\frac{1}{3\lambda}$ b) $t=\frac{4}{3}-\frac{1}{3\lambda}$ c) $t>\frac{4}{3}-\frac{1}{3\lambda}$

Fig. A3. Magnetization versus external field for the case of $3/8<\lambda<1/2$. h_T represents the transition field from antiferromagnetic state to paramagnetic state.

At a temperature $t=4/3-1/3\lambda$, the top of the $h\sim y$ curve is flat and, since the coefficient of y^3 in (A.7) is negative, the curve looks like type I but it is flat at the top. Above this temperature, the curve is of type I, which diminishes to a point as t approaches 1. Below this temperature, the curve must be of type II. Since m is a decreasing function of

m' or y, as mentioned before, the relation between m and h must be as shown by Fig. A.3 in this temperature range; an antiferro-paramagnetic transition of the first kind must occur at a certain field at which the area of the shaded portions of the curve become equal. In the higher temperature region the transition is naturally of the second kind.



a) $t<\frac{4}{3}-\frac{1}{3\lambda}$ b) $t=\frac{4}{3}-\frac{1}{3\lambda}$

c) $\frac{4}{3}-\frac{1}{3\lambda}<t<t_2<t_1$ d) $t=t_1$ e) $t>t_1$

Fig. A4. Magnetization versus external field for the case of $1/4<\lambda<3/8$.

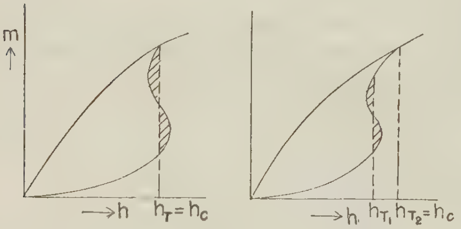


Fig. A5. Magnetization versus external field for the case of $1/4<\lambda<3/8$.

3) $1/4<\lambda<3/8$

Since the coefficient of y^3 in Eq. (A.7) is positive in this case, the curve of h versus y at $t=4/3-1/3\lambda$ looks like type II but it is flat at the bottom of the concave part. For $t<4/3-1/3\lambda$, the carve first changes to type III and then to type I with increasing temperature. The temperature at which the curve changes from type III to type I will be denoted by t_1. The change of the $m\sim h$ curve with varying temperature is shown in Fig. A.4. Just below t_1, a transition of this first kind from an antiferromagnetic state to another antiferromagnetic state must occur, as shown in the second figure of Fig. A.5, at a field which is lower than the field of the antiferro-paramagnetic transition. The latter is of the second kind. The first figure of Fig. A.5 represents the transition at another temperature, t_2, at which the character of the antiferro-paramagnetic transition changes from the first kind to the second kind. A double transition occurs in the range $t_2<t<t_1$. An example of determing these temperatures, t_1 and t_2, is given in the text.

4) $0<\lambda\leq1/4$

In this case the coefficient of y in Eq. (A.7) is always negative and so the curve $h\sim y$ is of type I or type III. However, considering the behaviour of the curve at absolute zero, the curve must be of type III at sufficiently low temperatures. There exists a temperature, t_1, at which change from type III to type I occurs, and also t_2, as in the previous case (see Fig. A.5).

5) $\lambda\leq0$

In this case m is a monotonously increasing function of h, as mentioned before, and the antiferro-paramagnetic transition is always of the second kind. The transition field is that given by Garrett.[13)]

Crystal Structure of 2-Amino Azulene

By Yoshito TAKAKI, Yoshio SASADA and Isamu NITTA

Faculty of Science, Osaka University

(Received February 26, 1959)

A systematization was proposed for the determination of the crystal structure when the crystal consists of the molecules with known shape. The main feature of this method is to separate the refinements by the least squares at an early stage into (1) successive improvements of the position and orientation of the molecule and (2) correction of the molecular shape fixing the molecular position and orientation.

The result of the application of this method to the crystal of 2-amino azulene (a=11.62, b=10.76, c=6.32 Å, Z=4, space group $Pbn2_1$) was given.

§1. Introduction

While several systematic procedures, such as Fourier methods, have been used for the refinements of structure in the X-ray crystal analysis, there remains unsolved an important problem, how to obtain systematically the approximate parameters as the starting point of the refinement. If, for example, a molecule without centre of symmetry contains light atoms only, it is often difficult to obtain satisfactory results by the so-called direct methods proposed heretofore. Such being the case, instead of applying these methods, the authors have attempted to use fully the information given by the intensity data for individual reflexions as well as known molecular shape.

The present account will describe a systematization of the method of this kind, applied to the crystal of 2-amino azulene which was taken up as a part of the serial investigations of crystal structures of the compounds containing planar seven-memberd carbon rings1)−7).

§2. Experimental

Crystals are obtained as very fine reddish violet needles elongated along the direction of the c axis.

Crystallographic and physical data are obtained as follows.

2-Amino azulene; $C_{10}H_9N$, m.p. 93–94°C.
Orthorhombic; $a=11.62\pm0.04$, $b=10.76\pm0.04$, $c=6.32\pm0.03$Å.
Absent spectra; $(0kl)$ when k is odd, $(h0l)$ when $h+l$ is odd.
Space group; $Pbn2_1-C_{2v}^9$.
Four molecules per unit cell.
Volume of unit cell; 790.2Å^3.
Density (by floatation); 1.20 g.cm^{-3}.
Density (calculated); 1.20 g.cm^{-3}.
Linear absorption coefficient for CuK_α radiation, μ=6.5 cm^{-1}.
Total number of electrons per unit cell, $F(000)=304$.

For the structure analysis, a complete set of relative intensities for $(hk0)$, $(hk1)$, $(hk2)$ and $(hk3)$ were obtained by the integrated Weissenberg procedure. The specimen used has the following maximum and minimum dimensions at right angle to the axis of rotation: 0.01×0.006 cm.

Intensities were estimated by visual comparison with a calibrated scale. The multiple-film technique was used to correlate strong and weak reflexions, ranging in relative intensities from 5100 to 1. Reflexions from only 96 planes were observed out of 163 possible $(kh0)$'s. The corrections for polarization and Lorentz factors were made in the usual way, and that of absorption was neglected.

§ 3. Structure Determination of (001) Projection

Analysis was made in the following sequence:

a) The molecule of 2-amino azulene was assumed to possess the dimensions as shown in Fig. 1.

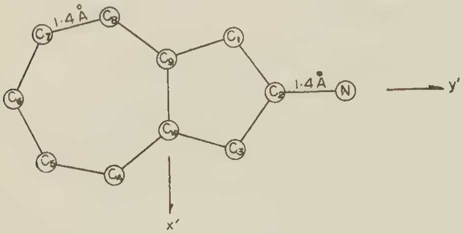

Fig. 1. Assumed model of the molecule.

b) The approximate position and orientation of the molecule were chosen by using the structure factor maps[4].

c) At such stage, the application of the ordinary least squares, sometimes leads to false structures (see Appendix). In order to avoid such confusions, the authors allowed for the shape of the molecule as the limiting conditions in the application of this method.

Let

(x_i, y_i, z_i) the coordinates of the i-th atom in the molecule with respect to the crystal axes a, b and c,

$(x_i', y_i', 0)$ the coordinates of the same atom with respect to the molecular axes as shown in Fig. 1,

$(p, q, 0)$ the coordinates of the origin of the molecular axes in the (001) projection,

$(\lambda_1, \mu_1, \nu_1)$, $(\lambda_2, \mu_2, \nu_2)$, $(\lambda_3, \mu_3, \nu_3)$ the direction cosines of the molecular axes x', y' and z' with respect to the crystal axes a, b and c respectively,

Δx_i, Δy_i, Δp, Δq corrections,

F_0, F_c observed and calculated structure factors,

w weight.

From simple consideration of the analytical geometry,

$$\left.\begin{aligned} x_i &= x_i'\lambda_1 + y_i'\lambda_2 + p \\ y_i &= x_i'\mu_1 + y_i'\mu_2 + q \end{aligned}\right\} . \tag{1}$$

Then

$$\left.\begin{aligned} \Delta x_i &= x_i'\Delta\lambda_1 + y_i'\Delta\lambda_2 + \Delta p \\ \Delta y_i &= x_i'\Delta\mu_1 + y_i'\Delta\mu_2 + \Delta q \end{aligned}\right\} . \tag{2}$$

If $F = \sum_i F_i(x_i, y_i)$, where the summation is taken over all the atoms in the cell, each structure factor gives observational equation,

$$\begin{aligned} w\Delta F = w \sum_i \{&(\partial F/\partial x_i)(x_i'\Delta\lambda_1 + y_i'\Delta\lambda_2 + \Delta p) \\ &+ (\partial F/\partial y_i)(x_i'\Delta\mu_1 + y_i'\Delta\mu_2 + \Delta q)\} . \end{aligned} \tag{3}$$

To find the most probable values, usual procedures of the least squares are applied.

d) After several successive applications of the above-mentioned method, there remain some comparatively large discrepancies between observed and calculated structure factors, even for the reflexions with lower order indices, although the values of the corrections decrease with advancing refinement processes. This is mainly due to the insufficiency of the parameters contained in the assumed model.

In the following step of refinement, the authors tried to shift each atom in the molecule, so as to keep the molecular symmetry of C_{2v} with all the atoms except the nitrogen. From equation (1), it follows

$$\left.\begin{aligned} \Delta x_i &= \lambda_1\Delta x_i' + \lambda_2\Delta y_i' + \Delta p \\ \Delta y_i &= \mu_1\Delta x_i' + \mu_2\Delta y_i' + \Delta q \end{aligned}\right\} . \tag{4}$$

Then the observational equation is written as

$$\begin{aligned} w\Delta F = w\sum_i \, [&\{(\partial F/\partial x_i)\lambda_1 + (\partial F/\partial y_i)\mu_1\}\Delta x_i' \\ &+ \{(\partial F/\partial x_i)\lambda_2 + (\partial F/\partial y_i)\mu_2\}\Delta y_i' \\ &+ (\partial F/\partial x_i)\Delta p + (\partial F/\partial y_i)\Delta q] \end{aligned} \tag{5}$$

where there are thirteen independent parameters and $\sum_i$ means the summation over all these independent parameters. These parameters were corrected by the successive three least squares processes. Discrepancy index, $R = \sum||F_0| - |F_c||/\sum|F_0|$, decreased by about 0.1. Agreement between the observed and calculated structure factors showed remarkable improvement, especially for some reflexions with relatively lower indices.

e) Finally, the coordinates obtained in this way were refined by means of least squares without keeping the symmetry C_{2v} among atoms in the molecule.

In the application of the least squares, the authors have experienced difficulties due to the effect that the higher order reflexions decreased rapidly owing to large temperature factor.

The magnitudes of the coefficients in the observational equation are proportional to $hf \cdot \exp(-B\xi^2/4\lambda^2)$ if $\sin 2\pi(hx_i+ky_i)$ is assumed to be constant. As the maximum h for a given ξ is $a\xi/\lambda$, they can be considered to be proportional to $\xi f \cdot \exp(-B\xi^2/4\lambda^2)$, as shown in Fig. 2 for several B. In the present case, magnitudes of coefficients corresponded to those shown by the lowest curve in Fig. 2, and the effect from the reflexions with larger ξ than 1.0 were very small. In order to accelerate convergence, $\exp(+0.7\xi^2)$ was taken as the weight in the least squares. Using this value, the coefficients in the observational equation were adjusted to be of almost equal magnitudes in the range of higher angle than $\xi=0.5$. By this means, it was possible to obtain the satisfactory solution which gave fair agreement between observed and calculated structure factors over all the range of ξ.

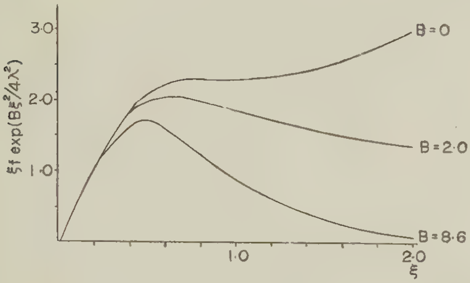

Fig. 2. Variation of magnitudes of the coefficients in the observational equation with ξ.

The final discrepancy index became 0.18

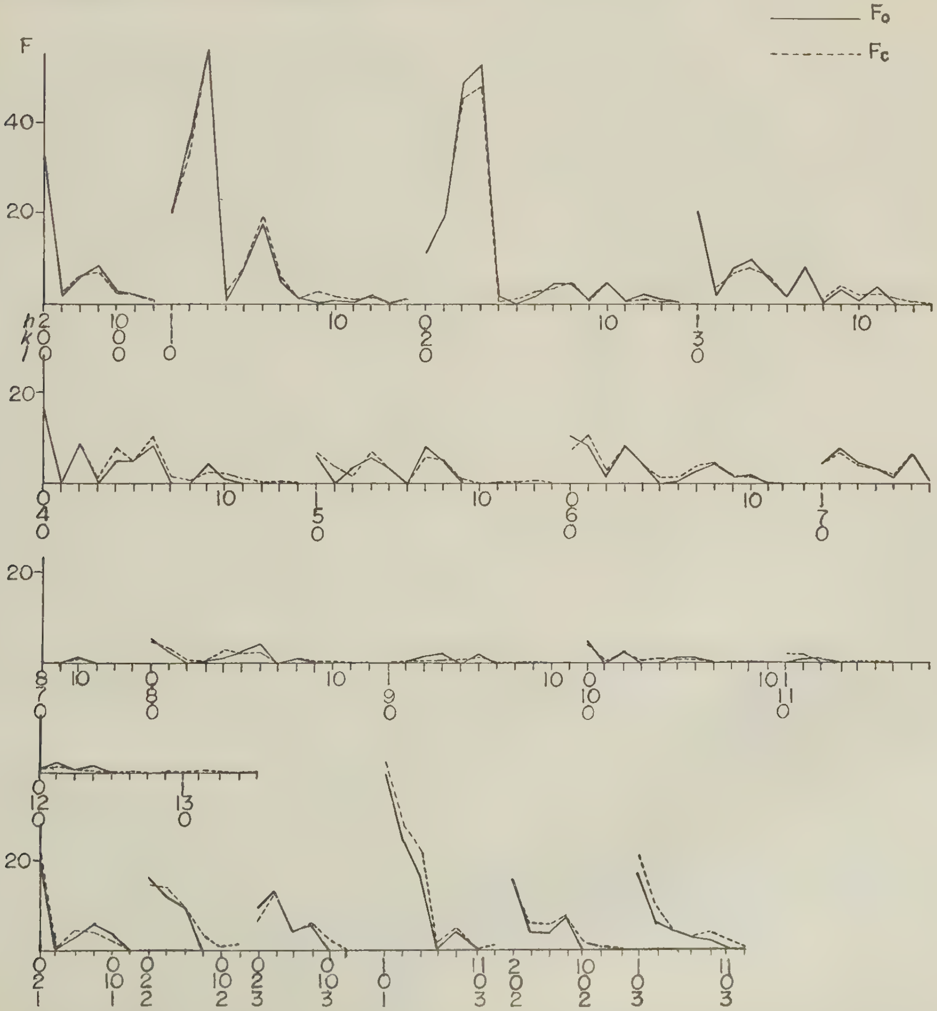

Fig. 3. Observed and calculated structure factors for $(hk0)$, $(0kl)$ and $(h0l)$.

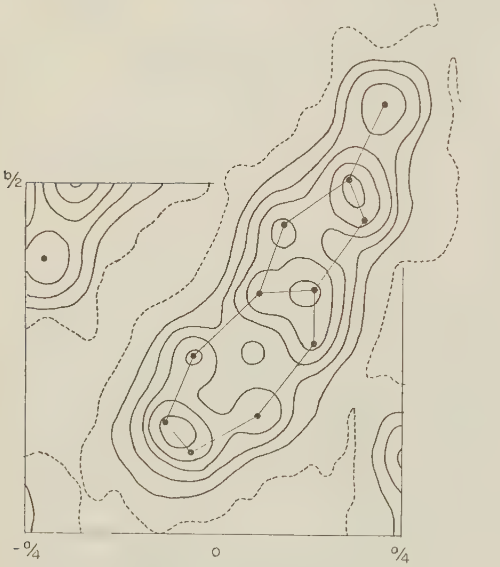

Fig. 4. The final electron-density projection along the c axis. Contours at intervals of 1 $e\text{Å}^{-2}$ with the lowest solid contour at 2 $e\text{Å}^{-2}$. The broken one shows 1 $e\text{Å}^{-2}$ level.

($R=0.13$ if non-observed reflexions were omitted in the calculation). Throughout these calculations, the atomic scattering factors were taken from McWeeny[8], using for carbon the values for 'valence states'. The best B factor was 8.6. In Table I are listed the final atomic coordinates. Fig. 3 shows the comparison between observed and calculated structure factors $F(hk0)$ and Fig. 4 the final Fourier projection of the electron density on the (001) plane.

§ 4. Determination of z Coordinates

Structure factors $F(0kl)$ and $F(h0l)$ were taken from the equi-inclination Weissenberg photographs about the c axis for the first, second and third layer lines. As the accuracy of intensity measurements is rather low and moreover the data is small in number, ordinary procedure of the analysis could not be applied. Therefore, approximate z coordinates were first estimated on the basis of x and y coordinates already obtained and the assumed planarity of the molecule. It is noted that any one of the atoms can take its z value equal to zero as the c axis is polar. Ten parameters were refined by the trial method. The final values are also listed in Table I and the comparison between observed and calculated structure factors $F(0kl)$ and $F(h0l)$ is shown in Fig. 3.

§ 5. Description of the Structure and Conclusion

Crystal structure projected on the (001) plane is shown in Fig. 5. Intra-molecular distances are between 1.37 and 1.41Å except C_9–C_{10} for which a value of 1.52Å is found. Intermolecular distances in contact with each other are between 3.6 and 4.0Å. It may be concluded that the crystal is formed mainly by van der Waals forces, and the crystal structure as a whole can be taken as one somewhat modified from the structure of naphthalene[9]. This is probably due to the similar shape and small dipole moment of this substance (2.09 D[10]). Recently it becomes clear[11] that, although azulene (an isomer of naphthalene) belongs to the same space group as that of naphthalene, a simple random reversal of direction of successive azulene molecules was observed in the crystal. It is interesting to note that, while the orientation of azulene molecules (with smaller dipole moment (1.0 D)) is random, the present structure shows the regular reversal of direction of successive molecules.

In conclusion, the authors wish to make some comments for the method described in this paper. At the present stage of development of the phase problem, it is necessary to use fully and systematically the definitely known physical and chemical evidences, in order to solve the structure of a crystal with minimum efforts. The process mentioned above, which is an attempt of this kind, consists of two parts, that is, the first is the

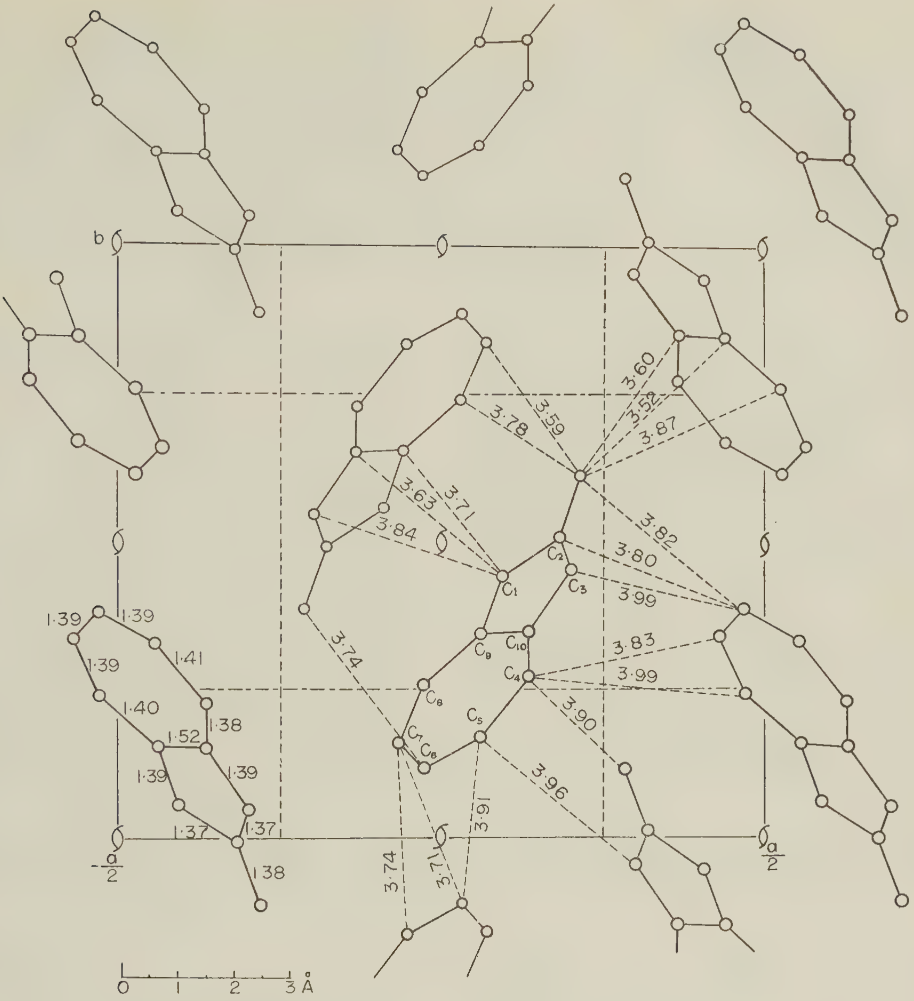

Fig. 5. Arrangement of molecules in the (001) projection.

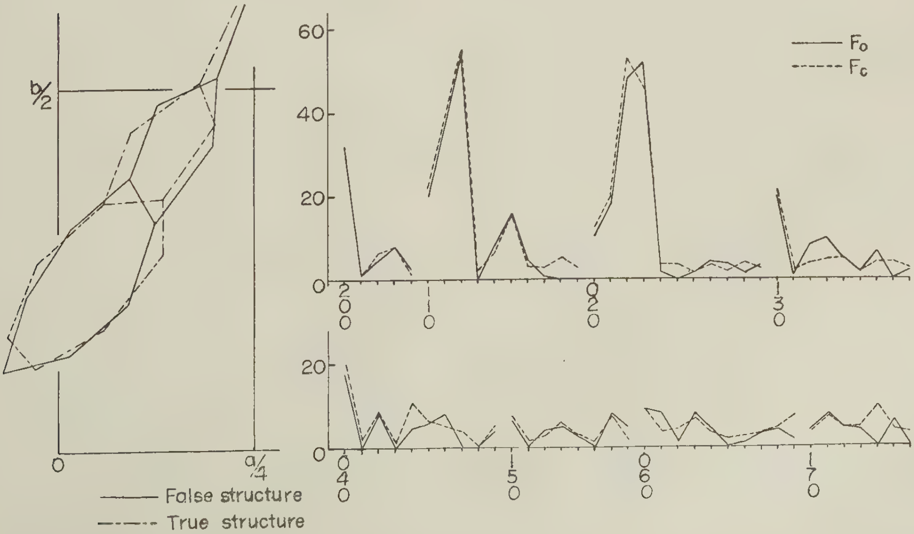

Fig. 6. Observed and calculated structure factors $F(hk0)$ calculated for the false structure (a part).

determination of approximate position and orientation of the molecule using the structure factor map and the second is the improvement by the least squares with the limiting conditions. It is possible in many cases to limit allowable sets of molecular positions and orientations severely enough to apply the second process, as far as the molecule is not of too large magnitude. On the other hand, we can avoid by the second process any false structures which often appear in routine applications of the least squares and lead the structure which is sufficiently enough to achieve further refinement by the orthodox procedure. The authors think that the procedure described in this paper is simple and practical, even for the cases with molecules having no centre of symmetry provided that their molecular shapes are roughly known.

The authors wish to express their sincere thanks to Professor T. Nozoe for supplying the sample and for continued interest. The authors are also indebted to Professor T. Watanabé for kind discussion of the results of this investigation.

Appendix. Example of False Structure

The authors drew attention elsewhere about the fact that the routine application of any systematic processes sometimes leads to false structures. An example of the false structures which was derived starting from a crude structure by the least squares without consideration of molecular shape is shown in Fig. 6 in the form of comparison between observed and calculated structure factors with corresponding false molecular position.

Study of Segmental Motion in Polymer Solutions by Nuclear Magnetic Resonance

By Akira ODAJIMA

Research Institute of Applied Electricity,
Hokkaido University Sapporo

(Received March 4, 1959)

Experimental and theoretical considerations of segmental motion in chain molecules were studied from the view point of nuclear mognetic resonance.

By using the high resolution type spectrometer of NMR, it was verified that the line widths of phenyl group and CH_2 group in polystyrene-CCl_4 solutions were almost all independent of chain lengths in dilute solutions. These values of line widths indicate that the so-called segmental motion in a chain is performed in the unit of about ten monomers.

The segmental motion hindered by the potential field was discussed by using the generalized theory of Brownian motion. The influences of restricted motion upon T_1 and T_2 in polyisobutylene-CCl_4 solution are examined. The results of our theory are as follows. The activation energy of segmental motion tends to the activation energy of solvent when the concentration of polymer decreases. The value of activation energy increases with the increase of concentration of polymer. These results are in a good agreement with these of mechanical and dielectric measurements. Furthermore, the values of hindering potential are calculated from the data of T_1 and T_2 in PIB solutions.

Finally, it is verified that the rigidity of polymer solution in the high frequency measurement should be caused by the potential field hindering the micro-Brownian motion of segment.

§1. Introduction

The development of experimental methods[1),2)] of observing nuclear magnetic resonance (NMR) has brought a renewed interest in the theory of high polymer solutions. Although only a few experiments have been reported, they have revealed a posibility of certain connections between the motions indicated by NMR and the mechanical and dielectric properties of high polymer solutions.

Hitherto, theoretical treatments of the motion of chain molecules have been introduced by Kirkwood et al[3)] and by Rouse[4)] and Bueche[5)]. In the Kirkwood theory, it is assumed that the bond lengths and the bond angles of each polymer molecule are constant, but that the azimuth angles are free to rotate. Thus, they introduced the coordinates describing the configuration of a molecule, and gave the equation of diffusion in the multidimensional space defined by these coordinates. On the other hand, more simplified theories by Rouse and Bueche assume that a polymer molecule is divided into a number of submolecules whose end-to-end distance shows the Gaussian distribution. That is to say, it is assumed that the molecules are replaced by a number of beads of submolecules linked by Hookean springs, and a frictional constant ζ of the bead is taken into consideration.

In NMR measurements, the micro-motions of individual group in the chain molecules are observed in detail. In this meaning, the models proposed by Rouse and Bueche may not be suitable, unless they are modified with some devices.

On the contrary, the rigorous method of Kirkwood seems to be helpful to apply to the NMR theory concerning to the internal motions of polymer solutions. Recently, Miyake[6)] developed a theory based on the statistical mechanical theory of irreversible processes given by Kirkwood[7)]. However, a great difficulty[8)] has been pointed out in the derivation of an actual distribution of correlation times of segmental motions from the Kirkwood equation[3].

Moreover, the experimental results[9] in dielectric dispersion in the polar polymer solutions were in disagreement with the Kirkwood theory[3]. According to this theory[3], the average relaxation time $\bar{\tau}_D$ is proportional to α power of the degree of polymerization. In Gaussian chain $\alpha=1/2$, but α may be larger than 1/2 as a result of the excluded volume effect. However, the experimental data[9] showed that $\bar{\tau}_D$ did not change systematically with the molecular weight, and its observed variation was less rapid than the one predicted by the theory in the dilute concentrations.

In the Kirkwood theory[3] hydrodynamic interactions between the segment in molecules are considered, but no interactions between polymer molecules are included. Therefore, the predicted dependence should be applied in the case of very dilute solutions.

It is worth while to study by NMR method whether the spin-lattice relaxation time T_1 and the spin-spin relaxation time T_2 in the polymer solution also depend upon the molecular weight or not. According to our measurements and the one by Nolle[2], T_2 is independent of the degree of polymerization, in the dilute range. In the concentrated region of the solutions, T_2 seems to be dependent upon the degree of polymerization. However, in such a concentrated region, the Kirkwood theory is rather inapplicable and the molecular weight dependency of T_2 should be explained by a different mechanism*.

Further, Nolle[10] has recently made a detailed measurement of T_1 and T_2 in polyisobutylene (PIB)–CCl_4 solutions by means of the spin-echo transient method, which is not yet published**. Herein, the present author finds interesting problems in the T_1 and T_2 behaviors concerning to the temperature and concentration as well as the molecular weights.

In the aspect of theoretical study, on the other hand, a great progress has been achieved in the magnetic resonance absorption since the BPP theory[11] was proposed. Kubo-Tomita[12] presented a theory which treated the motion of spins by a quantum-statistical method based on the linear theory of irreversible process. Another theories essentially similar to this were also presented by Solomon[13] and Red-field[14].

Strictly speaking, however, these theories do not take sufficiently the complicated motions of segments in polymer systems into consideration. Therefore they may not be suitable to explain the mechanisms of T_1 and T_2 in polymer solutions. In this paper, the author will deal with the relaxation problem of NMR in polymer solutions on the basis of new theoretical approach concerning to the Brownian motion of segments in chain molecules.

§ 2. Experimental Results

I. *NMR methods*

When the molecular motion becomes rapid and its correlation time is small, a high homogeneity of the magnetic field is required for the measurement of the line width of absorption line. Accordingly, few attempt[1] has been made to obtain the absorption lines in polymer solutions.

By employing a high resolution magnet of Varian Association Spectrometer***, measurements of absorption line of polystyrene (PS) and polyisobutylene (PIB) in solutions were undertaken. In order to obtain their high resolution spectra, it is necessary to select a solvent without containing a proton. This requirement was satisfied by using CCl_4 and CS_2 as the solvent.

Samples were placed in 5 mm O.D. glass tube. The portion of the magnetic field occupied by the samples was found to be uniform within about 2 c/s or about 0.5 milligauss. All measurements were carried out at room temperature.

---

* The experimental result that the motional narrowing of line width is related with the molecular weight was found in polystyrene, solid polymer, by Guth et al. (L. V. Holroyd, R. S. Codrington, B. A. Mrowca, and E. Guth: J. Appl. Phys. **12** (1951) 696). As well known in the thermal properties of solid polymer, owning to the fact that the free volume for segmental motion is related with molecular weight, the line width transition temperature of polystyrene may depend upon molecular weight. So, this dependency should be caused by a mechanism different from the one in the Kirkwood theory.

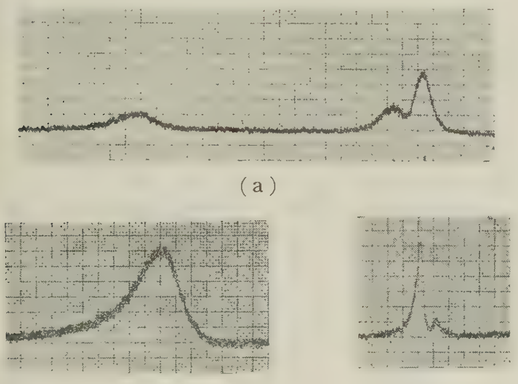
** A copy of Nolle's paper unpublished was privately sent through Mr. Sohma who was now at Department of Physics, University of Maryland.

*** Measurements were carried out at the Chemical Research Institute of Non-Aqueous Solutions, Tohoku University.

II. *Effects of molecular weight and concentration on T_1 and T_2*

The proton spectra of PS and PIB solutions are shown in Fig. 1. The multiple structures of these lines are in accord with the chemical shifts predicted from the structures of $(-CH\cdot C\cdot(C_6H_5)\cdot CH_2-)_n$ and $(-C\cdot(CH_3)_2\cdot CH_2-)_n$, respectively.

In four samples of fractionized PS used in the measurements*, the half widths of their each groups are obtained over the concentration range of 2.7 g/100 cc to 11 g/100 cc, as shown in Table I.



(a)

(b) (c)

(a) PS (d.p.$=1.1\times10^3$)-CCl_4 solution (6.5 g/10 cc). Reading from left to right the peaks corresponding to resonance absorption in CH_2, CH, and C_6H_5 groups.

(b) Absorption line of CH_2 group in the spectrum of PS (d.p.$=1.02\times10^4$)–CCl_4 solution (11 g/100 cc).

(c) PIB–CCl_4 solution (6.5 g/100 cc). Reading from left to right the peaks corresponding to CH_3 and CH_2 groups.

Fig. 1. Example of spectra of the proton resonance absorption in PS and PIB solutions. (Resonance frequency, 40 Mc/s. Sweep rate, 4 c/s per second).

The half line widths of the CH_2 group in PS are larger than those of the phenyl group. It is supposed that the two lines of CH_2 group and CH group in PS may have fine structures due to the $I-I$ coupling with the CH group and CH_2 group in the neighbour on the chain, respectively. The large widths of CH_2 group and CH group lines are probably caused by a multiple structure of lines, the splitting of which is unseparable.

The widths of phenyl group are almost independent of the concentrations in the range mentioned above, It is also verified that the line width of phenyl group is not dependent on the molecular weight in dilute solutions as well as the dielectric relaxation time of polar polymer solutions⁹⁾. On the other hand, it is presumed that the values of the width of CH_2 group increase as the concentration

Table I.

	Degree of polymerization	Concentration (g/100 cc)	Half width (c/s)	
			phenyl group	CH_2-group
	10^4	11.0	16	35
		4.1	15	28
PS	4×10^3	2.7	15	27
	10^3	6.5	15	28
	7×10^2	10.0	16	30
			CH_3-group	CH_2-group
PIB	2×10^4	6.5	6.5	~10
		3.0	6	~10

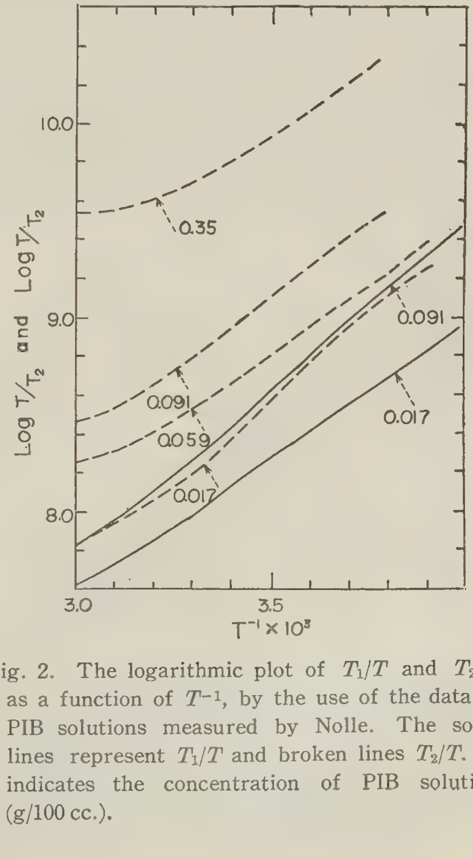


Fig. 2. The logarithmic plot of T_1/T and T_2/T as a function of T^{-1}, by the use of the data of PIB solutions measured by Nolle. The solid lines represent T_1/T and broken lines T_2/T. **c** indicates the concentration of PIB solution (g/100 cc.).

---

* The fractionation of PS was performed by Mr. Miyake, Dept. of Phys., Hokkaido University.

increases.

One kind of PIB sample, the molecular weight of which is about 10^6 is used*. The half widths of CH_2 ond CH_3 groups seem to be almost constant under the concentration of 6.5 g/100 cc, and they are smaller than those of the CH_2 and CH groups in PS.

It is interesting that Nolle[10] also found both T_1 and T_2 in PIB–CCl_4 solutions became substantially independent of concentrations and molecular weights in sufficiently dilute solutions. But he found further that they fell rapidly with increasing concentration above a fairely well defined critical value. This point will be discussed in section 6.

III. *Effects of on T_1 and T_2 temperature*

By the use of Nolle's data of the T_1 and T_2 vs. temperature curves in PIB solution, both T/T_1 and T/T_2 are plotted against the inverse of temperature T^{-1} in Fig. 2. Here, it is found that the T_1 curves are approximately linear. The T_2 curves, however, are less linear in higher region of temperature when the solution becomes dense.

§ 3. Brownian Motion in the Potential Field

We shall now consider, in the classical theory, the general Brownian motion under the influence of the potential field[15].

When it is assumed that the Brownian movement can be idealized as a Markoff process, the probability distribution $W(\Delta\vec{r}, \Delta\vec{u}; \Delta t)$ in a phase space can be derived from the following equation:

$$\frac{\partial W}{\partial t}+(W, \mathscr{H})=\eta\, \mathrm{div}_u (W\vec{u})+q\nabla_u{}^2 W\,, \quad (1)$$

where ( ) means the Poisson's blacket. The coefficients η and q are given by

$$\left\{\begin{aligned} -\eta\vec{u}&=\frac{\langle\Delta\vec{u}\rangle}{\Delta t} && \text{(2a)}\\ q&=\frac{\langle\Delta u^2\rangle}{\Delta t}\,. && \text{(2b)}\end{aligned}\right.$$

However, if we are interested only in time interval very large compared to the "time of relaxation" η^{-1}, we can reduce Eq. (1) to the Fokker-Planck equation in configuration space independently of the velocity space.

We shall also suppose that the force $-\mathrm{grad}\, U$ does not change appreciably over a distance of the order of $(q/\eta^3)^{1/2}$. With this assumption, the transition probability $\omega(\Delta\vec{r}; \Delta t)$ that suffers an increment $\Delta\vec{r}$ in the coordinate space in time $\Delta t \gg \eta^{-1}$ is obtained from the equation in the form

$$\frac{\partial\omega}{\partial t}=\mathrm{div}\,(q/\eta^2\, \mathrm{grad}\, \omega+\omega/\eta\cdot \mathrm{grad}\, U)\,, \quad (3)$$

where q and η are related to the diffusion constant D as

$$D=q/\eta^2\,. \quad (4)$$

Here we draw attention to the fact that this equation is valid only if we ignore the effects which happen in time intervals of the order of η^{-1} and space intervals of the order of $(q/\eta^3)^{1/2}$. When such effects are of interest, we should go back to Eq. (1) which is rigorously valid in the phase space.

We think, however, the approach by Eq. (3) is helpful to explain the motions of segments in polymer solutions as will be desbribed in section. The entanglment between the chain molecules is considered to give a steric hinderance to the rotational motion of the segment. And it may be supposed that such a hindrance is expressed by the potential barrier against the segmental motion.

In this case, we start from the motions of proton pairs isolated in the chain molecule which rotate under a hindering potential. However, these results should be applicable not only to those of the chain molecules but to the other rotational motions in general.

From Eq. (3), the differential equation of the rotational Brownian motion of proton pair is given as

$$\frac{\partial f}{\partial t}=\frac{k_0T}{\eta}\left\{\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\sin\theta\left(\frac{\partial f}{\partial\theta}+\frac{1}{k_0T}\frac{\partial U}{\partial\theta}f\right)+\frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\varphi^2}f+\frac{1}{k_0T\sin^2\theta}\frac{\partial}{\partial\varphi}f\frac{\partial U}{\partial\varphi}\right\}. \quad (5)$$

The spherical coordinate system-(θ, φ) is defined so that the hindering potential of rotation is expressed by

$$U(\theta)=-W\cos\theta\,. \quad (6)$$

---

* This sample was supplied through the kindness of Dr. Iwayanagi, Scientific Research Institute, Tokyo.

Substituting Eq. (6) into Eq. (5) and putting $\cos\theta=v$, we get

$$\frac{\partial f}{\partial t}=\frac{k_0T}{\eta}\left\{\frac{\partial}{\partial v}(1-v^2)\frac{\partial f}{\partial v}+\frac{1}{1-v^2}\frac{\partial^2}{\partial\varphi^2}f-\frac{W}{k_0T}\frac{\partial}{\partial v}(1-v^2)f\right\}. \tag{7}$$

In order to solve Eq. (7), we consider the operator

$$L_0=\frac{d}{dv}(1-v^2)\frac{d}{dv}-\left(\frac{W}{2k_0T}\right)^2(1-v^2)+\frac{W}{k_0T}v-\frac{m^2}{1-v^2}. \tag{8}$$

By supposing that L_0 is self-adjoint, let us consider the eigenvalue problem,

$$L_0X+\lambda X=0. \tag{9}$$

L_0 will possess a set of eigenvalues $-\lambda_{mn}$ and eigen functions X_{mn} forming a complete orthogonal set.

Thus, a solution of Eq. (7) may be written in a series of the orthogonal set as

$$f=\sum_{mn}c_{mn}e^{(W/2k_0T)v}\cdot X_n{}^m\cdot e^{-\lambda_{mn}t}. \tag{10}$$

At $t=0$, the direction of nucleus pair is in the position (θ_0, φ_0), and the distribution function in the initial state is

$$f(0)=\delta(\theta-\theta_0)\cdot\delta(\varphi-\varphi_0). \tag{11}$$

From this condition, the expansion coefficient is determined as

$$c_{mn}=\frac{e^{-im\varphi_0}X_n{}^{m*}(v_0)e^{-(W/2k_0T)v_0}}{\int_{-1}^{1}|X_n{}^m|^2dv\cdot\int_{-1}^{1}e^{(W/k_0T)v}dv}. \tag{12}$$

§ 4. Spin-Lattice Relaxation Time and Spin-Spin Relaxation Time for the Rotations Restricted

By following the Solomon's theory[13], the relaxation of two-spin systems was treated by a random semiclassical perturbation.

Though his theory may be not rigorous enough, it was verified to be correct[14] when the fluctuations of the dipolar field are rapid as in liquids. Therefore, it may be reasonable to apply this method for the rubbery state of polymers.

The Hamiltonian of an interacting pair of like spins, in a magnetic field H_0 along the z' direction is

$$\mathscr{H}=\mathscr{H}_m-\hbar\gamma H_0(I_{1z'}+I_{2z'})+\mathscr{H}', \tag{13}$$

$\mathscr{H}_m$ is the Hamiltonian of the motion of the particles and commutes with the spin operators. The next terms are the Zeeman energies of two spins in the constant magnetic field H_0. We will consider only spin of value $\frac{1}{2}$ so that there is no quadrapole interaction. H' is the spin-spin interaction term considered as a perturbation which is expressed by

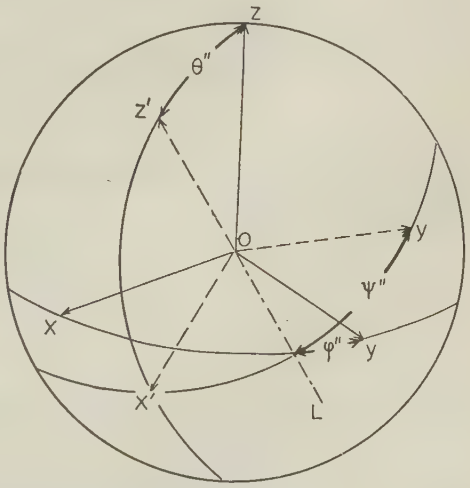

Fig. 3. Diagram illustrating the transformation between (θ, ϕ, ψ)-coordinate and $(\theta'\ \phi', \psi')$-coordinate. The magnetic field H is applied to the z'-direction. The Eulerian angles are illustrated by θ'', ϕ'', and ψ'', respectively.

$$\mathscr{H}'=[I_{1z'}\cdot I_{2z'}-\tfrac{1}{4}(I_{1+}\cdot I_{2-}+I_{1-}\cdot I_{2+})]F_0+[I_{1+}\cdot I_{2z'}+I_{1z'}\cdot I_{2+}]\cdot F_1$$
$$+[I_{1-}\cdot I_{2z'}+I_{1z'}\cdot I_{2-}]\cdot F_1{}^*+(I_{1+}\cdot I_{2+})\cdot F_2+(I_{1-}\cdot I_{2-})F_2{}^*\ , \tag{14}$$

where

$$\left\{\begin{aligned} &F_0(t)=k(1-3\cos^2\theta'(t)) && \text{(15a)}\\ &F_1(t)=-\tfrac{3}{2}k\sin\theta'(t)\cos\theta'(t)e^{i\varphi'(t)} && \text{(15b)}\\ &F_2(t)=-\tfrac{3}{4}k\sin^2\theta'(t)e^{2i\varphi'(t)}\ , && \text{(15c)}\end{aligned}\right.$$

and

$$k=\hbar^2\gamma^2/b^3\ , \tag{16}$$

and $I_\pm$ are the raising and lowering operators of the nuclear spin and $I_{z'}$ is the longitudinal component of the magnetic moment.

Now, as is shown in Fig. 3, the transformation of the coordinate system-(θ,φ) given in the preceding section into the coordinate system-(θ',φ') with the z' axis in the direction of the magnetic field, gives the following relations:

$$\left\{\begin{aligned} &\sin\theta'\cos\varphi'=(\cos\psi''\cos\varphi''\cos\theta''-\sin\psi''\sin\varphi'')\sin\theta\cos\varphi+(\cos\psi''\sin\varphi''\cos\theta''\\ &\qquad+\sin\psi''\cos\varphi'')\sin\theta\sin\varphi-(\cos\psi''\sin\theta'')\cos\theta\ . && \text{(17a)}\\ &\sin\theta'\sin\varphi'=(-\sin\psi''\cos\varphi''\cos\theta''-\cos\psi''\sin\varphi'')\sin\theta\cos\varphi+(-\sin\psi''\sin\varphi''\cos\theta''\\ &\qquad+\cos\psi''\cos\varphi'')\sin\theta\cdot\sin\varphi+(\sin\psi''\sin\theta'')\cos\theta\ . && \text{(17b)}\\ &\cos\theta'=(\cos\varphi''\sin\theta'')\sin\theta\cos\varphi+(\sin\varphi''\sin\theta''\cos\theta'')\sin\theta\cos\theta\sin\varphi\ . && \text{(17c)}\end{aligned}\right.$$

Transforming (θ',φ')-representations of F_0, F_1 and F_2 in Eqs. (15) into (θ,φ)-representations, we get

$$\left\{\begin{aligned} F_0/k=&-\tfrac{1}{2}(1-3\cos^2\theta)(1-3\cos^2\theta'')-\tfrac{3}{4}\sin 2\theta\,(e^{i\varphi}+e^{-i\varphi})\sin 2\theta''\\ &-\tfrac{3}{4}\sin^2\theta(e^{2i\varphi}+e^{-2i\varphi})\sin^2\theta'' && \text{(18a)}\\ F_1/k=&-\tfrac{3}{8}(1-3\cos^2\theta)\sin 2\theta''e^{-i\psi''}-\tfrac{3}{8}\sin 2\theta e^{i\psi}(\cos 2\theta''+\cos\theta'')e^{-i\psi''}\\ &-\tfrac{3}{8}\sin 2\theta e^{-i\psi}(\cos 2\theta''-\cos\theta'')e^{-i\psi''}-\tfrac{3}{8}\sin^2\theta\cdot e^{2i\varphi}\sin\theta''(1+\cos\theta'')e^{-i\psi''}\\ &+\tfrac{3}{8}\sin^2\theta e^{-2i\varphi}\sin\theta''(1-\cos\theta'')e^{-i\psi''}\ . && \text{(18b)}\\ F_2/k=&\tfrac{3}{8}(1-3\cos^2\theta)\sin^2\theta''e^{-2i\psi''}+\tfrac{3}{8}\sin 2\theta e^{i\varphi}\sin\theta''(1+\cos\theta'')e^{-2i\psi''}\\ &-\tfrac{3}{8}\sin 2\theta e^{-i\varphi}\sin\theta''(1-\cos\theta'')e^{-2i\psi''}+\tfrac{3}{16}\sin^2\theta e^{2i\varphi}(1+\cos\theta'')^2e^{-2i\psi''}\\ &+\tfrac{3}{16}\sin^2\theta\cdot e^{-2i\varphi}(1-\cos\theta'')^2e^{-2i\psi''} && \text{(18c)}\end{aligned}\right.$$

According to Solomon[13)], we have a couple of transition probabilities for the longitudinal component $I_{z'}$ as follows:

$$\left\{\begin{aligned} &w_1=\frac{1}{t\hbar^2}\left|\int_0^t\frac{1}{2}F_1(t')e^{-i\omega t'}dt'\right|^2\ . && \text{(19a)}\\ &w_2=\frac{1}{t\hbar^2}\left|\int_0^t\frac{1}{2}F_2(t')e^{-2i\omega t'}dt'\right|^2\ . && \text{(19b)}\end{aligned}\right.$$

In order to perform the integration of Eqs. (19), the following correlation functions corresponding to Eqs. (18) have to be determined.

$$K_i(\tau)=\langle F_i(t)\cdot F_i{}^*(t+\tau)\rangle\ . \qquad (i=0,\,1,\,2) \tag{20}$$

If we apply the distribution function of the Brownian motion expressed by Eq. (10), with the initial condition given by Eq. (11), to the correlation functions $K_i(\tau)$, and when the average over the initial values (θ_0,φ_0) and the average over Eulerian angles (θ'',φ'') are taken, the transition probabilities become

$$\left\{\begin{aligned} w_1&=\frac{3}{20}\left(\frac{k}{\hbar}\right)^2\left\{\frac{1}{4}\sum_n\frac{A_n\tau_n}{1+\omega^2\tau_n{}^2}+\frac{3}{4}\sum_n\frac{B_n\tau_n}{1+\omega^2\tau_n{}^2}+\frac{3}{4}\sum_n\frac{C_n\tau_n}{1+\omega^2\tau_n{}^2}\right\} &&\text{(21a)}\\ w_2&=\frac{3}{20}\left(\frac{k}{\hbar}\right)^2\left\{\sum_n\frac{A_n\tau_n}{1+4\omega^2\tau_n{}^2}+3\sum_n\frac{B_n\tau_n}{1+4\omega^2\tau_n{}^2}+3\sum_n\frac{C_n\tau_n}{1+4\omega^2\tau_n{}^2}\right\}, &&\text{(21b)}\end{aligned}\right.$$

where

$$\left\{\begin{aligned} A_n&=\left\{\int_{-1}^{1}(3v^2-1)X_n{}^0\exp\left(\frac{W}{2k_0T}\,v\right)dv\right\}^2\Big/\int_{-1}^{1}|X_n{}^0|^2dv\cdot\int_{-1}^{1}e^{(W/k_0T)v}dv &&\text{(22a)}\\ B_n&=\left\{\int_{-1}^{1}2v\sqrt{1-v^2}\,X_n{}^1\exp\left(\frac{W}{2k_0T}\,v\right)dv\right\}^2\Big/\int_{-1}^{1}|X_n{}^1|^2dv\cdot\int_{-1}^{1}e^{(W/k_0T)v}dv &&\text{(22b)}\\ C_n&=\left\{\int_{-1}^{1}(1-v^2)X_n{}^2\exp\left(\frac{W}{2k_0T}\,v\right)dv\right\}^2\Big/\int_{-1}^{1}|X_n{}^2|^2dv\cdot\int_{-1}^{1}e^{(W/k_0T)v}dv\,, &&\text{(22c)}\end{aligned}\right.$$

and A_n, B_n ,and C_n correspond to $m=0$, ±1, and ±2, respectively. When these values in Eq. (21) are used, the spin-lattice relaxation time T_1, the derivation of which is given in Appendix, is expressed as follows:

$$T_1{}^{-1}=2(w_1+w_2)=\frac{3}{8}\left(\frac{k}{\hbar}\right)^2\sum(A_n+3B_n+3C_n)\left(\frac{\tau_n}{1+\omega^2\tau_n{}^2}+\frac{4\tau_n}{1+4\omega^2\tau_n{}^2}\right). \tag{23}$$

On the other hand, the expressions of the transition probabilities of the transversal components are

$$\left\{\begin{aligned} u_1&=\frac{1}{t\hbar^2}\left|\frac{1}{4}\int_0^t\{e^{-i\omega t'}F_1(t')+e^{i\omega t'}F_1{}^*(t')-e^{-2i\omega t'}F_2(t')+e^{2i\omega t'}F^*(t')\}dt'\right|^2 &&\text{(24a)}\\ u_2&=\frac{1}{t\hbar^2}\left|\frac{1}{4}\int_0^t\left\{\frac{3}{2}F_0(t')+2e^{-\omega t'}F_1(t')-2e^{i\omega t'}F_1{}^*(t')+e^{-2i\omega t'}F_2(t')+e^{2i\omega t'}F_2{}^*(t')\right\}dt'\right|^2. &&\text{(24b)}\end{aligned}\right.$$

Following the similar procedure, we get the transition probabilities as follows:

$$\left\{\begin{aligned} u_1&=\frac{3}{20}\left(\frac{k}{\hbar}\right)^2\sum_{n=1}\left(\frac{A_n+3B_n+3C_n}{8}\right)\left(\frac{\tau_n}{1+\omega^2\tau_n{}^2}+\frac{\tau_n}{1+4\omega^2\tau_n{}^2}\right) &&\text{(25a)}\\ u_2&=\frac{3}{20}\left(\frac{k}{\hbar}\right)^2\sum_{n=1}\left(\frac{A_n+3B_n+3C_n}{8}\right)\left(3\tau_n+\frac{4\tau_n}{1+\omega^2\tau_n{}^2}+\frac{\tau_n}{1+4\omega^2\tau_n{}^2}\right). &&\text{(25b)}\end{aligned}\right.$$

As will be shown in Appendix, the spin-spin relaxation time T_2 can be represented with the above transition probabilities as

$$T_2{}^{-1}=2(u_1+u_2)=\frac{3}{10}\left(\frac{k}{\hbar}\right)^2\sum_{n=1}\frac{(A_n+3B_n+3C_n)}{8}\left(3\tau_n+\frac{5\tau_n}{1+\omega^2\tau_n{}^2}+\frac{2\tau_n}{1+4\omega^2\tau_n{}^2}\right). \tag{26}$$

However, we have to take the contribution of the term of $\lambda_{mn}=0$ to T_2 into account. This term in Eq. (10) is

$$\psi_{00}(v)=e^{(W/2k_0T)v}X_0{}^0=\exp\{W/(k_0T)\cdot v\}\,, \tag{27}$$

and

$$C_{00}=\left(\int_{-1}^{1}e^{(W/k_0T)v}dv\right)^{-1}. \tag{28}$$

This indicates that starting from an arbitary initial distribution $f(\theta_0,\varphi_0:0)$, the Boltzmann distribution in the potential $U(\theta)$ will be established after the time interval of $\Delta t\gg\eta^{-1}$. Hereafter we call $\psi_{00}(v)$ the stationary component. It is emphasized that the stationary component is obtained from the local magnetic field fluctuating rapidly due to the thermal motions restricted in the potential field but is independent of time.

As will be easily seen from the form of Fourier integral in Eqs. (19), the stationary component gives no contribution to T_1. But it contributes to T_2 through the term of $F_0(t)$ in Eq. (25b). The contribution must be calculated by a different method from the one described above. By using Eq. (27), the function corresponding to Eq. (20) is obtained from F_0 in Eq. (18a) by

$$K_s=\frac{1}{5}\frac{\left\{\int_{-1}^{1}(1-3v^2)e^{(W/k_0T)v}dv\right\}^2}{\left\{\int_{-1}^{1}e^{(W/k_0T)v}dv\right\}^2}\,. \tag{29}$$

This corresponds to the time-independent component in the local magnetic field. Therefore, according to BPP theory[11)], K_s is related to the term of $(T_2)_s$ that is the contribution of the stationary component to T_2. The relation between K_s and $(T_2)_s$ is

$$(T_2)_s^{-1}=\frac{\sqrt{3}}{2}\sqrt{I(I+1)}\left(\frac{k}{\hbar}\right)K_s^{1/2}\,. \tag{30}$$

Hence, the spin-spin relaxation time for the rotation hindered by the given potential barrier is expressed as the sum of two contributions mentioned above. That is,

$$T_2^{-1}=(T_2)_m^{-1}+(T_2)_s^{-1}\,, \tag{31}$$

where $(1/T_2)_m$ is obtained as Eq. (27).

§ 5. Case of $W/k_0T<1$

Although it is generally rather difficult to solve Eq. (9), the solutions of the case we shall deal become easy, because the assumption of the hindering potential W is assumed to be $W/k_0T<1$. In this case, X_n^m and λ_{mn} in Eq. (9) can be expanded as a power series of W/k_0T as follows:

$$\left\{\begin{aligned} &X_n^m=\exp\left(\frac{W}{2k_0T}v\right)\cdot\left(X_n^{m(0)}+\left(\frac{W}{k_0T}\right)X_n^{m(1)}+\left(\frac{W}{k_0T}\right)^2X_n^{m(2)}+\cdots\right) && \text{(32a)}\\ &\lambda_{mn}=\lambda_{mn}^{(0)}+\left(\frac{W}{k_0T}\right)\lambda_{mn}^{(1)}+\left(\frac{W}{k_0T}\right)^2\cdot\lambda_{mn}^{(2)}+\cdots\,. && \text{(32b)}\end{aligned}\right.$$

The zero-order approximations of Eqs. (32) are

$$\left\{\begin{aligned} &X_n^{m(0)}=\hat{P}_n^m(v) && \text{(33a)}\\ &\lambda_{mn}^{(0)}=n(n+1)\cdot k_0T/\eta\,, && \text{(33b)}\end{aligned}\right.$$

where $\hat{P}_n^m(v)$ is the normalized Legendre function. Moreover, $\lambda_{mn}^{(1)}$ is given by the equation

$$\lambda_{mn}^{(1)}=\int\hat{P}_n^m v\hat{P}_n^{m*}dv=0\,. \tag{34}$$

Therefore, the eigenvalue is not influenced by the existence of the hindering potential for the first order approximation.

On the other hand, using the first order approximation of X_n^m, we get the following equations for the coefficients A_n, B_n and C_n in Eqs. (22).

$$\left\{\begin{aligned} &A_1^{(1)}=\frac{3}{25}\left(\frac{W}{k_0T}\right)^2\left[1+\left\{\frac{1}{6}+\frac{3}{5}+\frac{1}{3^2}\left(1+\frac{1}{5^2}\right)\right\}\left(\frac{W}{k_0T}\right)^2\right]^{-1}\\ &A_2^{(1)}=\frac{4}{5}\left[1+\left\{\frac{1}{6}+\frac{11}{21}+\frac{1}{5^2}\left(\frac{1}{3^2}+\frac{1}{7^2}\right)\right\}\left(\frac{W}{k_0T}\right)^2\right]^{-1}\\ &A_3^{(1)}=\frac{7}{27}\left(\frac{W}{k_0T}\right)^2\left[1+\frac{23}{45}+\left\{\frac{1}{6}+\frac{1}{7^2}\left(\frac{1}{5^2}+\frac{1}{9^2}\right)\right\}\left(\frac{W}{k_0T}\right)^2\right]^{-1}\\ &A_l^{(1)}=0 \qquad (l\neq 1,2,3)\end{aligned}\right. \tag{35}$$

$$\left\{\begin{aligned} B_1^{(1)}&=\frac{3}{50}\left(\frac{W}{k_0T}\right)^2\left[1+\frac{1}{5}+\left(\frac{W}{k_0T}\right)^2\left(\frac{1}{6}+\frac{1}{5^2}\right)\right]^{-1}\\ B_2^{(1)}&=\frac{8}{15}\left[1+\left(\frac{W}{k_0T}\right)^2\left\{\frac{1}{6}+\frac{4}{7}+\frac{1}{5^2}\left(1+\frac{8^2}{7^2}\right)\right\}\right]^{-1}\\ B_3^{(1)}&=\frac{14}{27}\times\frac{4^2}{5^2}\left[1+\left(\frac{W}{k_0T}\right)^2\left\{\frac{1}{6}+\frac{7}{15}+\frac{1}{7^2}\left(\frac{8^2}{5^2}+\frac{9^2}{3^2}\right)\right\}\right]^{-1}\\ B_l^{(1)}&=0\qquad (l\neq 1,\, 2,\, 3) \end{aligned}\right. \tag{36}$$

$$\left\{\begin{aligned} C_2^{(1)}&=\frac{8}{15}\left[1+\left(\frac{W}{k_0T}\right)^2\left\{\frac{3}{28}+\frac{1}{6}+\frac{8^2}{7^2}\right\}\right]^{-1}\\ C_3^{(1)}&=\frac{14}{135}\left(\frac{W}{k_0T}\right)^2\left[1+\frac{1}{3}+\left(\frac{W}{k_0T}\right)^2\left\{\frac{1}{6}+\frac{1}{7^2}(8^2+20^2)\right\}\right]^{-1}\\ C_l^{(1)}&=0\qquad (l\neq 2,\, 3)\,. \end{aligned}\right. \tag{37}$$

For the term corresponding to $n=0$, that is, the stationary component, we get the following equation neglecting the higher decimals than the order of three in the expansion:

$$K_{0s}=\frac{1}{5}\left(\frac{2}{15}\right)^2\left(\frac{W}{k_0T}\right)^4\left\{1-\frac{4}{21}\left(\frac{W}{k_0T}\right)^2\right\}\,. \tag{38}$$

Then we can estimate both T_1 and T_2 according to the following expressions with the first order approximation of X_n^m and λ_{mn}:

$$\left\{\begin{aligned} T_1^{-1}&=\frac{\eta}{k_0T}\left(\frac{k}{\hbar}\right)^2\left\{0.25-0.033\left(\frac{W}{k_0T}\right)^2\right\} && \text{(39a)}\\ T_2^{-1}&=0.045\left(\frac{k}{\hbar}\right)\left(\frac{W}{k_0T}\right)^2+\frac{\eta}{k_0T}\left(\frac{k}{\hbar}\right)^2\left\{0.25-0.033\left(\frac{W}{k_0T}\right)^2\right\}\,. && \text{(39b)} \end{aligned}\right.$$

For the case of $W/k_0T>1$, the perturbation theory is not applicable. Thus, it is difficult to get the solutions of X_n^m and λ_{mn}, but we can obtain the average value $\langle\lambda_{mn}\rangle$. The detailed discussion on this point will be reported in near future.

§ 6. Discussions

I. *Some properties of T_1 and T_2 in PIB solutions*

(I) *A note of the critical concentration in polymer solution.*

Before attempting to apply our theory described in the preceding sections to the results of T_1 and T_2 measured in polymer solutions, it must be noted that both T_1 and T_2 tend to have certain values which are independent of the molecular weight as the concentration decreases. As mentioned in the preceding section, both T_1 and T_2 fall rapidly with increasing concentration above a fairly well defined critical value. Fig. 4 shows the critical concentration, corresponding to the knee in T_2 curve at 25°C, as a function of the molecular weight. The critical concentration is presumably the concentration above which each polymer molecule has a kind of entanglement each other as Nolle[10] pointed out. From this presumption, he estimated the critical concentration theoretically as follow:

$$W_c=7.1M_s^{3/2}/\alpha^3Al^3M^{1/2}\,, \tag{40}$$

where M_s stands for molecular weight of the basic unit, α for "excluded volume", A for Avogadro's number, l for the length of segment, and M for the Molecular weight of the chain molecule.

Nolle[10] thought that Eq. (40) was not satisfied with his experimental data, as is shown in the solid line in Fig. 4, but it is supposed that the experimental data is in fairly good agreement with Eq. (40) in the range of the molecular weight higher than 10^5, as is shown by the broken line in Fig. 4. Under the molecular weight of 10^5, the assumption that each long chain molecule coils up in a sphere and α can be taken as unity does not presumably hold, and then the curve of W_c would shift from the proportional line to $M^{-1/2}$.

The dependency of viscosity of liquid polymers and concentrated solutions on the molecular weight[16) is known to change at the molecular weight 10^3, that is, to show a different characteristic beyond this boundary of polymerization. This might essentially have a connection with the phenomenon of polymer solutions mentioned above.

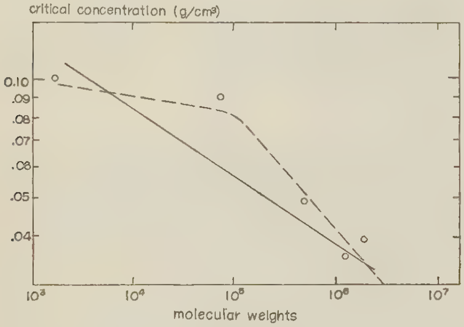

Fig. 4. Critical concentration of PIB solution, corresponding to the knee in T_2 curve at 25°C, as a function of molecular weight (obtained by Nolle). The solid line plotted by Nolle represents critical concentration proportional to the $-1/6$ power of molecular weight. The broken line added by the author represents $-1/2$ power of molecular weight, above that of 10^5.

(II) *A kinematic unit of segmental motions.* There is another important connection between the properties of liquid polymers and the polymer solutions. In the viscous flow of liquid polymers[17), it has been suggested that the elementary process of flow consists of the displacement or jump of only a small segment of molecule rather than the displacement of the entire molecules as a unit. As the evidence of supporting this hypothesis for long chain polymers, it was found that the values of the activation energy were low (only several times the values of their monomer unit) and independent of chain length.

On the other hand, the half widths shown in Table I or T_1^{-1} and T_2^{-1} in the Nolle's data[10) are independent of the molecular weights. And their values are more than ten times of the order of the monomer molecules, for instance, T_1 of PIB solutions (C=0.0173 g/cm³) at 20°C is 0.09 sec[10) and T_1 of distilled water (η=1.02 centi-poise) at 20°C is 2.3 sec[11). Consequently, it is readily interpreted that the reorientation or the displacement is carried out by such a small segment with about ten monomer units as the segment in liquid polymers*.

(III) *A mechanism of segmental motions.* It is found from the above mentioned data that the frictional constants of segmental motions in the high frequency region are not related to the chain length. This frequency region is correspondent to more than O(10^6 c/s). Below this frequency, spectral lines are unobservable by the Varian Spectrometer.

The result that the relaxation times are independent of the molecular weight suggests us that the motional behavior of each segment is not so markedly influenced by the interaction of other segments on the same chain that the Kirkwood theory[3) predicted. This theory gives the mobility of segments a large inhomogeneity for their positions on the chain so that the theoretical result does not become to agree with the experimental results.

From NMR data, it may reasonably be assumed that the mobilities of segments in the high frequency motions are homogeneous concerning to the position on the chain to which the segments belong. When the concentration increases, however, the entanglement among the chain molecules must be considered. The entanglement may give a kind of steric hinderance to the reorientation and the displacement of the segments. Herein, we assume for simplicity that such a hinderance can be expressed independently of each molecular group in the segment by equation:

$$V(\theta_{i\lambda}) = -W\cos\theta_{i\lambda}\,, \tag{41}$$

where the suffix means i-th gronp in λ-th segment. The Eulerian angles (θ'', ψ'') given in Eq. (17) are expressed on coordinates defined in each molecular group, in each segment, respectively.

It should be noted that such hindering potentials can not in general be assumed to be

---

[*] It is well known in experimental results of T_1[11) that the correlation time τ of molecular motion is given by

$$\tau = 4\pi\eta a^3/3k_0T\,. \tag{53}$$

In the above PIB-CCl_4 solution, the viscosity coefficient of CCl_4 is 0.97 centi-poise[4 at 20°C, so effective volume of PIB for segmental motion is approximately twenty five times of that of water molecule.

fixed in the space. The potential field should be understood to fluctuate because of the motion of the chain molecule or the large group of segments as a whole. According to the dynamical study, for instance, in PIB (molecular weight, 3.87×10^{6})-cychlohexane solution (1%)[18], the characteristic frequency of the motion of large group of segments is 550 c/s.

Therefore, in polymer solutions, the stationary component in Eq. (27) gives the contribution to T_2 in somewhat modified form. That is to say, the contribution of motion due to the segment group to T_2 becomes as follows when the motional effect derived from the Kubo-Tomita equation[12], are taken into consideration:

$$(T_2^{-1})_g=\frac{2}{\pi}(T_2^{-1})_s\cdot\tan^{-1}\left(\frac{\pi\tau_g}{4\log 2\cdot T_2}\right), \quad (42)$$

where $(T_2^{-1})_s$ was given in Eq. (30) and τ_g is the correlation time of motion of submolecule group as a whole.

In conclusion, the present model is divided into two parts for the segmental motions: the one is the micro-rotational motion of segment, and the other the motion of segment group as a whole.

II. *Some notes concerning application of theory of T_1 and T_2 to polymer solutions*

Based on the above described assumptions, the NMR in PIB solution can be treated as the problem of NMR in the system in which two-spin system of CH_2 groups and three-spin system of CH_3 groups exist independently each other. The theory concerning to this problem was discussed in the former sections.

First, the following points must be taken into consideration. One is the point that an absorption line of PIB solution in Fig. 1 consists of two lines and each of them comes from the CH_3 and the CH_2 groups. Hence Nolle's values of both T_1 and T_2 measured by "spin-echo" method should be considered as a kind of average value of the two groups. The average is assumed to be

$$\frac{1}{T_i}=\frac{1}{4}\left(\frac{1}{T_i}\right)_{CH_2}+\frac{3}{4}\left(\frac{1}{T_i}\right)_{CH_3}, \quad (i=1,\ 2) \qquad (43)$$

where the coefficients 3/4 and 1/4 come from the ratio of the number of protons in the CH_3 and the CH_2 groups in PIB molecule.*

The next problem is the estimation of influence of the interaction due to inter-group protons upon T_1 and T_2. Powles[1] found from the measurement of the second moment of PIB that the spin-spin interaction due to the inter-groups was unexpectedly large. In a solution, however, each group rotates with a sufficient rapidness about the $C-C$ axis so that the local magnetic field due to the inter-group interaction would be more remarkably averaged than due to the intra-group interaction. In other words, it may be able to assume, by neglecting the inter-group interaction, that only the intra-group interaction contributes to both T_1 and T_2 in a solution.

Furthermore, it must be noted that the Solomon's theory[13] is not generally applicable to the system with more two spins. Kubo-Tomita's theory[12] shows, however, that T_1 and T_2 can be given by similar equations with the relations obtained from Solomon's theory[13] even for the systems with many spins, when the correlation function is expressed by

$$K(\tau)=\exp(-|t|/\tau_c)\ .^{**} \qquad (46)$$

---

* The reasonability of T_1 and T_2 that can be computed from Eq. (43) will be examined compared with the experimental data in PIB-solutions. The half widths of the CH_3 and CH_2 groups in the PIB solution (6.5 g/100 cc) are 6.5 c/s and about 10 c/s, respectively, as shown in Table I. By subtracting the width of the inhomogeneous magnetic field $\Delta\nu'$ of 2 c/s, and by using the relation of $T_2^{-1}=\pi(\Delta\nu_{1/2}-\Delta\nu')$, Eq. (43) gives the value of T_2^{-1} as

$$T_2^{-1}\approx 17\ \text{sec}^{-1}\ . \qquad (44)$$

On the other hand, the Nolle's data give the following value of T_2^{-1} at $c=0.059$ g/cm³ and $T=20$°C.

$$T_2^{-1}\approx 20\ \text{sec}^{-1}\ . \qquad (45)$$

Thus, T_2 calculated from the line width in the present measurements is in fairly good agreement with that in Nolle's data.

** In this theory, T_1 and T_2 are

$$\begin{cases} T_1^{-1}=\sigma_P{}^2B\left(\dfrac{2}{5}\dfrac{\tau_c}{1+\omega^2\tau_c{}^2}+\dfrac{8}{5}\dfrac{\tau_c}{1+4\omega^2\tau_c{}^2}\right) & (47a)\\ T_2^{-1}=\sigma_P{}^2B\left(\dfrac{3}{5}\tau_c+\dfrac{\tau_c}{1+w^2\tau_c{}^2}+\dfrac{2}{5}\dfrac{\tau_c}{1+4\omega^2\tau_c{}^2}\right), & (47b)\end{cases}$$

where

$$\begin{cases} \sigma_P{}^2=I(I+1)(k/\hbar)^2 & (48a)\\ B=\sum_j (b/r_{ij})^\gamma\ . & (48b)\end{cases}$$

When Eqs. (47) are applied to two-spin systems, the same solutions as Solomon's equation can be described.

And, in case of such a modified correlation function as Eq. (10), it is assumed that Eqs. (27) and (31) obtained in the preceding section are applicable, by substituting $\sigma_P{}^2B$ for $I(I+1)(k/\hbar)^2$, in three-spin systems, too. The $\frac{3}{5}\tau_P{}^2B$ in Eqs. (47) is the second moment of rigid state[12)], and is given by

$$\tfrac{3}{5}\sigma_P{}^2B=\gamma^2\langle \Delta H^2\rangle_{\text{rig}}\ . \tag{49}$$

Therefore, $\frac{3}{5}\sigma_P{}^2B$ in Eq. (49) is

$$\tfrac{3}{5}\sigma_P{}^2B=\tfrac{3}{4}(\gamma^2\langle \Delta H^2\rangle_{\text{rot}})_{\text{CH}_3}+\tfrac{1}{4}(\gamma^2\langle \Delta H^2\rangle)_{\text{CH}_2}=5.03\times 10^9(\text{sec}^{-2})\ .^{*} \tag{50}$$

III. *Comparison of the present theory with the experimental results*

Nolle's measurements of both T_1 and T_2 were carried out at the resonance frequency $\omega/2\pi$ of 28 Mc/s. Therefore, as shown in Fig. 2, the small values of $T_1{}^{-1}$ and $T_2{}^{-1}$ of PIB solutions in his data indicate the condition of $\tau_n \ll \omega^{-1}$ for the correlation times in Eqs. (39). Hence, by using Eq. (50), Eqs. (39) are applicable to this case in such forms as

$$\left\{\begin{aligned} &T_1{}^{-1}=\frac{\eta}{k_0T}\sigma_P{}^2B\left\{0.33-0.044\left(\frac{W}{k_0T}\right)^2\right\} && \text{(52a)}\\ &T_2{}^{-1}=0.052\sqrt{\sigma_P{}^2B}\left(\frac{W}{k_0T}\right)^2\frac{2}{\pi}\tan^{-1}\frac{\pi\tau_g}{4\log 2\cdot T_2}+\frac{\eta}{k_0T}\sigma_P{}^2B\left\{0.33-0.044\left(\frac{W}{k_0T}\right)^2\right\}\ , && \text{(52b)}\end{aligned}\right.$$

where the mobility of segmental motion is expressed by

$$\beta=\eta^{-1}=\beta_0\exp(-U/k_0T)\ . \tag{54a}$$

It is clear, from $\log T/T_1$ curves represented approximately with a straight line in Fig. 2, that Eq. (52a) is in a good agreement with the experimental curve, if the hindering potential W in Eq. (52a) is understood to satisfy $W/k_0T<1$.

Table II. The activation energies of segmental motion.

Concentration (g/cm³)	(A) from T_1 curves	(B) from T_2 curves in the consideration of stationary component	(C) from T_2 curves without the stationary component
0.017	2.6		3.2
0.059		3.8	2.9
0.091	3.6	4.1	2.9
0.350		5.4	2.7

As is shown in Table II (A), for the solution of lower concentration (0.017 g/cm³), the activation energy U estimated from the the gradient of $\log T/T_1$ curve in Fig. 2 is

$$U=2.6\ \text{Kcal/mol}\ . \tag{54b}$$

It is note-worthy that this value is approximately same with 2.4 Kcal/mole of the activation energy of the solvent, CCl_4**.

For the solution of higher concentration (0.091 g/cm³), the gradient of the curve becomes steeper and less linear. On the other hand, $\log T/T_2$ curves shown in Fig. 2 are less linear than the curve of $\log T/T_1$. When the solution becomes more dense, the deviation of the curve from the straight line becomes appreciable. This tendency is especially remarkable in the region of high temperature.

Another noticeable result is that T_1 is larger than T_2 in dilute solutions in spite of the other theoretical prediction[11)-13)] of $T_1\approx T_2$ when $\tau_N<\omega^{-1}$. According to the present theory, however, Eq. (52b) is also in a good agreement with the experimental curves of T_2.

---

* The second moments of both methylene and methyl groups in PIB molecule can be calculated as follows, by assuming the tetrahedral structure:

$$\left\{\begin{aligned} &(\langle \Delta H^2\rangle)_{\text{CH}_2}=11.3\ \text{gauss}^2 && \text{(51a)}\\ &(\langle \Delta H^2\rangle)_{\text{CH}_3}=22.5\ \text{gauss}^2\ . && \text{(51b)}\end{aligned}\right.$$

However, the CH_3 groups in PIB solutions rotate more rapldly about C_3-symmetric axis than motions with the other freedoms in a molecule. According to Gutowsky and Pake[20)], in a C_3-rotation, the effective value of the second moment of CH_3 group is one forth of the second moment in a irrotational state. Namely,

$$(\langle \Delta H^2\rangle_{\text{rot}})_{\text{CH}_3}=5.6\ \text{gauss}^2\ . \tag{51c}$$

** The value of activation energy for CCl_4 was calculated from the temperature variation of the viscosity of CCl_4 which was tabulated on the chemical table in "Kagaku-Binran", (Maruzen press, 1958) 476.

Thus the author is inclined to consider that this agreement is due to the stationary component in Eq. (52b).

Since the temperature variation of the stationary component in Eq. (52b) is less than that of the other terms, the contribution of the stationary component to T_2 should become effective at high temperature.

Even at lower concentration of C=0.017 g/cm³, at which individual chain molecule is supposed to be independent and separated, as was described in the preceding section, the $\log T/T_2$ curve also deviated considerably from a linearity and is not equal to $\log T/T_1$. The reason of this trend is not clear at the present state.

Table III. The hindering potential energies.

Concentration (g/cm³)	W/k_0T
0.017	1.2×10^{-2}(50°C)
0.091	2.5×10^{-2}(60°C)

The values of hindering potential can be determined from the ratio of T_1 and T_2 by using the Eqs. (52), if the correlation time τ_g of submolecular group in Eq. (42) is known. Assuming $\tau_g > T_2$ in Eq. (52b), for simplicity, we obtain the value of W as shown in Table III. It is supposed that the small values of hindering potential energy in Table III are due to the flexible rotation of each molecular group around the $C-C$ axis in a chain molecule in spite of the fact that the translational motion of molecule as a whole is hindered by the entanglements among chains in solutions.

Further, the relation

$$T\left\{T_2^{-1}-0.052\sqrt{\sigma_P{}^2 B}\left(\frac{W}{k_0T}\right)^2\right\} = 0.33\frac{\sigma_P{}^2 B}{k_0\beta_0}\exp\left(\frac{U}{k_0T}\right) \tag{55}$$

is plotted against the inverse of temperature T^{-1} in Fig. 5 for three cases of C=0.059, 0.091, and 0.35 (g/cm³). Here, the values of W are assumed as $2.1\times10^{-2}\,k_0T$, $2.3\times10^{-2}\,k_0T$, and $4.6\times10^{-2}\,k_0T$, respectively.

When the approximation introduced in the above discussion is considered, the linearity of the curve shown in Fig. 5 is satisfactory. The activation energy U obtained from T/T_2 curves by Eq. (55) is tabulated for various concentrations in Table II (A and B). As are shown in Table II, both W and U increase with the concentration.

On the other hand, the values of activation energy which are calculated, by following the conventional way, in an approximation of neglecting the contribution of the stationary component in Eq. (52b) are added in Table II(C). It can be seen that the activation energy decreases as the concentration increases, if the conventional way is employed. In many studies of NMR, for instance, concerning to valcanized rubbers[1] and plasticized PIB[19], it is also reported that an opening the freedom of segmental motions introduces an increases of activation energy.

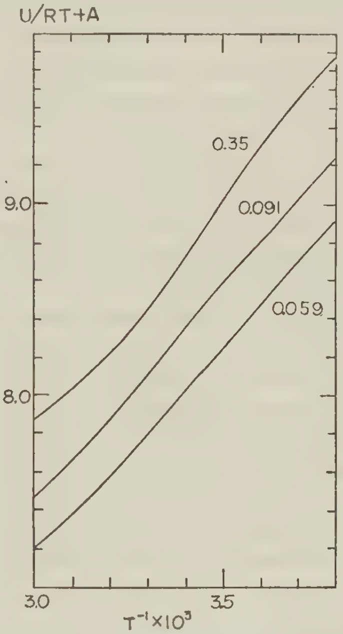

Fig. 5. Plot of U/k_0T against $1/T$ obtained by the use of Eq. (55), at the three concentrations (g/100 cc) of PIB solution which are indicated in the curves, respectively.

In the other measurements of mechanical[17] and dielectric relaxations[21], however, it is well known that the activation energy decreases with the concentrations of solvents. As the freedom of segmental motion depends upon the entanglement among chain molecules, it is rather acceptable that the activation energy would decrease with the increase of solvents. Thus, in this case, above mentioned results which is derived from Eq. (52b) with the stationary component, may seem to be plausible.

Table IV. The correlation times and the relaxation times in polymer solutions.

Method	Sample	Solvent	(sec)	Concentration	Temperature (°C)
NMR	PIB	CCl_4	2×10^{-9}	6.5 g/100 cc	20
	PS	CCl_4	4.6×10^{-9}	6.5 g/100 cc	20
Dielectric	PVAc	toluene	7×10^{-9}	6 g/100 cc	−10
	PMA	toluene	1.6×10^{-8}	6 g/100 cc	−10
Ultrasonic	PIB	cyclohexane	4.5×10^{-7}	1%	25

IV. *Correlation time and hindering potential*

The correlation time τ_N* and the relaxation times τ_D and τ_M are presented in Table IV, respectively. The τ_M used in Table IV is the value which is obtained from the dispersion of ultrasonic shear wave in the PIB-cyclohexane solution (1%). It has been explained that the ultrasonic relaxation time in this case is related to the twisting motion of the smallest segment group in a chain, since the stiffness of PIB-cyclohexane solution becomes from 890 dyne/cm² to 84,000 dyne/cm² in the frequency region of $\omega>\tau_N^{-1}$.[18] The τ_N is the value of PIB–CCl_4 solution obtained from our measurement. The value of τ_N is remarkably smaller than τ_M. This suggests to us that the mechanism of segmental motion observed by the ultrasonic relaxation is different from the one detected by NMR.

As shown in Table IV, however, τ_N may be of the same order of τ_D at the same concentration and temperature which is obtained by extrapolating from the experimental data[9], even if the samples employed are not same in both cases.

These data seem to be very interesting and important facts in making clear the mechanisms of segmental motions in a chain molecule.

Next, it is very desirable to verify how the hindering potential W described in the present theory is connected with the other physical quantities characterising the motions of polymer molecule. As mentioned above, the stiffness of polymer solutions is markedly large in the regions of high frequency. Hence, it is supposed that in this case the flow of segment group as a whole is quenched but the micro-Brownian motions of segments are occured in a certain restricted region. That is to say, the rigidity of polymer molecule depends upon the so-called energy effect rather than the so-called entropy effect concerning the rotational motion of segment around each C–C bond, even if the entropy effect is an origin of the rubber elasticity in polymer systems in static case.

Following the above consideration, the rigidity of polymer system in the high frequency field can be simply estimated as follows. It may be reasonable to adopt Eq. (6) as the potential energy concerning the rotational displacement of each segment.

Hence, for a small displacement, the potential energy per 1 cc of polymer systems, for example, PIB solutions (1 g/100 cc) is given by

$$E=\frac{1}{2}W\theta^2\frac{N}{M}\times0.01\,, \tag{56a}$$

where M is the molecular weight of the monomer and N is Avogadro's number.

If we assume $W=10^{-2}\,k_0T$, in the consideration of our results shown in Table III, the value of energy at 300°K becomes

$$E=\frac{4.3}{2}\times10^{4}\cdot\theta^2\,. \tag{56b}$$

On the other hand, the energy of this should be same as the elastic energy in the system caused by the ultrasonic shear wave, that is

$$E=\frac{1}{2}G\cdot\theta^2\cdot V\,, \tag{57}$$

where G is the rigidity and V the volume in the system. Therefore, in the above case, G is

$$G=4.3\times10^4\ \text{dyne/cm}^2\,. \tag{58}$$

This value is in a pretty good agreement with the experimental value of rigidity, 8.4× 10 dyne/cm², in PIB-cyclohexane solution (1%) which has the similar condition with the one assumed in Eq. (56b).

---

* τ_N was calculated from the data of line width shown in Table I, by using Eqs. (47). Here we assumed a single correlation time in the polymer solutions.

In conclusion, it may be sure that the potential field hindering the motions of segments in a chain exists even in fairly dilute solutions of polymer, and the results that the hindering potential has an effect on segmental motions become more and more marked in high frequency measurements.

It seems to us, that the present theory of the segmental motion is more proper in such a case than the Kirkwood[3)] or the Rouse[4)] and Bueche[5)] theories, though it has not been applied to a number of problems concerning relaxational phenomena other than NMR one in polymer solutions.

Acknowledgement

The author would like to express his sincere thanks to Professor Y. Yokozawa for his continuous interests in this study. Grateful thanks are also due to Professor G. Hazato and his coworkers at Tohoku University for their kind cooperations to carry out the measurements. The author would also like to extend his thanks to my friends Dr. M. Arie, Assistant Professor J. Sohma, and Mr. Y. Miyake, Hokkaido University for invaluable discussions and helps.

Appendix. Relaxation Processes in Two-Spin System

According to the Solomon's paper[13)], we define two eigenstates $|+\rangle$ and $|-\rangle$ of the unperturbed Hamiltonian for spin I_1 of value $\frac{1}{2}$ corresponding to both energies E_+ and E_-, respectively.

Similar two eigenstates of spin I_2 of value $\frac{1}{2}$ are defined as $|+)$ and $|-)$.

Thus we define four eigenstates of two spins by the following relations

$$\left\{\begin{aligned} &I_{1\zeta}|+\rangle=\tfrac{1}{2}|+\rangle \\ &I_{1\zeta}|-\rangle=-\tfrac{1}{2}|-\rangle \\ &I_{2\zeta}|+)=\tfrac{1}{2}|+) \\ &I_{2\zeta}|-)=-\tfrac{1}{2}|-)\ . \end{aligned}\right. \tag{A1}$$

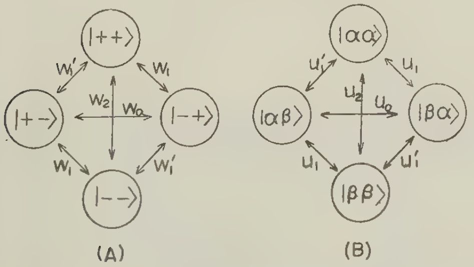

Fig. 6. (A) Transition probabilities between the eigenstates of the longitudinal components of the spin operators. (B) Transition probabilities between the eigenstates of the transverse components of the spin operators.

Therefore the four unperturbed eigenstates of two-spin system become $|+,+\rangle$, $|+,-\rangle$, $|-,+\rangle$ and $|-,-\rangle$ with the respective occupation members N_{++}, N_{+-}, N_{-+} and N_{--}. The transition probabilities between these four states shown in Fig. 6(a) are represented by w_0, w_1, w_1' and w_2.

Next, four eigenstates of the transverse components of the magnetic moment must be also defined. These four eigenstates of the spins are expressed by

$$\left\{\begin{aligned} &I_{1\xi}|\alpha\rangle=\tfrac{1}{2}|\alpha\rangle \\ &I_{1\xi}|\beta\rangle=-\tfrac{1}{2}|\beta\rangle \\ &I_{2\xi}|\alpha)=\tfrac{1}{2}|\alpha) \\ &I_{2\xi}|\beta)=-\tfrac{1}{2}|\beta)\ . \end{aligned}\right. \tag{A2}$$

Hence the four states of a pair, $|\alpha,\alpha\rangle$, $|\alpha,\beta\rangle$, $|\beta,\alpha\rangle$ and $|\beta,\beta\rangle$, are not eigenstates of the energy. According to Solomon's theory, however, we can define the occupation numbers $N_{\alpha\alpha}$, $N_{\alpha\beta}$, $N_{\beta\alpha}$ and $N_{\beta\beta}$, and the transition probabilities u_0, u_1, u_1' and u_2 between these states, as are indicated on Fig. 6(b).

The macroscopic magnetic moments of $\bar{I}_{1\zeta}$ and $\bar{I}_{2\zeta}$ are given by the following equations:

$$\left\{\begin{aligned} &K\bar{I}_{1\zeta}=(N_{++}+N_{+-})-(N_{-+}+N_{--}) && \text{(A3a)} \\ &K\bar{I}_{2\zeta}=(N_{++}+N_{-+})-(N_{+-}+N_{--})\ . && \text{(A3b)} \end{aligned}\right.$$

Similar equations are also given for the transverse components $\bar{I}_{1\xi}$ and $\bar{I}_{2\xi}$.

Thus, the equations of motion of the longitudinal component and the transverse one in the two spin system lead to the following equations, respectively:

$$\left\{\begin{aligned} &\frac{d(\bar{I}_{1\zeta}+\bar{I}_{2\zeta})}{dt}=-2(w_1+w_2)(\bar{I}_{1\zeta}+\bar{I}_{2\zeta}-2\bar{I}_0) && \text{(A4a)} \\ &\frac{d(\bar{I}_{1\xi}+\bar{I}_{2\xi})}{dt}=-2(u_1+u_2)(\bar{I}_{1\xi}+\bar{I}_{2\xi})\ . && \text{(A4b)} \end{aligned}\right.$$

In conclusion, the longitudinal relaxation time T_1 and the transverse one T_2 are given respectively by

$$\left\{\begin{aligned} &1/T_1=2(w_1+w_2) && \text{(A5a)} \\ &1/T_2=2(u_1+u_2)\ . && \text{(A5b)} \end{aligned}\right.$$

Effects of Gamma Rays on Aqueous Solution of Polyvinyl Alcohol

By Osamu SAITO

Faculty of Engineering, Chuo University, Bunkyo-ku, Tokyo

(Received March 4, 1959)

The general treatment developed in previous papers is applied to the case where the aqueous solution of polyvinyl alcohol is irradiated by gamma rays and the results are compared with Danno's measurements. The behaviours of irradiated aqueous solution of polyvinyl alcohol before and after gelation are well explained by the author's general theory. It is concluded from the analysis that end-linking instead of cross-linking occurs in the solution and also that only one molecular end out of the two which are produced by molecular scission of a polymer links with a monomer unit of another polymer molecule. It is also shown that if any impurity, especially oxygen, is not contained, the intrinsic viscosity of polyvinyl alcohol increases with radiation dose.

§ 1. Introduction

The author developed in his previous papers$^{1)-3)}$ a general theory concerning the effects of high energy radiation on polymers. In this paper the theory will be applied to the case where the aqueous solution of polyvinyl alcohol is irradiated by gamma rays. A. Danno measured the intrinsic viscosity and the gel point of polyvinyl alcohol irradiated by gamma rays$^{4)}$. These results are shown in Figs. 1 and 2. The change in viscosity-average degree of polymerization with increasing amount of radiation dose is represented in Fig. 1, and the dose for the incipient gel formation shown in Fig. 2 has a minimum at a certain value of concentration. The properties shown in these figures must be accounted for by a general theory.

When a polymer is irradiated by ionizing radiation, the intrinsic viscosity $[\eta]$ will change its value with the radiation dose R. It has been shown in the previous paper[3] that in the early period of irradiation we have the relation:

$$[\eta]/[\eta]_0=1+A_1R+A_2R^2+\cdots\,, \qquad (1)$$

where $[\eta]_0$ is the intrinsic viscosity before irradiation. The viscosity-average degree of polymerization $\bar{p}$ is likewise expressible in the following form:

$$\bar{p}/\bar{p}_0=1+B_1R+B_2R^2+\cdots\,, \qquad (2)$$

where $\bar{p}_0$ is the initial value of $\bar{p}$ and

$$B_1=A_1/\alpha,\ B_2=(A_2/2)+(1-\alpha)A_1^2/2\alpha,\ \cdots. \qquad (3)$$

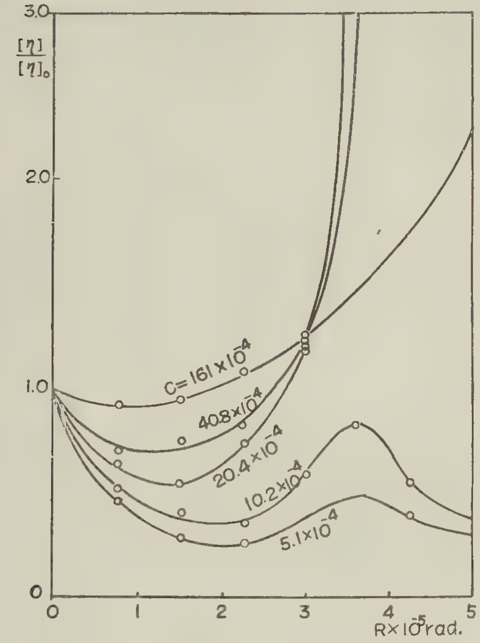

Fig. 1.

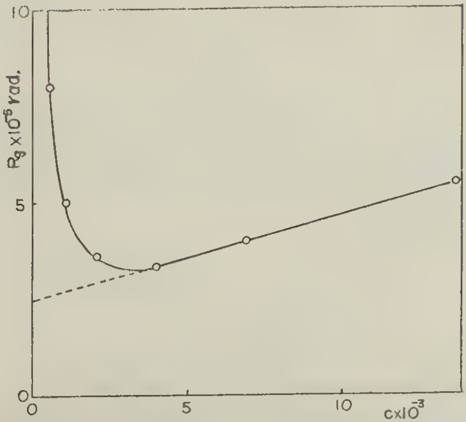

Fig. 2.

If cross-linking and degration occur in the irradiated polymer, the coefficients are given by the following formulas:

$$A_1=u\dot{c}\alpha\left\{\frac{(\alpha+2)(\alpha+7)}{6}-\lambda\right\}, \qquad (4)$$

$$A_2=\frac{u^2\dot{c}^2\alpha(\alpha+1)}{2}\left\{\frac{(\alpha+2)(\alpha+3)(\alpha+7)(\alpha+14)}{90}-\frac{(\alpha+2)(\alpha+7)}{3}\lambda+\lambda^2\right\}, \qquad (5)$$

where u is the number-average degree of polymerization before irradiation, α is the exponent in the relation between the intrinsic viscosity and number-average molecular weight, $\dot{c}$ is the probability that a monomer unit irradiated by radiation of unit dose will cross-link with a monomer unit of another molecule, and $\lambda=\dot{r}/\dot{c}$, where $\dot{r}$ is the probability that a monomer unit irradiated by radiation of unit dose will be scissored. The value of α may vary with radiation dose. In the early period of irradiation, however, it may not differ greatly from the value before irradiation. We may, therefore, use 0.62[5] for the value of α of polyvinyl alcohol.

If the polyvinyl alcohol whose number-average degree of polymerization is u is irradiated by gamma rays and the change of intrinsic viscosity is measured, the values of A_1 and A_2 will easily be calculated from the viscosity curve. Then we obtain $\dot{c}$ and λ by solving Eqs. (4) and (5). And the radiation dose necessary for the incipient gel formation is given by

$$R_g=1/u\dot{c}(4-\lambda)\,. \qquad (6)$$

It is usually difficult to get the accurate value of A_2. When the value of $\dot{c}$ is very small, the values of $\dot{c}$ and λ cannot be accurately calculated from Eqs. (4) and (5). We must then use Eq. (6) instead of Eq. (5).

When the end-linking occurs in the irradiated polymer, the coefficients A_1 and A_2 are given by the following formulas[3]:

$$A_1=u\dot{r}\alpha\{(\alpha+3)\sigma-1\}\,, \qquad (7)$$

$$A_2=\frac{u^2\dot{r}^2\alpha(\alpha+1)}{2}\left\{\frac{3}{4}\sigma^2(\alpha+2)(\alpha+3)-2\sigma(1-\sigma)(\alpha+2)+(1-\sigma)^2\right\}, \qquad (8)$$

where σ is the probability that a molecular end prouced by a main chain scission will link with a monomer unit of another molecule. We get $\dot{r}$ and σ by solving these equations.

Then the radiation dose necessary for the incipient gel formation is given by

$$R_g=1/\dot{r}(4\sigma-1)\,. \tag{9}$$

When the value of $\dot{r}$ is very small, we must calculate $\dot{r}$ and σ from Eqs. (7) and (9).

These results were derived for polymers not in solution. However, if we consider the fact that the probabilities $\dot{c}$, $\dot{r}$ and σ are determined by the circumstances around the ploymer molecule, they may be expected to be applicable to the cases where polymers are in solution or contain impurities.

§ 2. Cross-linking and Degration

As is shown in Fig. 2 gel is formed in the irradiated aqueous solution of polyvinyl alcohol. This fact indicates that cross-linking or end-linking is produced in the solution. Let us now assume that cross-linking occurs in it. In Fig. 2 the curve for larger concentration is linear. When the linear portion is extended back to lower concentration, it does not go through the origin. Danno[4] showed that the product uR_{gi} is independent of the value of u, where u is the initial degree of polymerization of polyvinyl alcohol and R_{gi} is the dose corresponding to the intersection of the extended line and the ordinate axis. This fact can be accounted for by the consideration that a fraction of radiation energy is consumed by some impurity perhaps oxygen, and R_g-R_{gi} is the net dose necessary for the incipient gel formation. We should notice the fact that the coefficients A_1 and A_2 of Eq. (1) are much influenced by impurity. On the contrary, if we use R_g-R_{gi} instead of R_g of Eq. (6), the right hand side of the equation must be independent of the effect of impurity.

When the aqueous solution of polyvinyl alcohol is irradiated, the following two cases may be conceivable. The first is that the radiation reacts upon polymer molecules directly and produces active centres, for example free redicals, which cross-link with monomer units of other molecules. The second is that the radiation reacts upon water molecules and dissociates some of them. The products give active centres to polymer molecules, and the active centres cross-link with monomer units of other molecules. Let us call the former the direct action and the latter the indirect action of radiation. For the case where the polymer is degraded by radiation, the direct and indirect action are also conceivable. Let us denote by $\dot{c}_0$ the probability that a monomer unit irradiated by radiation of unit dose will cross-link directly with a monomer unit of another polymer molecule. $\dot{c}_0$ is independent of the concentration of polymer. If we denote by $\dot{a}_1$ the probability that a water molecule will be dissociated by radiation of unit dose, the probability that a monomer unit irradiated by radiation of unit dose will indirectly cross-link is

$$\dot{a}_1(1-c)/c\,, \tag{10}$$

where the effect of impurity is neglected and the ratio of the total number of monomer units and the number of water molecules is expressed as $c:1-c$. When the effect of impurity is not neglected, the probability becomes

$$\dot{a}_1\frac{1-c}{c}\,\frac{c}{c+k_1}=\dot{a}_1\frac{1-c}{c+k_1}\,, \tag{11}$$

where k_1 is proportional to the amount and the reaction rate of impurity, but it does not depend on the concentration c. Thus the total probability that a monomer unit irradiated by radiation of unit dose will cross-link is given by

$$\dot{c}=\dot{c}_0+\dot{a}_1\frac{1-c}{c+k_1}\,. \tag{12}$$

Similarly the total probability that a monomer unit irradiated by radiation of unit dose will be ruptured is given by

$$\dot{r}=\dot{r}_0+\dot{a}_2\frac{1-c}{c+k_2}\,, \tag{13}$$

where $\dot{r}_0$ is the probability that a monomer unit will be directly ruptured by radiation of unit dose, $\dot{a}_2$ is the probability that a water molecule will be dissociated by radiation of unit dose, and k_2 is proportional to the amount and the reaction rate of impurity. In general, $\dot{a}_1$ will not have the same value as $\dot{a}_2$. Substituting Eqs. (12) and (13) into Eqs. (3) and (4), we obtain

$$B_1=u\left[\{\beta(\dot{c}_0-\dot{a}_1)-(\dot{r}_0-\dot{a}_2)\}+\beta\dot{a}_1\frac{1+k_1}{c+k_1}\right.$$
$$\left.-\dot{a}_2\frac{1+k_2}{c+k_2}\right], \tag{14}$$

where $\beta=(\alpha+2)(\alpha+7)/6$. Since the effect of impurity is not included in the radiation dose R_g-R_{gi}, we obtain from Eq. (6) the relation:

$$\frac{1}{R_g+R_{gi}}=u(4\dot{c}\psi-\dot{r})$$
$$=u\left\{4(\dot{c}_0-\dot{a}_1)\phi-(\dot{r}_0-\dot{a}_2)+\frac{4\dot{a}_1\phi-\dot{a}_2}{c}\right\}, \tag{15}$$

where ϕ has been introduced for the following reason. It is very difficult for polymer molecules in lower concentration to interact upon each other. The larger are the polymer molecules, the smaller are their mobilities. When the polymer concentration is very small, large molecules will hardly interact upon each other, and the probability of cross-linking $\dot{c}$ will be diminished. ϕ is a factor expressing this property, and it varies with the concentration c and becomes unity for larger concentration. If we plot $1/(R_g-R_{gi})$ against $1/c$, we must obtain a straight line for the smaller values of $1/c$. This is the case for Fig. 3, where the values of $1/(R_g-R_{gi})$ for the aqueous solution of polyvinyl alcohol is plotted against $1/c$. From this linear portion we obtain the relations:

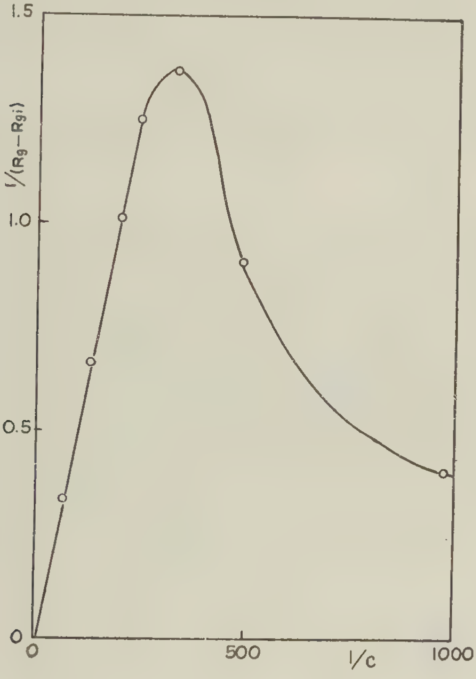

Fig. 3.

$$4(\dot{c}_0-a_1)-(\dot{r}_0-\dot{a}_2)=0\ , \tag{16}$$
$$4\dot{a}_1-\dot{a}_2=5.51\times10^{-6}\ . \tag{17}$$

It is shown by Eq. (14) that if we plot B_1 against $1/c$, a straight line must be obtained for smaller values of $1/c$. This is the case for Fig. 4. From the slope of this line we get the relation:

$$\beta\dot{a}_1(1+k_1)-\dot{a}_2(1+k_2)=3.10\times10^{-3}\ . \tag{18}$$

And for $c=0$ we also get the following values from extrapolating the measured values in Fig. 5.

$$B_1=-1.11 \quad \text{and} \quad dB_1/dc=-177\ . \tag{19}$$

By solving Eqs. (16)~(19), we obtain

$$\dot{a}_1=0\ , \quad \dot{a}_2=-5.51\times10^{-6}\ ,$$
$$k_1=0\ , \quad k_2=-2.8\times10^{-3}\ .$$

These results are unreasonable. On the other hand, by determining the parameters of Eq. (14) so that it may well represent all the measured values of B_1, the following values are obtained:

$$\dot{a}_1=0.855\times10^{-5}\ , \quad \dot{a}_2=2.58\times10^{-5}\ ,$$

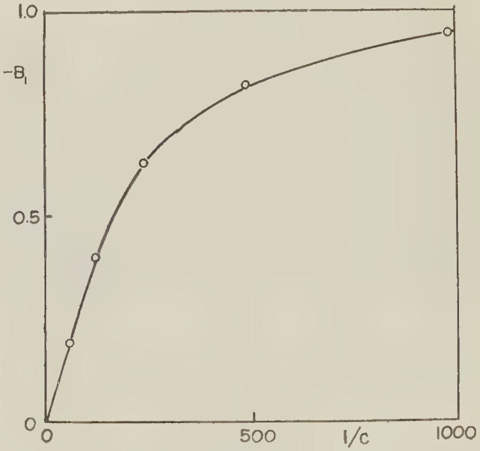

Fig. 4.

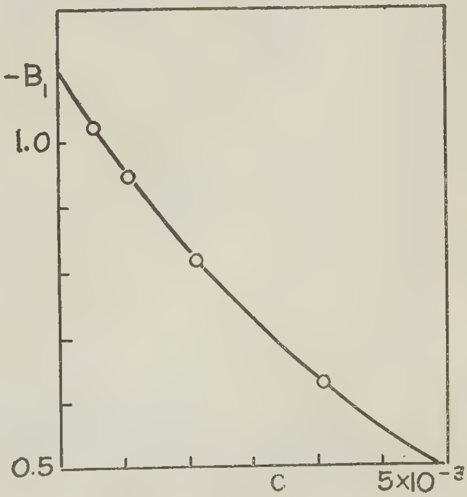

Fig. 5.

$$k_1=2.0\times10^{-2}\ , \qquad k_2=1.0\times10^{-2},$$

From these results we get

$$4\dot{a}_1-\dot{a}_2=8.40\times10^{-6}\ .$$

This is contradictory to Eq. (17). We may, therefore, conclude that cross-linking does not occur in the irradiated aqueous solution of polyvinyl alcohol.

§ 3. End-linking

Now we assume that end-linking occurs in the irradiated aqueous solution of polyvinyl alcohol. Linkage and scission are independent of each other in cross-linking, but they are correlated with each other in end-linking. In end-linking the probabilities $\dot{r}$ and σ are the fundamental parameters. Since $\dot{r}$ is the same as that in the preceding section, it is expressed as follows:

$$\dot{r}=\dot{r}_0+\dot{a}\frac{1+c}{c+k_1} \tag{20}$$

where $\dot{r}_0$ is the probability that a monomer unit will be directly ruptured by radiation of unit dose, $\dot{a}$ is the probability that a water molecule will be dissociated by radiation of unit dose, and k_1 is proportional to the amount and the reaction rate of impurity, but not dependent on the polymer concentration. The probability σ that an active end produced by molecular scission will link with a monomer unit of another molecule is expressed as

$$\sigma=\sigma_0\frac{c}{c+k_2}\ , \tag{21}$$

where σ_0 is the value of the probability σ for large polymer concentration and negligibly small amount of impurity, and k_2 is proportional to the amount and the reaction rate of impurity which inhibits the end-linking. The value of σ_0 is the same as that of σ for solid polyvinyl alcohol. Substituting Eqs. (20) and (21) into Eqs. (3) and (7), we get

$$B_1=u\left\{\dot{r}_0+\dot{a}\frac{1-c}{c+k_1}\right\}\left\{\frac{(\alpha+3)\sigma_0 c}{c+k_2}-1\right\}\ , \tag{22}$$

and hence Eq. (9) gives

$$\frac{1}{R_g-R_{gi}}=u\left\{\dot{r}_0+\dot{a}\frac{1-c}{c}\right\}(4\sigma_0\phi-1)\ , \tag{23}$$

where ϕ is the same factor as that considered in the preceding section. If we determine the parameters in Eqs. (20) and (21) by considering the linear portion in Fig. 3 and the measured values of B_1, the following results are obtained:

$$\dot{r}_0=2.28\times10^{-5}\ , \quad \dot{a}=2.28\times10^{-5}\ , \quad \sigma_0=0.31\ ,$$
$$k_1=2.0\times10^{-2}\ , \qquad k_2=1.0\times10^{-2}\ .$$

The value of σ_0 is larger than $1/(\alpha+3)=0.276$. We know[3], therefore, that the viscosity-average molecular weight of polyvinyl alcohol irradiated in aqueous solution increases with radiation dose, if no impurity is contained.

The G-value of the dissociation of water molecules is given by the formula:

$$G_a=\frac{(\text{Avogadro number}/18)\,\dot{a}}{\text{absorbed energy in e.v./gram/dose}}\times100$$
$$=12\ ,$$

the G-value of main chain rupture of solid polyvinyl alcohol by

$$G_r=\frac{(\text{Avogadro number}/44)\,\dot{r}_0}{\text{absorbed energy in e.v./gram/dose}}\times100$$
$$=5.0\ ,$$

and the G-value of end-linking for solid polyvinyl alcohol by

$$G_{\text{e.l.}}=\frac{(\text{Avogadro number}/44)\,2\dot{r}_0\sigma_0}{\text{absorbed energy in e.v./gram/dose}}\times100$$
$$=3.1\ .$$

Therefore, the energy for producing an end-linkage is 32 e.v.. It is assumed in this case that two ends produced by a molecular scission are active. If we assume that only one of the two ends is active, the G-value becomes a half of the above-mentioned value, and the energy for producing an end-linkage is 62 e.v., which agrees with Danno's experimental result.

Thus it is concluded that end-linking occurs in the irradiated aqueous solution of polyvinyl

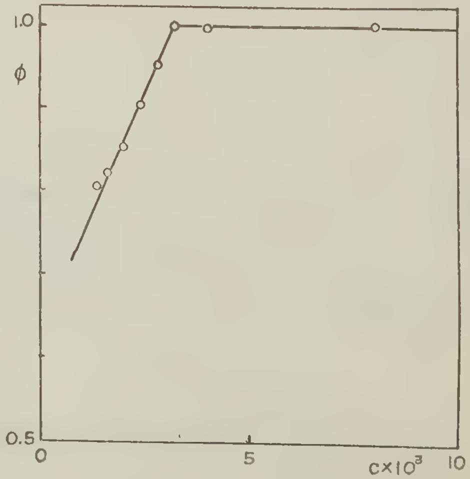

Fig. 6.

alcohol and that only one of the two molecular ends produced by a molecular scission is active and links with a monomer unit of another molecule.

The factor ϕ in Eq. (23) is equal to unity for larger value of c. Comparing Eq. (23) with the curve in Fig. 3, we should obtain the relation between ϕ and c. However, there being only a few observed values, we could not hope to find correct relation. Therefore, in order to know the approximate behaviour of ϕ, we have calculated the values of ϕ, by interpolating the values of $1/(R_g-R_{gi})$ in Fig. 3. The result is shown in Fig. 6. It will be seen that the curve of ϕ against c is approximately linear. From this fact it may be considered that the probability that an active centre will end-link with a monomer unit of another molecule is proportional to the number of polymer molecules contained in a sphere of definite radius with centre at the active centre. The more correct measurments are, however, necessary in order to know the details.

§ 4. Summary

Effects of radiation on aqueous solution of polymers have been discussed by a few authors. There has, however, been no successful attempt to explain the properties before and after gelation at a single stroke. The author applies his theory to the irradiated aqueous solution of polyvinyl alcohol and shows that end-linking instead of cross-linking occurs in the solution. He also calculates G-values of molecular scission and end-linking, the values thus obtained being in good agreement with those obtained by A. Danno. The author concludes that only one molecular end out of the two which are produced by molecular scission links with a monomer unit of another polymer molecule. It is also shown that if no impurity is present, the intrinsic viscosity and the viscosity-average molecular weight of irradiated polyvinyl alcohol in aqueous solution increase with radiation dose. When the concentration of polymer is very low, linking between large molecules is hindered and the gel formation suppressed. This is the reason why the radiation dose necessary for the incipient gel formation has a minimum. In order to know the details, more accurate experiments are desired.

Acknowledgement

The author wishes to express his sincere thanks to Professor A. Amemiya, for his continued interest and support in all phases of this research. He wishes to thank Professor A. Harasima, Dr. K. Shinohara and Mr. A. Danno for their valuable suggestions as well as guidances and also the members of the Group for the Study of Irradiated Polymers in Tokyo for discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 6, JUNE, 1959

Effect of Impurity on Molecular Linking of Irradiated Polymer

By Osamu SAITO

Faculty of Engineering, Chuo University Bunkyo-ku, Tokyo

(Received March 4, 1959)

The effect of impurity on cross-linking or end-linking of an irradiated polymer is discussed theoretically. It is shown that the radiation effect on a pure polymer can be found by measuring the intrinsic viscosity and the gel point of an irradiated polymer containing an impurity. The theory is compared with Chapiro's measurements. One of the important results is that when impurity hinders cross-linking, all the relations between physical quantities of an irradiated polymer containing impurity can be reduced to those of the polymer containing no impurity, if use is made of a reduced radiation dose instead of the real dose. This is not the case for the effect of impurity on end-linking. Such a difference is expected to enable us to distinguish between cross-linking and end-linking.

§ 1. Introduction

The author has developed in his previous papers[1)-3)] a theory concerning the effects of high energy radiation on polymers. In this paper the theory will be extended to cover the effect of impurity. Polymers contain usually some impurity, for example, oxygen. Polymer in the market contain more or less additives, the effect of which may not be neglected. The effect of oxygen is especially important, because a little amount of oxygen gives a fairly large effect on polymers and it is very difficulty to remove oxygen completely out of them. On the contrary, if we know how it reacts upon polymers, we may be able to know the radiation effects on pure polymers by analyzing the experimental results for various pressure of oxygen.

§ 2. Effect of Impurity on Cross-linking

When a polymer contains some radical scavenger, radiation cross-linking will be hindered by it. The mechanism is considered as follows. Active centres will be produced by radiation on some of monomer units.

This probability will be denoted by $\dot{c}$ as in the previous paper. When a polymer contains some impurity, $\dot{c}$ is lowered by the effect. Let us denote by $n(p, R)$ the number of polymer molecules which give the degree of polymerization p and are irradiated by radiation of dose R. When the radiation dose is increased from R to $R+dR$, the increment of $n(p, R)$ is given by

$$dn(p, R) = -pn(p, R)\dot{c}dR\left(\frac{kN}{kN+k'n_i}\right) - N\dot{c}\left(\frac{kpn(p, R)}{kN+k'n_i}\right)dR + \int_0^p ln(l, R)\,dl\,\dot{c}\,dR\left\{\frac{k(p-l)n(p-l, R)}{kN+k'n_i}\right\}, \tag{1}$$

where N is the total number of monomer units, n_i is the number of impurity molecules, k is the reaction rate constant for the active centre and monomer unit, and k' is the constant for the active centre and impurity. If we write

$$m(p, R) = n(p, R)/N, \quad m_i(R) = n_i(R)/N, \quad k_i = k'/k,$$

Eq. (1) becomes

$$\frac{\partial m(p, R)}{\partial R} = \frac{1}{(1+k_i m_i)}\left\{-2pm(p, R) + \int_0^p l(p-l)m(l, R)m(p-l, R)\,dl\right\}. \tag{2}$$

If we introduce a new variable

$$\bar{R} = \int_0^R \frac{dR}{1+k_i m_i}, \tag{3}$$

Eq. (2) becomes

$$\frac{\partial m(p,\ \overline{R})}{\partial \overline{R}}=-2pm(p,\ \overline{R})+\int_0^p l(p-l)m(l,\ \overline{R})m(p-l,\ \overline{R})dl\,. \tag{4}$$

This is the same as the equation for the polymer containing no impurity, which has been considered in detail in our previous papers.[1)-3)]

The increment of the number of impurity molecules is given by

$$dn_i(R)=-N\dot{c}dR\left(\frac{k'n_i}{kN+k'n_i}\right)+N\phi dR\,, \tag{5}$$

where ϕ represents the amount of impurity which is supplied from outside per monomer unit and per unit radiation dose. This equation can be written in another form:

$$\frac{dm_i}{dR}=-\frac{\dot{c}k_i m_i}{1+k_i m_i}+\phi\,, \tag{6}$$

where $m_i=n_i/N$. This can be easily solved, when ϕ is known.

Case A. m_i=const. When the supply of impurity from outside is enough, m_i takes a constant value, say A. In this case Eq. (3) gives

$$R/\overline{R}=1+k_iA. \tag{7}$$

$\overline{R}$ can be easily obtained from the experimental curves as shown in Fig. 1, where the abscissa is the radiation dose and the ordinate is any one of physical quantities, for example, viscosity, molecular weight, melting point and so forth. The relation between R and $\overline{R}$ is linear. The slope varies with A. The radiation dose R_g necessary for the incipient gel formation is related to the dose R_g for the polymer containing no impurity by the following formula:

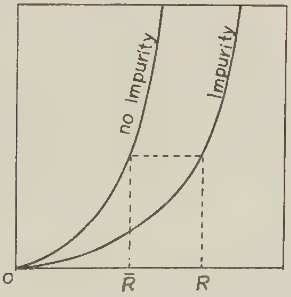

Fig. 1.

$$(R_g-\overline{R}_g)/\overline{R}_g=k_iA \tag{8}$$

The left hand side must, therefore, by proportional to the amount of impurity A. When a thin film of polymer is irradiated in air by radiation of low dose rate, the amount of oxygen in the polymer will always be constant. If we perform experiments under various pressures of oxygen, $(R_g-\overline{R}_g)/\overline{R}_g$ plotted against the pressures of oxygen will give a straight line, because A will be proportional to the pressure.

Case B. $\phi\equiv0$. This is the case where there is no supply of impurity from outside and this is more easily realized by experiment than the preceding case. When the initial value of m_i is A, Eq. (6) gives

$$R=\overline{R}+(A/\dot{c})\{1-\exp(-k_i\dot{c}\overline{R})\}\,. \tag{9}$$

Then we get

$$\left(\frac{dR}{d\overline{R}}\right)=1+k_iA\exp(-k_i\dot{c}\overline{R}) \tag{10}$$

and after a certain value of R, we get the following relation

$$\frac{dR}{d\overline{R}}=1\,. \tag{11}$$

Chapiro[4)] measured the change in melting point of polyethylene film irradiaed in air. The relation between R and $\overline{R}$ deduced form the measurement is represented is Fig. 2. The initial slope of the curve is 7.5. The slope decreases gradually to the ultimate value unity. For larger values of $\overline{R}$ Eq. (9)

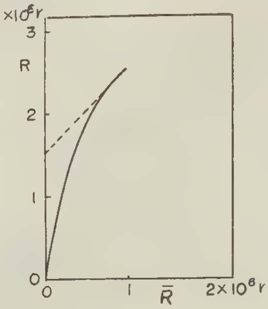

Fig. 2.

is reduced to

$$R=\overline{R}+A/\dot{c}\,. \tag{12}$$

This is a linear relation. If we extend the line back to $\overline{R}=0$, the intersection of the line and the ordinate axis gives

$$\frac{A}{\dot{c}}=1.54 \quad (10^6\mathrm{r})^{-1}.$$

If we assume that the G-value of cross-linking of irradiated polyethylene is 6.8,⁵⁾ we obtain

$$\dot{c}=1.8\times10^{-4} \quad (10^6\mathrm{r})^{-1},$$

so that

$$A=2.8\times10^{-4}.$$

This value means that there existed initially 2.8 oxygen molecules per 10^4 monomer units. Since ϕ is not zero in Chapiro's experiment, the abovementioned value of A will be a little larger than the true value.

At the gel point Eq. (9) becomes

$$R_g=\overline{R}_g+(A/\dot{c})\{1-\exp(-k_i\dot{c}\overline{R}_g)\}\,. \tag{13}$$

This shows that the radiation dose necessary for the incipient gel formation is a linear function of the amount of impurity. We can calculate the parameters A, $\dot{c}$, R_g and k_i form Eq. (10) and (13) and the value of $A/\dot{c}$ which is obtained from Eq. (12).

Case C. $k_i m_i \ll 1$. In this case Eq. (6) becomes

$$\frac{dm_i}{dR}+\dot{c}k_i m_i=\phi\,, \tag{14}$$

When ϕ is a known function of R, the solution is

$$m_i=\exp(-k_i\dot{c}R)\left\{\int_0^R \phi\exp(k_i\dot{c}R)dR+A\right\}. \tag{15}$$

Let us consider the case where m_i is equal to A for $0\leqq R\leqq R_1$, and then $\phi\equiv0$ for $R>R_1$, then Eq. (15) gives

$$m_i=\begin{cases}A\,, & \text{for } 0\leqq R\leqq R_1\,,\\ A\exp\{-k_i\dot{c}(R-R_1)\}\,, & \text{for } R_1<R\,,\end{cases} \tag{16}$$

and Eq. (3) becomes

$$\overline{R}=\begin{cases}R/(1+k_iA)\,, & \text{for } 0\leqq R\leqq R_1\,,\\ R-R_1-(A/\dot{c})[1-\exp\{-k_i\dot{c}(R-R_1)\}]\,, & \text{for } R_1<R\,.\end{cases} \tag{17}$$

For large R it becomes

$$\overline{R}=R-R_1-A/\dot{c}\,. \tag{18}$$

If ϕ is proportional to $A-m_i$, that is

$$\phi=\kappa(A-m_i)\,, \tag{19}$$

then Eq. (14) becomes

$$\frac{dm_i}{dR}+(\dot{c}k_i+\kappa)m_i=\kappa A\,, \tag{20}$$

which can be integrated to give

$$m_i=\frac{\kappa A}{\kappa+\dot{c}k_i}\left[1+\left(2+\frac{\dot{c}k_i}{\kappa}\right)\exp\{-(\kappa+\dot{c}k_i)R\}\right], \tag{21}$$

and hence from Eq. (3) we get

$$\overline{R}=\left(1-\frac{\kappa k_iA}{ck_i+\kappa}\right)R+\frac{k_iA(2\kappa+\dot{c}k_i)}{(\dot{c}k_i+\kappa)^2}\left[\exp\{-(\dot{c}k_i+\kappa)R\}-1\right]. \tag{22}$$

For large R it becomes

$$\overline{R}=\left(1-\frac{\kappa k_iA}{ck_i+\kappa}\right)R-\frac{k_iA(2\kappa+\dot{c}k_i)}{(\dot{c}k_i+\kappa)^2} \tag{23}$$

This is a linear relation but the slope is not equal to unity. Thus the behaviour is not the same as that in the preceding cases.

§ 3. Effect of Impurity on Cross-linking with Degradation

When degradation as well as cross-linking occurs in an irradiated polymer, the effects of impurity must be considered at the same time.

(i) Let us first consider the case where cross-linking is hindered by impurity, but degradation is not affected at all. In this case the following equations are derived

$$\frac{\partial m(p,\ \overline{R})}{\dot{c}\partial R}=-2pm(p,\ \overline{R})+\int_0^p l(p-l)m(l,\ \overline{R})m(p-l,\ \overline{R})dl\ , \tag{24}$$

$$\overline{R}=\int_0^R \frac{dR}{1+k_i m_i}\ . \tag{25}$$

However, the distribution function for $\overline{R}=0$ must be given by[1]

$$\left\{m(p,\ 0)+2\dot{r}p\int_p^\infty m(p,\ 0)dp+\dot{r}^2p^2\int_p^\infty dp\int_p^\infty m(p,\ 0)dp\right\}\exp(-p\dot{r}R)\ . \tag{26}$$

When the molecular weight distribution before irradiation is of the Poisson type, Eq. (26) becomes

$$\left(\frac{1}{u}+\dot{r}R\right)^2\exp\left\{-\left(\frac{1}{u}+\dot{r}R\right)p\right\}\ , \tag{27}$$

where u is the number-average degree of polymerization before irradiation.

When the supply of impurity is enough, m_i is equal to a constant, say A.

Then the relation between R and $\overline{R}$ becomes

$$\overline{R}=R/(1+k_iA) \tag{28}$$

if we assume

$$\dot{c}_i=\dot{c}/(1+k_iA) \tag{29}$$

Eq. (24) becomes equal to that for the polymer containing no impurity. Therefore, if we use rupturing probability $\dot{r}$ and reduced cross-linking probability $\dot{c}_i$, the behaviour of irradiated polymer including impurity is reduced to that for the polymer containing no impurity. For instance, the number and the weight-average molecular weight are given respectively by

$$M_n(R)=M_n(0)/\{1+(\dot{r}-2\dot{c}_i)nR\}\ , \tag{30}$$

$$M_w(R)=M_w(0)/\{1+(\dot{r}-4\dot{c}_i)uR\}\ , \tag{31}$$

and the intrinsic viscosity is given by[3]

$$\frac{[\eta]}{[\eta]_0}=\frac{2\sin(\alpha\pi)}{\pi\alpha(\alpha+1)(1+u\dot{r}R)^\alpha}\int_0^1\frac{y^{\alpha+1}dy}{(1-y)^\alpha\{1-Ky(y+1)\}^\alpha}\ , \tag{32}$$

where

$$K=2u\dot{c}_iR/(1+u\dot{r}R)\ . \tag{33}$$

When R is sufficiently small

$$[\eta]/[\eta]_0=1+a_1R+a_2R^2+\cdots\ , \tag{34}$$

where

$$a_1=u\alpha\left\{\frac{(\alpha+2)(\alpha+7)}{6}c_i-r\right\}\ ,\qquad \text{etc.} \tag{35}$$

The radiation dose necessary for the incipient gel formation is given by

$$R_g=1/\{u(4\dot{c}_i-\dot{r})\}\ . \tag{36}$$

The relation between R_g and A is not linear. When A is very small, Eq. (36) becomes

$$1/R_g=u(4\dot{c}-\dot{r})-4u\dot{c}k_iA\ . \tag{37}$$

If the initial slope a_i in Eq. (34) is measured, and the value and the slope of $1/R_g$ at $A=0$ are determined, the parameters $\dot{c}$, $\dot{r}$ and k_i can all be calculated from Eq. (35) and (37). When there is no supply of impurity during irradiation, the following formula is derived:

$$R=\overline{R}+(A/\dot{c})\{1-\exp(-k_i\dot{c}\overline{R})\}\ . \tag{38}$$

The number- and the weight-average molecular weight are repectively

$$M_n(R)=M_n(0)/\{1+u\dot{r}R-2u\dot{c}\overline{R}\}\ ,$$

$$M_w(R)=M_w(0)/\{1+u\dot{r}R-4u\dot{c}\overline{R}\}\ . \tag{39}$$

We know from the last formula that if there hold inequalities

$$4/(1+R_iA)<\dot{r}/\dot{c}<4\ , \tag{40}$$

the weight-average molecular weight has a minimum. Such a behaviour never occurs for polymers containing no impurity. We must, however, remember the fact that the viscosity-average molecular weight for a polymer including no impurity may have also a minimum.

The dose for incipient gel formation is given by

$$R_g=(1+4u\dot{c}\overline{R}_g)/u\dot{r} \tag{41}$$

where $\overline{R}_g$ satisfies the equation:

$$1+u\overline{R}_g(\dot{r}-4\dot{c})+(u\dot{r}A/\dot{c})\{1-\exp(-k_i\dot{c}\overline{R}_g)\}=0\ . \tag{42}$$

When A is not small, the relation between R_g and A is not linear. On the contrary, when A is sufficiently small, $1/R_g$ becomes a linear function of A, that is

$$\frac{1}{R_g}=u(4\dot{c}-\dot{r})-4u^2(4\dot{c}-\dot{r})A\left[1-\exp\left\{-\frac{k_i\dot{c}}{u(4\dot{c}-\dot{r})}\right\}\right]. \tag{43}$$

On the other hand, the intrinsic viscosity is given by

$$\frac{[\eta]}{[\eta]_0}=\frac{2\sin(\alpha\pi)}{\pi\alpha(\alpha+1)(1+u\dot{r}R)^\alpha}\int_0^1\frac{y^{\alpha+1}dy}{(1-y)^\alpha\{1-Ky(y+1)\}^\alpha}\ , \tag{44}$$

where

$$K=2u\dot{c}\overline{R}/(1+u\dot{r}R)\ . \tag{45}$$

When $\overline{R}_g$ is sufficiently small, Eq. (44) can be expanded in a series

$$\frac{[\eta]}{[\eta]_0}=1+u\alpha\left\{\frac{(\alpha+2)(\alpha+7)}{6(1+k_iA)}\dot{c}-\dot{r}\right\}R+\cdots\ . \tag{46}$$

If we measure the initial value and the slope of intrinsic viscosity $[\eta]$ as well as the value and the slope of $1/R_g$ at $A=0$, we can calculate the values $\dot{c}$, $\dot{r}$ and k_i from Eqs. (43), (46).

(ii) Let us next consider the case in which an impurity molecule not only combines with a molecular end produced by a molecular scission but also it hinders cross-linking. In this case the equation corresponding to Eq. (5) is given by

$$\frac{dm_i}{dR} = -\dot{c}\frac{k_c m_i}{1+k_c m_i} - 2\dot{r}\frac{k_r m_i}{1+k_r m_i} + \phi\,, \tag{47}$$

where k_c and k_r are the ratios of reaction rate constants and correspond respectively to cross-linking and rupture. When $k_c m_i \ll 1$ and $k_r m_i \ll 1$, Eq. (47) becomes

$$\frac{dm_i}{dR} = -(\dot{c}k_c + 2\dot{r}k_r)m_i + \phi\,. \tag{48}$$

Now let us divide m_i into two fractions m_i' and m_i'', where m_i' is the fraction of impurity which hinders cross-linking and m_i'' is the fraction of impurity which combines with molecular ends produced by scission. Then we obtain the relation:

$$dm_i' : dm_i'' = \dot{c}\frac{k_c m_i}{1+k_c m_i} : 2\dot{r}\frac{k_r m_i}{1+k_r m_i}\,. \tag{49}$$

Therefore

$$\frac{dm_i'}{dm_i} = \dot{c}\left(\frac{1}{k_r} + m_i\right)\Big/\left\{\frac{\dot{c}}{k_r} + \frac{2\dot{r}}{k_c} + (\dot{c} - 2\dot{r})m_i\right\}. \tag{50}$$

Since $k_c m_i \ll 1$ and $k_r m_i \ll 1$, Eq. (50) becomes

$$\frac{dm_i'}{dm_i} = \frac{k_c\dot{c}}{k_c\dot{c} + 2k_r\dot{r}} = \frac{1}{1 + 2\lambda\mu} \tag{51}$$

where $\lambda = \dot{r}/\dot{c}$ and $\mu = k_r/k_c$, so that

$$m_i' = m_i/(1+2\lambda\mu)\,. \tag{52}$$

Case A. When the supply of impurity during irradiation is enough, m_i has a constant value, say A. Then

$$m_i' = A/(1+2\lambda\mu)\,. \tag{53}$$

Accordingly

$$\frac{R}{\overline{R}} = 1 + \frac{k_c A}{1+2\lambda\mu}\,. \tag{54}$$

If we put

$$c_i = \dot{c}/(1+k_i A) \qquad \text{and} \qquad k_i = k_c/(1+2\lambda\mu)\,, \tag{55}$$

we can made the same discussions as those about Eqs. (30)∼(36).

Case B. When there is no supply of impurity, Eq. (48) gives

$$m_i = A\exp\{-(k_c\dot{c} + 2k_r\dot{r})R\} \tag{56}$$

and then

$$m_i' = A(1+2\lambda\mu)^{-1}\exp\{-(k_c\dot{c} + 2k_r\dot{r})R\}\,. \tag{57}$$

Therefore, we get

$$\overline{R} = R + \frac{1}{k_c\dot{c} + 2k_r\dot{r}}\log\left[1 - \frac{k_c A}{1+2\lambda\mu+k_c A}\left[1 - \exp\{-(k_c\dot{c} + 2k_r\dot{r})R\}\right]\right]. \tag{58}$$

Since $k_i A$ is very small, the following relation is derived:

$$R = \overline{R} + \frac{A}{\dot{c}(1+2\lambda\mu)^2}[1 - \exp\{-k_c\dot{c}(1+2\lambda\mu)R\}]\,. \tag{59}$$

Comparing Eq. (38) with (56), we know that if we replace $\dot{c}(1+2\lambda\mu)$ by $\dot{c}$ and $A/(1+2\lambda\mu)$ by A, Eq. (59) becomes the same as Eq. (38). Therefore, the same discussion as those about (38)$\sim$(46) can be repeated here.

(iii) Let us assume lastly that the scission of polymer molecules occurs at the same time in two ways, one way is that a monomer unit is directly ruptured by radiation and the other is that a cross-linking unit produced by radiation combines with an impurity and then ruptures instead of making cross-linking. In this case the equation for degradation becomes

$$\frac{\partial m(p,\ R)}{\partial R}=-p\left(\dot{r}+\frac{\dot{c}k_i m_i}{1+k_i m_i}\right)m(p,\ R)+2\int_p^\infty\left(\dot{r}+\frac{\dot{c}k_i m_i}{1+k_i m_i}\right)m(l,\ R)dl\,. \tag{60}$$

If we put

$$\overline{\overline{R}}=\int_0^R\left\{1+\frac{\dot{c}k_i m_i}{\dot{r}(1+k_i m_i)}\right\}dR\,, \tag{61}$$

Eq. (60) becomes

$$\frac{\partial m(p,\ \overline{\overline{R}})}{\dot{r}\partial\overline{\overline{R}}}=-pm(p,\ \overline{\overline{R}})+2\int_p^\infty m(l,\ \overline{\overline{R}})dl\,. \tag{62}$$

This is the same as for the polymer containing no impurity. When the initial molecular weight distribution is of the Poisson type, the degradation changes the distribution into the following form:

$$m(p,\ \overline{\overline{R}})=\left(\frac{1}{u}+r\overline{\overline{R}}\right)^2\exp\left\{-\left(\frac{1}{u}+\dot{r}\overline{\overline{R}}\right)p\right\}\,. \tag{63}$$

The effect of cross-linking on the molecular weight distribution is represented by Eqs. (24) and (25), and the change of the number of impurity molecules is given by Eq. (6).

Case A. When the supply of impurity is enough, m_i will have a constant value, say, A. If we replace $\dot{r}$ in the formulas for the case of no impurity by $\dot{r}+\dot{c}k_iA/(1+k_iA)$ and $\dot{c}$ in them by $\dot{c}/(1+k_iA)$, we obtain the formulas which take into account the effect of impurity.

Case B. When there is no supply of impurity during irradiation, the relations among R, $\overline{R}$ and $\overline{\overline{R}}$ are given by

$$R=\overline{R}+(A/\dot{c})\{1-\exp(-\dot{c}k_i\overline{R})\}\,, \tag{64}$$

$$R=A\exp(-\dot{c}k_iR)\{A-\dot{r}(\overline{\overline{R}}-R)\}\exp\{-\dot{c}k_i(\overline{\overline{R}}-R)\}\,. \tag{65}$$

The number- and the weight-average molecular weight are given respectively by

$$M_n(R)=M_n(0)/(1+u\dot{r}\overline{\overline{R}}-2u\dot{c}\overline{R})\,, \tag{66}$$

$$M_w(R)=M_w(0)/(1+u\dot{r}\overline{\overline{R}}-4u\dot{c}\overline{R})\,. \tag{67}$$

When A is sufficiently small, we get

$$\overline{R}=R+(A/\dot{c})\{1-\exp(-\dot{c}k_iR)\}+\cdots\,, \tag{68}$$

$$\overline{\overline{R}}=R+(A/\dot{r})\{1-\exp(-\dot{c}k_iR)\}+\cdots\,, \tag{69}$$

and the radiation dose for the incipient gel formation R_g is given by

$$1/R_g=u(4\dot{c}-\dot{r})-3u^2(4\dot{c}-\dot{r})A[1-\exp\{-k_i\dot{c}/(4\dot{c}-\dot{r})u\}]+\cdots\,. \tag{70}$$

The intrinsic viscosity is given by[3)]

$$\frac{[\eta]}{[\eta]_0}=\frac{2\sin(\alpha\pi)}{\pi\alpha(\alpha+1)(1+u\dot{r}\overline{\overline{R}})^\alpha}\int_0^1\frac{y^{\alpha+1}dy}{(1-y)^\alpha\{1-Ky(y+1)\}^\alpha}\,, \tag{71}$$

where

$$K=2u\dot{c}\overline{R}/(1+u\dot{r}\overline{\overline{R}})\,. \tag{72}$$

Where R is sufficiently small,

$$\frac{[\eta]}{[\eta]_0}=1+u\alpha\left\{\frac{(\alpha+2)(\alpha+7)}{6(1+k_iA)}\dot{c}-\dot{r}\right\}R+\cdots. \tag{73}$$

By comparing the measured values with Eqs. (70) and (73), we obtain the values of $\dot{c}$, $\dot{r}$ and k_i.

§ 4. Effect of Impurity on End-linking

The fundamental parameters in end-linking of an irradiated polymer are $\dot{r}$ and σ; the former is the same as the degrading probability $\dot{r}$ in degradation and the latter is the probability that an end produced by molecular scission will link with a monomer unit of another polymer molecule. The effect of impurity will reduce the value of σ. By the same consideration as that mentioned in the previous sections, σ will be expressed as follows:

$$\sigma=\sigma_0/(1+k_im_i)\,, \tag{74}$$

where σ_0 is the probability σ for no impurity.

Case A. When the supply of impurity from outside is sufficient, m_i is equal to a constant, say A. Then σ has also a constant value, that is

$$\sigma_i=\sigma_0/(1+k_iA)\,. \tag{75}$$

If we use the reduced probability σ_i instead of σ in the case where no impurity is contained, the radiation effect could be estimated. For instance, the number- and the weight-average molecular weight are respectively

$$M_n(R)=M_n(0)/\{1+(1-2\sigma_i)u\dot{r}R\} \tag{76}$$

$$M_w(R)=M_w(0)/\{1+(1-4\sigma_i)u\dot{r}R\} \tag{76}$$

where the initial molecular weight distribution is assumed to be of the Poisson type.

The radiation dose R_g necessary for the incipient gel formation is given by

$$R_g=\frac{1}{u\dot{r}(4\sigma_i-1)}\,, \tag{78}$$

when $k_iA\ll1$

$$\frac{1}{R_g}=u\dot{r}\left(\frac{4\sigma_0}{1+k_iA}-1\right)=u\dot{r}\{(4\sigma_0-1)-4\sigma_0k_iA\}\,. \tag{79}$$

The intrinsic viscosity is given by

$$\frac{[\eta]}{[\eta]_0}=\{1+(1-\sigma_i)u\dot{r}R\}^{-\alpha}\int_0^1\frac{y^{\alpha+1}dy}{(1-y)^{\alpha}(1-Ky)^{\alpha}}\,, \tag{80}$$

where

$$K=\frac{1+u\dot{r}R}{1+(1-\sigma)u\dot{r}R}\,. \tag{81}$$

When R is sufficiently small

$$[\eta]/[\eta]_0=1+\alpha\{\sigma_i(\alpha+3)-1\}u\dot{r}R+\cdots\,. \tag{82}$$

If we measure the value and the slope of $1/R_g$ at $A=0$ and also the slope of intrinsic viscosity at $R=0$, we can calculate the values of $\dot{r}$, σ_0 and k_i.

Case B. When there is no supply of impurity from outside, the variation of the number of impurity molecules is expressed by

$$\frac{dm_i}{dR} = -\frac{2\dot{r}\sigma_0 k_i m_i}{1+k_i m_i} . \tag{83}$$

The solution satisfying the initial condition $m_i(0)=A$ is given by

$$2k_i\dot{r}\sigma_0 R = k_i(A-m_i)+\log(A/m_i) . \tag{84}$$

When A is sufficiently small, it becomes

$$m_i = A\exp(-2k_i\dot{r}\sigma_0 R)[1+Ak_i\{1-\exp(-2k_i\dot{r}\sigma_0 R)\}+\cdots] , \tag{85}$$

therefore, we obtain

$$\sigma_0/\sigma = 1+k_iA\exp(-2k_i\dot{r}\sigma_0 R)+\cdots . \tag{86}$$

The radiation dose R_g for the incipient gel formation is given by

$$1/R_g = u\dot{r}\{(4\sigma_0-1)-4k_iA\sigma_0\exp(-2k_i\dot{r}\sigma_0 R_g)\} . \tag{87}$$

On the other hand, when the radiation dose and the amount of impurity are both small, the intrinsic viscosity is given by

$$\begin{aligned}[\eta]/[\eta]_0 &= 1+\alpha\{\sigma_0(\alpha+3)-1+\sigma_0(\alpha+3)k_iA\exp(-2k_i\dot{r}\sigma_0 R)+\cdots\} \\ &= 1+\alpha\{(\alpha+3)\sigma_0-1\}+\alpha(\alpha+3)\sigma_0 k_iA\exp(-2k_i\dot{r}\sigma_0 R)+\cdots .\end{aligned} \tag{88}$$

If we measure the value and the slope of $1/R_g$ at $A=0$ and also the initial slope of the intrinsic viscosity, we can calculate the values of $\dot{r}$, σ_0 and k_i from Eqs. (87) and (88).

It is important to note that when impurity hinders cross-linking the reduced radiation dose $\overline{R}$ can be defined in such a manner that, in terms of $\overline{R}$ instead of R, all the relations between physical quantities of an irradiated polymer containing impurity, for example, average molecular weights, viscosity, and melting point, can be reduced to those of the polymer containing no impurity. This is not the case for the effect of impurity in end-linking. Such a difference in character may be expected to enable us to distinguish between cross-linking and end-linking.

§ 5. Summary

The effect of impurity on irradiated polymer is discussed. Polymer contains usually some impurities or additives. Among many impurities oxygen is the most important, because it gives a large effect on irradiated polymers and it is difficult to remove completely out of polymers. It is, however, concluded from our discussion that the radiation effect on pure polymers is known from the measurements of intrinsic viscosity and gel point of irradiated polymers containing impurities.

In the case where molecular linking is accompanied by degradation the analysis is performed by assuming that the statistical result is not altered by exchanging the order of molecular linking and molecular scission. The validity of this assumption is not verified. However, even if the assumption might not be correct the error would not be large in the period before the gel point, because an intial polymer molecule had, in the average, less than one linking unit before the incipient gel formation. The validity of our results will be justified by experiments.

Acknowledgements

The author wishes to express his sincere thanks to Professor A. Amemiya for his continued interest and support in all phases of this research. The author wishes to thanks Professor. A. Harasima and Dr. K. Shinohara for their kind guidance and also the members of the Group for the Study of Irradiated Polymer in Tokyo for their discussions.

A New Type of Antiferromagnetic Structure in the Rutile Type Crystal

By Akio YOSHIMORI

Department of Physics, University of Osaka Prefecture,
Mozu-Higashi, Sakai

(Received March 6, 1959)

A new type of antiferromagnetic spin arrangement, which is theoretically possible in the rutile type crystal and seems to be realized in polianite, MnO_2, is proposed. This spin arrangement, which will be named the *screw-type structure*, consists of spins screwing along the four-fold crystalline axis. The stability ranges of this and other spin structures are studied, assuming three different exchange interactions. The magnetic properties of the screw-type structure, including the anisotropy energy due to dipolar interaction and that due to crystalline field, the susceptibility, the spin waves, and the neutron diffraction pattern, are studied. Neutron diffraction data for polianite obtained by Erickson (unpublished) can well be accounted for by the screw-type structure with a pitch of $(7/2)c$. The magnetic properties of the MnO_2 crystal are discussed on the basis of this 7/2-pitch-structure.

§ 1. Introduction

The purpose of the present paper is to find out possible antiferromagnetic spin arrangements in the rutile type crystal and to study their magnetic properties. In this crystal we expect three different superexchange interactions with exchange integrals J_1, J_2 and J_3, the first being the exchange integral between neighboring corner cation and body-center cation, the second that between two cations neighboring along the c-axis, and the third that between two cations neighboring along the a- or b-axis. It will be shown on the basis of a classical energy consideration that, if the first two exchange interactions act in antiferromagnetic way ($J_1>0$, $J_2>0$), three types of spin superstructure will be possible, the relative stability of which depending on the relative magnitudes of the three exchange integrals. One of them is the MnF_2-type structure[1], in which the corner spins and body-center spins point antiparallel, the second is the structure suggested by Bizette[2], Erickson[3] and Yosida[4], in which the corner spins and the body-center spins form uncorrelated antiferromagnetic sublattices, and the last is a new spin arrangement which we propose and in which positive spins on the corner sites and negative spins on the body-center sites screw along the c-axis. This arrangement will be called the "screw-type" structure; the pitch of the screw depends on the value of J_2/J_1.

In the MnF_2-type spin structure, the exchange coupling between neighbors along the c-axis and that along the a-axis or b-axis act unfavorably, if $J_2>0$ and $J_3>0$, but the exchange coupling between neighboring corner and body-center cations acts favorably ($J_1>0$) and this stabilizes the structure. In the Bizette-Erickson-Yosida-structure, the first two couplings act favorably if $J_2>0$, $J_3>0$, while the third (J_1) is inactive. Therefore, if J_2 is large compared with J_1, both being assumed to be positive, and J_3 is small compared with J_1 and J_2, or J_3 is negative, these two structures will not be stable, and it can be shown that the new screw-type structure becomes more stable when $J_2/J_1>1$.

The screw-type structure seems to be realized in polianite, MnO_2. Bizette and Tsai[6] (1949) measured the powder susceptibility of polianite and found that its Néel temperature is at 84°K. Bizette[2] (1950) measured χ_a and χ_c of a single crystal of it and suggested that spins in this crystal might form two mutually uncorrelated antiferromagnetic sublattices whose spin axes are along [110] and [1$\bar{1}$0], respectively. Erickson[3] (1952) carried out a neutron diffraction experiment with a powder sample and found that the corner spins and the body-center spins separately form antiferromagnetic sublattices. Yosida[4] (1952) calculated the dipolar anisotropy energy assuming the Bizette-Erickson structure, and qualitatively explained the anisotropy of the susceptibility below and above the Néel temperature. A recent neutron diffraction experiment by Erickson[6] with a single crystal indicates, however, a different spin structure: the spins are in the c-plane but the magnetic unit cell is seven times as large as the chemical unit cell along the c-axis. It will be shown that the screw-type structure of a pitch of $(7/2)c$ will account for the lines observed by him.

By calculating the classical dipolar anisotropy energy in the screw-type structure, it was found for MnO_2 lattice that when the unit turning angle of the spins, corresponding to the unit c-axis, is less than about 100°, the spins are in an arbitrary plane which contains the c-axis, and that when the unit turning angle is greater than 100°, the spins become perpendicular to the c-axis. It was found further that the crystalline field anisotropy energy stabilizes, to a certain extent, the structures of pitches of simple rational numbers in units of c.

The ratio of the susceptibility in the easy plane to that perpendicular to the easy plane is found to be finite at absolute zero and to depend on the value of J_2/J_1. For a pitch of $(7/2)c$ a qualitative agreement with the experimental results obtained by Bizette[2] is found.

Spin waves in the screw-type structure are also calculated and two non-degenerate branches of the spin wave modes are obtained. It will be shown that there are three modes of antiferromagnetic resonance. Finally, neutron diffraction pattern expected from the screw-type structure will be discussed.

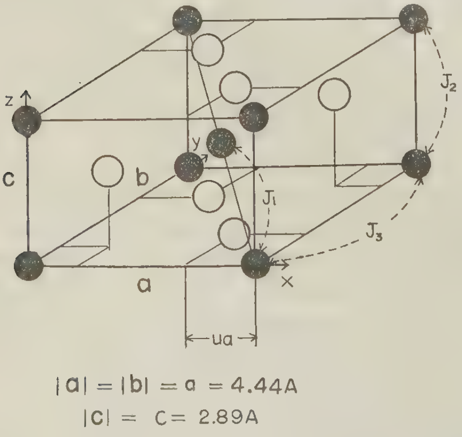

Fig. 1. The rutile type crystal structure of MnO_2. Solid circles are cations, open circles anions. The value of u is unknown for MnO_2. For MnF_2, NiF_2, $u=0.31$.

§ 2. Derivation of the Screw-type Structure

As mentioned in the preceding section, we shall assume three different exchange integrals J_1, J_2 and J_3 (see Fig. 1), and start with a Hamiltonian,

$$H_{\mathrm{ex}}=2J_1\sum_{<ii'>_1}\boldsymbol{S}_i\cdot\boldsymbol{S}_{i'}+2J_2\{\sum_{<ij>_2}\boldsymbol{S}_i\cdot\boldsymbol{S}_j+\sum_{<i'j'>_2}\boldsymbol{S}_{i'}\cdot\boldsymbol{S}_{j'}\}+2J_3\{\sum_{<ij>_3}\boldsymbol{S}_i\cdot\boldsymbol{S}_j+\sum_{<i'j'>_3}\boldsymbol{S}_{i'}\cdot\boldsymbol{S}_{j'}\}\,, \tag{1}$$

where i and j run over $N/2$ corner cations and i' and j' over $N/2$ body-center cations, $<\ >_1$ means pairs of neighboring corner and body-center cations, $<\ >_2$ pairs of cations neighboring along the c-axis, and $<\ >_3$ those along the a- or b-axis. For a while, we shall treat the spins as classical vectors and look for the minimum of H_{ex}. For this purpose we perform Fourier transformations on $\boldsymbol{S}_i$ and $\boldsymbol{S}_{i'}$:

$$\boldsymbol{S}_i=\sum_{\boldsymbol{k}}\boldsymbol{S}(\boldsymbol{k})\exp(i\boldsymbol{k}\cdot\boldsymbol{r}_i),\quad \boldsymbol{S}(-\boldsymbol{k})=\boldsymbol{S}^*(\boldsymbol{k}),$$
$$\boldsymbol{S}_{i'}=\sum_{\boldsymbol{k}}\boldsymbol{S}'(\boldsymbol{k})\exp(i\boldsymbol{k}\cdot\boldsymbol{r}_{i'}),\quad \boldsymbol{S}'(-\boldsymbol{k})=\boldsymbol{S}'^*(\boldsymbol{k}), \tag{2}$$

where $\boldsymbol{k}$ runs over $N/2$ wave vectors in the Brillouin zone corresponding to the chemical cell. Then, we have

$$H_{\mathrm{ex}}\cdot(2/N)=16J_1\sum_{\boldsymbol{k}}\gamma_{\boldsymbol{k}1}\boldsymbol{S}(\boldsymbol{k})\cdot\boldsymbol{S}'(-\boldsymbol{k})+\sum_{\boldsymbol{k}}(2J_2\gamma_{\boldsymbol{k}2}+4J_3\gamma_{\boldsymbol{k}3})(\boldsymbol{S}(\boldsymbol{k})\cdot\boldsymbol{S}(-\boldsymbol{k})+\boldsymbol{S}'(\boldsymbol{k})\cdot\boldsymbol{S}'(-\boldsymbol{k}))\,,$$

where

$$\gamma_{\boldsymbol{k}1}=\cos(k_xa/2)\cos(k_ya/2)\cos(k_zc/2),$$
$$\gamma_{\boldsymbol{k}2}=\cos(k_zc), \tag{3}$$
$$\gamma_{\boldsymbol{k}2}=\{\cos(k_xa)+\cos(k_ya)\}/2\,.$$

Since $\boldsymbol{S}_i^2=\boldsymbol{S}_{i'}^2=S^2$, we have

$$\sum_{\boldsymbol{k},\boldsymbol{k}'}\boldsymbol{S}(\boldsymbol{k})\cdot\boldsymbol{S}(\boldsymbol{k}')\exp\{i(\boldsymbol{k}+\boldsymbol{k}')\cdot\boldsymbol{r}_i\}=S^2,$$
$$\sum_{\boldsymbol{k},\boldsymbol{k}'}\boldsymbol{S}'(\boldsymbol{k})\cdot\boldsymbol{S}'(\boldsymbol{k}')\exp\{i(\boldsymbol{k}+\boldsymbol{k}')\cdot\boldsymbol{r}_{i'}\}=S^2\,.$$

Under conditions (4), we vary $\boldsymbol{S}(\boldsymbol{k})$ and $\boldsymbol{S}'(\boldsymbol{k})$ so as to make H_{ex} stationary. Then, equations determining these vectors are found to be as follows:

$$(4J_2\gamma_{\boldsymbol{k}2}+8J_3\gamma_{\boldsymbol{k}3})\boldsymbol{S}(\boldsymbol{k})+16J_1\gamma_{\boldsymbol{k}1}\boldsymbol{S}'(\boldsymbol{k})=\lambda\boldsymbol{S}(\boldsymbol{k}), \tag{5}$$

$$16J_1\gamma_{\boldsymbol{k}1}\boldsymbol{S}(\boldsymbol{k})+(4J_2\gamma_{\boldsymbol{k}2}+8J_3\gamma_{\boldsymbol{k}3})\boldsymbol{S}'(\boldsymbol{k})=\lambda\boldsymbol{S}'(\boldsymbol{k}), \tag{6}$$

where λ is the Lagrange multipier which we have assumed to be common to all the N conditions of (4) (for different $\boldsymbol{r}_i$ and $\boldsymbol{r}_{i'}$). This assumption means that we are here concerned with a simple sinusoidal change of the spin components in space, with a wave vector $\boldsymbol{k}$, only distinguishing between the corner and body-center sites, since without this assumption different $\boldsymbol{k}$ vectors will mix in the equations for $\boldsymbol{S}(\boldsymbol{k})$ and $\boldsymbol{S}'(\boldsymbol{k})$. We are therefore imposing only one condition

$$\sum_i \boldsymbol{S}_i{}^2+\sum_{i'} \boldsymbol{S}_{i'}{}^2=(N/2)\sum_{\boldsymbol{k}}(\boldsymbol{S}(\boldsymbol{k})\cdot\boldsymbol{S}(-\boldsymbol{k})$$
$$+\boldsymbol{S}'(\boldsymbol{k})\cdot\boldsymbol{S}'(-\boldsymbol{k}))=NS^2, \tag{7}$$

in place of N conditions (4). We have thus to test later whether or not the obtained solution will satisfy all the N conditions (4). $(N/2)\lambda S$ is the energy of the total system, H_{ex}, as one can see by multiplying both the sides of (5) by $\boldsymbol{S}(-\boldsymbol{k})$ and both the sides of (6) by $\boldsymbol{S}'(-\boldsymbol{k})$ and summing them over $\boldsymbol{k}$*.

In order to obtain a non-vanishing solution of (5) and (6), λ must take the following eigenvalues:

$$\lambda=\mp 16J_1\gamma_{\boldsymbol{k}1}+4J_2\gamma_{\boldsymbol{k}2}+8J_3\gamma_{\boldsymbol{k}3} \tag{8}$$

The corresponding eigen-vectors satisfy

$$\boldsymbol{S}(\boldsymbol{k})=\mp\boldsymbol{S}'(\boldsymbol{k})\ , \tag{9}$$

if $\gamma_{\boldsymbol{k}1}\neq 0$. If $\gamma_{\boldsymbol{k}1}=0$, $\boldsymbol{S}(\boldsymbol{k})$ and $\boldsymbol{S}'(\boldsymbol{k})$ are uncorrelated to each other. Now (4) can be written as

$$\boldsymbol{S}(\boldsymbol{k})^2\exp(2i\boldsymbol{k}\cdot\boldsymbol{r}_i)+\boldsymbol{S}(-\boldsymbol{k})^2\exp(-2i\boldsymbol{k}\cdot\boldsymbol{r}_i)$$
$$+2\boldsymbol{S}(\boldsymbol{k})\cdot\boldsymbol{S}(-\boldsymbol{k})=S^2,$$
$$\boldsymbol{S}'(\boldsymbol{k})^2\exp(2i\boldsymbol{k}\cdot\boldsymbol{r}_{i'})+\boldsymbol{S}'(-\boldsymbol{k})^2\exp(-2i\boldsymbol{k}\cdot\boldsymbol{r}_{i'})$$
$$+2\boldsymbol{S}'(\boldsymbol{k})\cdot\boldsymbol{S}'(-\boldsymbol{k})=S^2. \tag{10}$$

In order that the right-hand sides of these equations are independent of $\boldsymbol{r}_i$ and $\boldsymbol{r}_{i'}$, either k_xa, k_ya and k_zc must be integral multiples of π or $\boldsymbol{S}(\boldsymbol{k})^2=\boldsymbol{S}'(\boldsymbol{k})^2=0$. If k_xa, k_ya and k_zc are zero and $\boldsymbol{S}(\boldsymbol{k})=-\boldsymbol{S}'(\boldsymbol{k})$, we have the MnF$_2$-type antiferromagnetic structure; if $\boldsymbol{S}(\boldsymbol{k})=\boldsymbol{S}'(\boldsymbol{k})$, we have the ferromagnetic structure. If k_xa, k_ya and k_zc are all π, in which case $\gamma_{\boldsymbol{k}1}=0$, we have the Bizette-Erickson-Yosida structure. Now, if $\boldsymbol{S}(\boldsymbol{k})^2=\boldsymbol{S}'(\boldsymbol{k})^2=0$,

$$\boldsymbol{S}(\boldsymbol{k})=\mp\boldsymbol{S}'(\boldsymbol{k})=(\boldsymbol{u}_1-i\boldsymbol{u}_2)S/2, \tag{11}$$

where $\boldsymbol{u}_1$ and $\boldsymbol{u}_2$ are real unit vectors which are perpendicular to each other. For this solution, (2) becomes

$$\boldsymbol{S}_i=\{(\boldsymbol{u}_1-i\boldsymbol{u}_2)\exp(i\boldsymbol{k}\cdot\boldsymbol{r}_i)+\text{conj. comp.}\}S/2,$$
$$=\{\boldsymbol{u}_1\cos(\boldsymbol{k}\cdot\boldsymbol{r}_i)+\boldsymbol{u}_2\sin(\boldsymbol{k}\cdot\boldsymbol{r}_i)\}S, \tag{12}$$
$$\boldsymbol{S}_{i'}=\mp\{\boldsymbol{u}_1\cos(\boldsymbol{k}\cdot\boldsymbol{r}_{i'})+\boldsymbol{u}_2\sin(\boldsymbol{k}\cdot\boldsymbol{r}_{i'})\}S\ .$$

The corresponding spin structure is such that it can be derived from the MnF$_2$-type antiferromagnetic structure (for the $-$ sign in (12)) or from the ferromagnetic structure (for the $+$ sign) by rotating the spins in the $\boldsymbol{u}_1$, $\boldsymbol{u}_2$-plane in such a way that they screw along the direction of $\boldsymbol{k}$ with a pitch of $2\pi/k$. This may be called the screw-type structure.

The energy of the system, i.e., λ $(=(\text{total energy})\ (2/NS^2))$, is given as follows. For the MnF$_2$-type antiferromagnetic structure:

$$\lambda=-16J_1+4J_2+8J_3\ , \tag{13}$$

for the B. E. Y.-structure:

$$\lambda=-4J_2-8J_3\ , \tag{14}$$

and for the screw-type structure, λ is given by the minimum of (8). This minimum value and the corresponding $\boldsymbol{k}$-value are obtained from the equations

$$\sin(k_xa/2)\{\pm J_1\cos(k_ya/2)\cos(k_zc/2)$$
$$-J_3\cos(k_xa/2)\}=0,$$
$$\sin(k_ya/2)\{\pm J_1\cos(k_zc/2)\cos(k_xa/2)$$
$$-J_3\cos(k_ya/2)\}=0\ . \tag{15}$$
$$\sin(k_zc/2)\{\pm J_1\cos(k_xa/2)\cos(k_ya/2)$$
$$-J_2\cos(k_zc/2)\}=0.$$

There are several solutions of these equations, of which the following three are new:

(a) Spins in the same xy-plane are parallel, i. e., k_xa and k_ya are zero, and they screw along the z-axis with a unit screwing angle equal to k_zc (see Fig. 2), where k_zc satisfies.

$$\cos(k_zc/2)=J_1/J_2,$$
$$\text{provided that } |J_2|>|J_1|, \tag{16}$$

(see Fig. 3). The corresponding λ-value is

$$\lambda=-8(J_1{}^2/J_2)-4J_2+8J_3. \tag{17}$$

(b) Spins in the same yz-plane are parallel and they screw along the x-axis, with a unit screwing angle of k_xa, where

---

* More generally, we can replace λ of the right-hand of (6) by a different Lagrange multiplier λ', imposing two conditions: $\sum_i S_i{}^2=(N/2)S^2$ and $\sum_i S_{i'}{}^2=(N/2)S^2$. Then, the energy of the system becomes $(\lambda+\lambda')S^2/2$. λ and λ' are related to each other by the vanishing of the determinant of the equations, and it can be shown that the energy is a minimum when $\lambda=\lambda'$.

$\cos(k_x a/2) = J_1/J_3$, provided that $|J_3| > |J_1|$.

The corresponding λ-value is

$$\lambda = -8(J_1^2/J_3) + 4J_2 \,. \tag{19}$$

The x and y axes may be interchanged.

(c) A three-dimentional screw, with

$$\cos(k_x a/2/2) = \cos(k_y a/2) = \sqrt{J_2 J_3}/J_1,$$

$$\cos(k_z c/2) = J_3/J_1,$$

$$(|J_1| > \sqrt{J_2 J_3},\ J_2 J_3 > 0,\ |J_3| > |J_1|) \,.$$

The corresponding λ-value is given by

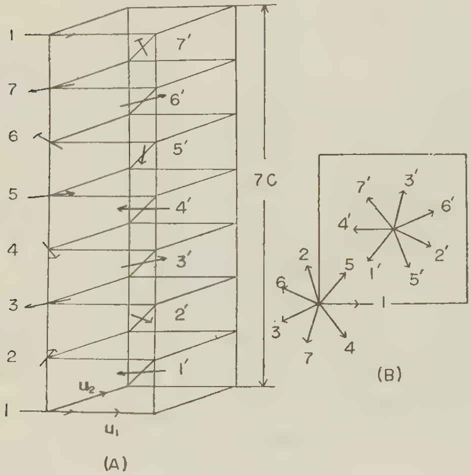

Fig. 2. (A) The screw-type structure with a pitch of 7/2 (proper screw-type structure). (B) Projection on the c-plane.

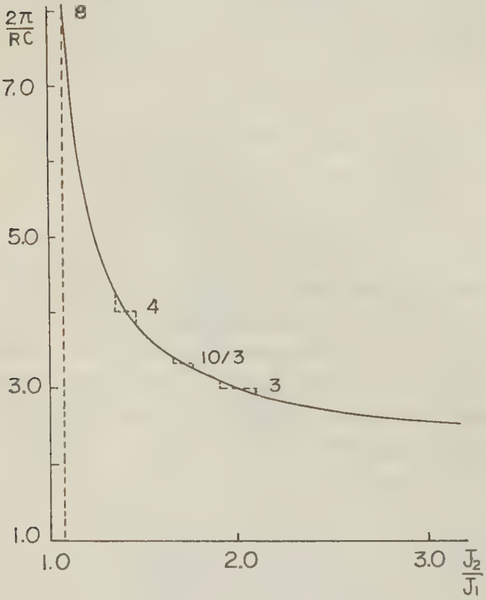

Fig. 3. Relation between the pitch of the screw and J_2/J_1. Dotted lines indicate (schematically) the modification in certain ranges of J_2/J_1 when the anisotropy energy is considered.

$$\lambda = 8J_2 J_3^2/J_1^2 - 4J_2 - 8J_3 \,. \tag{19}$$

It is interesting to note that the energy λ is the same for both the screwed ferromagnetic ($J_1 < 0$) and screwed MnF$_2$-type antiferromagnetic ($J_1 > 0$) structures in the above three cases, as it should be since J_1 appears only as J_1^2.

Now we compare the energy values of the various structures derived above. Comparing (13) with (14), it can be seen that the boundary of the relative stability of the correspond ing two structures is given by

$$J_2 + 2J_3 = 2J_1 \,. \tag{20}$$

If $J_2 + 2J_3 < 2J_1$, the MnF$_2$-type structure is more stable, but if $J_2 + 2J_3 > 2J_1$, the B. E. Y.-structure becomes more stable. The structure which screws along the c-axis appears when $J_2 > J_1$ (we assume $J_1 > 0$), and it can be shown that its stability range is bounded by

$$J_2 = J_1 \quad \text{and} \quad 2J_2 J_3 = J_1^2 \,. \tag{21}$$

The other two screw-type structures have no stability range. Therefore, the whole J_2/J_1, J_3/J_1-plane can be divided into four parts as shown in Fig. 4. In this figure, the structure for $J_2 < 0$ and $J_3 > J_1$ (>0) is such that the spins are parallel to each other along the c-axis and antiparallel along the a and b-axes while the corner spins and body-center spins are uncorrelated.

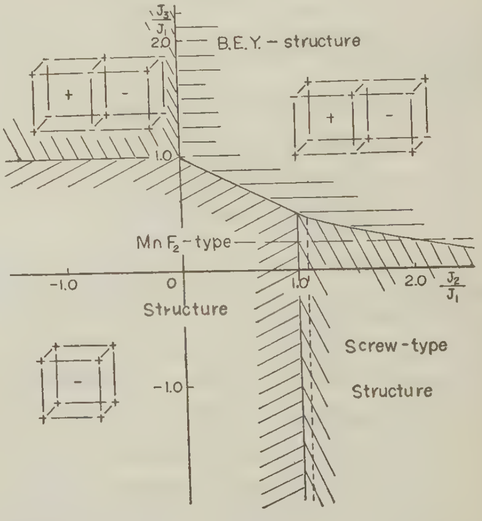

Fig. 4. The stability boundaries of various spin structures in the J_2/J_1, J_3/J_1-plane. Dotted vertical line shows the shift of the boundary due to dipolar anisotropy energy (assuming the calculated dipolar interaction in MnO$_2$ and estimating J_1, J_2, J_3 for the same crystal).

In the molecular field approximation, the Néel temperature, T_N, in the screw-type structure with a screw axis along the c-axis, is obtained through a simple calculation as

$$k_B T_N = \{S(S+1)/3\}(8J_1^2/J_2 + 4J_2 - 8J_3), \qquad (22)$$

(k_B: the Boltzmann constant) and the paramagnetic Curie temperature, Θ_p, as

$$k_B \Theta_p = \{S(S+1)/3\}(16J_1 + 4J_2 + 8J_3)\ . \qquad (23)$$

Their ration, Θ_p/T_N, is

$$\frac{\Theta_p}{T_N} = \frac{4+(J_2/J_1)+2(J_3/J_1)}{2(J_2/J_1)^{-1}+(J_2/J_1)-2(J_3/J_1)}\ . \qquad (24)$$

The maximum allowable value of Θ_p/T_N in the screw-type structure of a given pitch occurs at $2(J_3/J_1)=(J_2/J_1)^{-1}$, which is the largest allowable value of $2(J_3/J_1)$ in this structure, and

$$\left(\frac{\Theta_p}{T_N}\right)_{\max} = \frac{4+(J_2/J_1)^{-1}+(J_2/J_1)}{(J_2/J_1)^{-1}+(J_2/J_1)}\ .$$

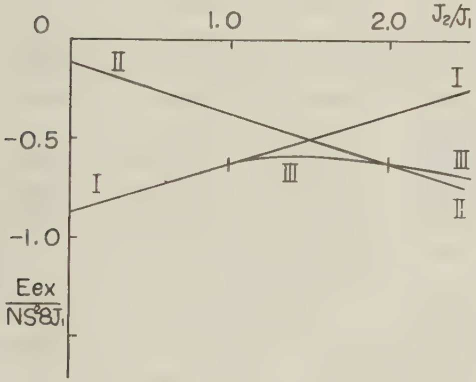

Fig. 5. The energy diagram for the various structures along the dashed line in Fig. 4 ($J_3/J_1 = 1/4$)
I MnF$_2$-type structure,
II B. E. Y.-structure,
III Screw-type structure.

The energies of the three superstructures are shown as functions of J_2/J_1 for $J_3/J_1=0.25$ in Fig. 5. It is noted that the energy curve of the screw-type structure makes a contact of the second order with that of the MnF$_2$-type structure at $J_2/J_1=1$.

Since the anisotropy energy has not yet been considered, the spins in the screw-type structure can be parallel to an arbitrary plane. If the spins are parallel to a plane which contains the c-axis, we may call the structure the "cycloidal structure" (Fig. 6). If the spins are perpendicular to the c-axis, i.e., the screw axis, the structure may be called the "proper screw-type structure". Whether the latter or the former is realized depends on the anisotropy energy, which will be the subject of the next section.

The "proper" 7/2-pitch-structure (Fig. 2) is expected as realized in MnO$_2$ from our analysis of the neutron diffraction data (unpublished) by Erickson⁶⁾. If we assume this, we expect from the conditions of stabilizing the screw-type structure, i.e. from Eq. (16) and $2J_2J_3 < J_1^2$, that in MnO$_2$ J_2/J_1 is 1.60 and J_3/J_1 smaller than 0.31. On the other hand, we can also determine J_3/J_1 from Eq. (24) and the observed ratio of Θ_p (316°K) to T_N (84°K) by Bizette and Tsai⁵⁾, and have $J_3/J_1 \approx 0.56$. This discrepancy will be discussed in section 7. We give here a rough estimate of J_1 for our later purpose assuming somewhat arbitrary $J_3/J_1=0.25$: using Eq. (22) and putting $S=3/2$ and $T_N=84$°K, we have $16J_1 \sim 90\ \mathrm{cm}^{-1}$.

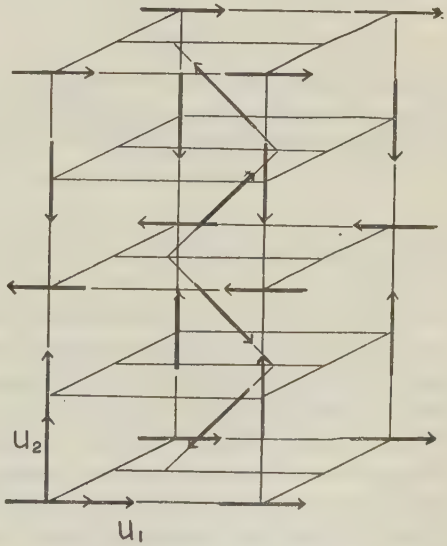

Fig. 6. The cycloidal structure with a pitch of 4.

§ 3. Role of the Anisotropy Energy in the Screw-type Structure

(A) *Anisotropy energy due to magnetic dipolar interaction*

The magnetic field at each cation due to the magnetic moments of other cations can be expressed as follows:

$$\boldsymbol{H}_n{}^{\mathrm{dip}} = \sum_l \Phi_{nl}\boldsymbol{\mu}_l + \sum_{l'} \Phi'_{nl'}\boldsymbol{\mu}_{l'},$$

$$\boldsymbol{H}_{n'}{}^{\mathrm{dip}} = \sum_{l'} \Phi_{n'l'}\boldsymbol{\mu}_{l'} + \sum_l \Phi'_{n'l}\boldsymbol{\mu}_l, \qquad (26)$$

where we number layers of corner cations and body-center cations successively along the c-axis, and denote by n and l the layers of corner cations and by n' and l' the layers of body-center cations; $\boldsymbol{H}_n{}^{\mathrm{dip}}$ and $\boldsymbol{H}_{n'}{}^{\mathrm{dip}}$ therefore mean, respectively, the field at a corner cation on the nth net-plane and the field at a body-center cation on the n'th net-plane, and $\boldsymbol{\mu}_l$ and $\boldsymbol{\mu}_{l'}$ are the magnetic moments of cations on the lth net-plane and l'th net-plane. $\boldsymbol{\Phi}_{nl}$ and $\boldsymbol{\Phi}'_{nl'}$ are tensors, and evidently

$$\boldsymbol{\Phi}_{nl}=\boldsymbol{\Phi}_{|n-l|},\quad \boldsymbol{\Phi}'_{nl'}=\boldsymbol{\Phi}'_{|n-l'|}.$$

When the principal axes of the crystal are taken to be the coordinates axes (Fig. 1), it is evident from the crystalline symmetry that $\boldsymbol{\Phi}_{nl}$ and $\boldsymbol{\Phi}'_{nl'}$ are diagonal, and the following relations hold between their principal values;

$$\Phi_{|n-l|,x}=\Phi_{|n-l|,y}=-(1/2)\Phi_{|n-l|,z}\ ,$$
$$\Phi'_{|n-l'|,x}=\Phi'_{|n-l'|,y}=-(1/2)\Phi'_{|n-l'|,z}\ ,$$

Here $\Phi_{|l|,z}$ for instance, is given by

$$\Phi_{|l|,z}=\sum_i r_{li}{}^{-3}\{3(z_l/r_{li})^2-1\}\ ,$$

where r_{li} means the distance from a given cation on the zeroth layer to the ith cation on the lth layer, and the summation extends over all i if $l\neq 0$, but it excludes $r_{0i}=0$ if $l=0$.

$$\boldsymbol{\mu}_l=g\mu_{\mathrm{B}}\boldsymbol{S}_l=g\mu_{\mathrm{B}}<S_\xi>\{\boldsymbol{u}_1\cos(kz_l)+\boldsymbol{u}_2\sin(kz_l)\}\ ,$$
$$\boldsymbol{\mu}_{l'}=g\mu_{\mathrm{B}}\boldsymbol{S}_{l'} \tag{27}$$
$$=g\mu_{\mathrm{B}}<S_\xi>\{-\boldsymbol{u}_1\cos(kz_{l'})-\boldsymbol{u}_2\sin(kz_{l'})\}\ ,$$

where S_ξ is the component of spin in the direction of the molecular field to which it is subjected and is common to all the spins. We take out two layers which are on the opposite sides of the nth layer at the same distance and combine their $\boldsymbol{\mu}$'s together in the sum of the first eqation of (26). Since the sum of these $\boldsymbol{\mu}$'s is a vector which is parallel to the magnetization of the nth layer, we can simplify the calculation of (26). It can be shown that $\boldsymbol{H}_n{}^{\mathrm{dip}}$ is expressed as

$$\boldsymbol{H}_n{}^{\mathrm{dip}}=(N/2)g\mu_{\mathrm{B}}<S_\xi>\varphi_A(\theta)\{(\boldsymbol{c}/c)(\boldsymbol{c}/c)-\boldsymbol{I}\}$$
$$\cdot\{\boldsymbol{u}_1\cos(kz_n)+\boldsymbol{u}_2\sin(kz_n)\}\ , \tag{28}$$

where $3(\boldsymbol{c}/c)(\boldsymbol{c}/c)-\boldsymbol{I}$ is a dyadic whose diagonal elements are -1, -1, 2, and

$$\varphi_A(\theta)=\{\varphi(\theta)-\varphi'(\theta)\}/2, \tag{29}$$
$$\varphi(\theta)=(2/N)\sum_l \Phi_{|l|,z}\cos(kz_l), \tag{30}$$
$$\varphi'(\theta)=(2/N)\sum_{l'} \Phi_{|l'|,z}\cos(kz_{l'}), \tag{31}$$

where $2\theta(=k_zc)$ is the unit screwing angle. $\boldsymbol{H}_{n'}{}^{\mathrm{dip}}$ can be expressed in a similar manner. Denoting by n_z the number of net-planes, the dipolar energy per unit volume, E_{dip}, is calculated as follows:

$$E_{\mathrm{dip}}=(N/2n_z)\{-\sum_n \boldsymbol{\mu}_n\cdot\boldsymbol{H}_n{}^{\mathrm{dip}}-\sum_n \boldsymbol{\mu}_{n'}\cdot\boldsymbol{H}_{n'}{}^{\mathrm{dip}}\},$$
$$=\{1-(3/2)(u_{1z}{}^2+u_{2z}{}^2)\}\varphi_A(\theta)(N\mu/2)^2,$$
$$\mu=g\mu_{\mathrm{B}}<S_\xi>.$$

If $\boldsymbol{u}_3$ is defined by $\boldsymbol{u}_3=\boldsymbol{u}_1\times\boldsymbol{u}_2$ and Θ is the angle between $\boldsymbol{u}_3$ and the c-axis, it follows that

$$u_{1z}{}^2+u_{2z}{}^2=1-u_{3z}{}^2=1-\cos^2\Theta.$$

Thus

$$E_{\mathrm{dip}}=(1/2)(3\cos^2\Theta-1)\varphi_A(\theta)(N\mu/2)^2. \tag{32}$$

The values of $\varphi(\theta)$ and $\varphi'(\theta)$ were calculated

Table I.

θ^0	$-\varphi(\theta)$	$-\varphi'(\theta)$	$\varphi_A(\theta)$
0	1.27	11.78	5.26
15	1.91	11.26	4.68
30	3.64	9.83	3.10
45	5.94	7.74	0.90
51.4	6.96	6.72	−0.12
60	8.20	5.29	−1.46
75	9.81	2.68	−3.57
90	10.39	0	−5.20

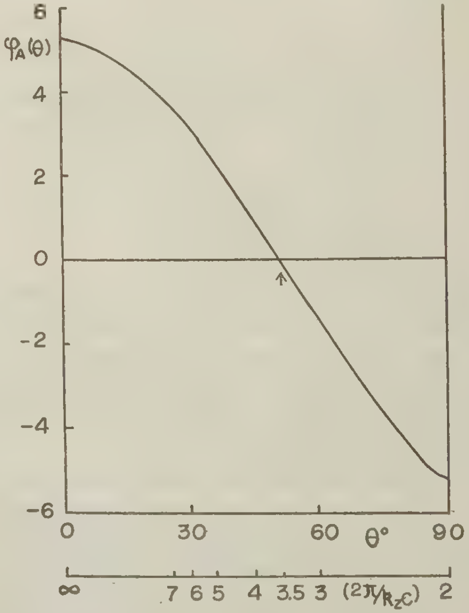

Fig. 7. The variation of $\varphi_A(\theta)$ versus θ in MnO$_2$. A small arrow indicates the point corresponding to a pitch of 3.5.

by the direct sum method first summing over cations on each net-plane and then summing over different net-planes. The results are shown in Table I and Fig. 7 for the lattice of MnO_2. Putting $S=3/2$ and $g=2$, E_{dip}/N becomes

$$E_{\mathrm{diq}}/N=0.0169\varphi_A(\theta)(<S_\xi>/S)^2(3\cos^2\Theta-1)\mathrm{cm}^{-1}. \tag{33}$$

If $\varphi_A(\theta)$ is positive, the easy planes of the spins is parallel to the c-axis ($\Theta=90°$), i.e., the cycloidal structure becomes stable, but if $\varphi_A(\theta)$ is negative, the proper screw-type structure ($\Theta=0°$) becomes stable. In Fig. 7 it is seen that $\varphi_A(\theta)$ changes sign at $\theta=50.8°$. In the 7/2-pitch-structure for which $\theta=51.4°$, θ is a little above this value and so the magnetizations are stabilized in the c-plane. E_{dip}/N of the 7/2-pitch-structure is

$$E_{\mathrm{dip}}/N=-0.002(<S_\xi>/S)^2(3\cos^2\Theta-1)\ \mathrm{cm}^{-1}. \tag{34}$$

This anisotropy energy is very small and may not be important compared with the crystalline field anisotropy energy which will be discussed later.

The dipolar energy of the MnF_2-type structure, in which spins point parallel to the c-axis, is $-(1/2)\varphi_A(0)(N\mu/2)^2$. This is twice as large as that of the cycloidal structure for vanishing θ. On the other hand, the difference in the exchange energy for the MnF_2-type and screw-type structures is very small when $J_2/J_1\sim1$, as mentioned in section 2. Therefore, if J_2 exceeds J_1 only a little, the MnF_2-type structure will remain to be more stable than the cycloidal structure, since the corresponding increase in exchange energy will be over-compensated by dipolar energy; in other words, the stability boundary shifts a little towards a larger value of J_2/J_1. For MnO_2, the difference in dipolar energy per cation corresponding to these two possible structure, namely $(1/2N)\varphi_A(0)(N\mu/2)^2$, is about $0.09\ \mathrm{cm}^{-1}$. In order to estimate the order of magnitude of the shift in this case, we assume $16J_1\sim90\ \mathrm{cm}^{-1}$ (see the preceding section), then the boundary value of J_2/J_1 turns out to be 1.08 (Fig. 4). The pitch corresponding to this new boundary is about 8, i.e., screw-type structures with larger pitches than about 8 are unstable (Fig. 3). The stability boundary shifts also due to the crystalline field anisotropy energy, which will be treated in the next subsection.

(B) *Anisotropy energy due to crystalline field*

The Mn^{4+} ions in polianite may have an anisotropy energy due to the crystalline field. Let us consider the orthorhombic anisotropy energy of the lowest order:

$$\begin{aligned}&D'\beta_3^2-E'\beta_1\beta_2,\\ &\qquad\text{for the corner cations,}\\ &D'\beta_3^2+E'\beta_1\beta_2,\\ &\qquad\text{for the body-center cations,}\end{aligned} \tag{35}$$

where β_1, β_2, β_3 are the direction cosines of the spins referred to the principal axes of the crystal. These energies are derived from the effective spin Hamiltonian,

$$\sum_i\{DS_{iz}^2-E(S_{ix}S_{iy}+S_{iy}S_{ix})\}+\sum_{i'}\{DS_{i'z}^2+E(S_{i'x}S_{i'y}+S_{i'y}S_{i'x})\}. \tag{36}$$

Making use of the molecular field approximation, we have

$$D'/D=E'/E=\{3<S_\xi>^2-S(S+1)\}/2. \tag{37}$$

Treating (35) as a classical perturbation to the exchange energy, one can easily obtain the first order crystalline anisotropy energy (per cation) to be

$$(D'/2)\sin^2\Theta, \tag{38}$$

(the terms with E' are averaged out to zero). Hence, for positive D' the proper screw-type and for negative D' the cycloidal structure are stabilized. For negative D', the stability boundary between the MnF_2-type structure and screw-type structure shifts in the same way as in the case of dipolar anisotropy energy.

The anisotropy energy in the easy plane of the proper screw-type structure will vary discontinuosly as a function of pitch due to E'-terms, if we go over to higher order perturbation calculation. Due to the E'-terms of (35), the corner spins tend towards [110] and the body-center spins towards [1$\bar{1}$0], assuming $E'>0$, and it can be shown that a structure with a pitch of a simple rational number is stabilized by this effect. For example, the anisotropy energy in the c-plane of the 6-pitch-structure is expressible as a combination of $\sin6\theta^*$ and $\cos6\theta^*$ and that of the 4-pitch-structure as a combination of $\sin8\theta^*$ and $\cos8\theta^*$, where θ^* specifies the angle of rotation of tne spins as a whole in the c-

plane, the minima of which these anisotropy energies depressing the total energy. The anisotropy energy in the easy plane may also come from the orthorhombic anisotropy energy of a higher order (for example, a higher order quantum-mechanical perturbation of the spin-orbit coupling). In any case, the anisotropy energy in the easy plane must appear at lower orders for simple pitches than for complex pitches. In particular, for irrational pitches we have no anisotropy energy. As a result, the pitch as a function of J_2/J_1 will become as shown schematically in Fig. 3. However, the width of each part of constant pitch in this figure may be very small, as it arises from a higher order perturbational calculation. We find a similar situation in the cycloidal structure considering only the dipolar interaction.

§4. Susceptibility

In calculating the susceptibility, we shall neglect the dipolar interaction, which will be of minor importance compared with the exchange interaction, if the Néel temperature of the substance is high ($\gg 1°$K). The crystalline field anisotropy energy will be taken into account through an anisotropic g-factor. By applying an external field, the pitch of of the screw will be slightly changed if the field is applied in the plane of the spins, but it can be shown that the change does not occur to first order in $\boldsymbol{H}$. Therefore, we shall assume that the pitch is a given constant.

When the external field $\boldsymbol{H}$ is applied perpendicularly to the plane in which the spins lie, we obtain a temperature-independent susceptibility, $\chi_{s\perp}$, as we shall show below. In this case, all the $\boldsymbol{\mu}_n$ and $\boldsymbol{\mu}_{n'}$ must make the same angle, τ ($<90°$), with $\boldsymbol{H}$. The torque on, say, $\boldsymbol{\mu}_n$ must vanish, i.e.

$$\boldsymbol{\mu}_n \times (\boldsymbol{H}_n^{\mathrm{ex}} + \boldsymbol{H}) = 0 \tag{39}$$

where

$$\boldsymbol{H}_n^{\mathrm{ex}} = -(\alpha_1/2)(\boldsymbol{\mu}_{n'} + \boldsymbol{\mu}_{n'-1}) - (\alpha_2/2)(\boldsymbol{\mu}_{n+1} + \boldsymbol{\mu}_{n-1}) - \gamma \boldsymbol{\mu}_n,$$

$$\alpha_1 = 16 J_1 (g\mu_{\mathrm{B}})^{-2}, \qquad \alpha_2 = 4 J_2 (g\mu_{\mathrm{B}})^{-2}, \qquad \gamma = 8 J_3 (g\mu_{\mathrm{B}})^{-2}. \tag{40}$$

If the z'-axis is taken along $\boldsymbol{H}$, x'-axis along the original $\boldsymbol{\mu}_n$-direction (for no external field) and the y'-axis perpendicular to the both, we have from the y'-component of (39),

$$\mu \cos\tau(\alpha_1 \mu \sin\tau \cos\theta - \alpha_2 \mu \sin\tau \cos 2\theta) - \mu \sin\tau(-\alpha_1 \mu \cos\tau - \alpha_2 \mu \cos\tau + H) = 0,$$

or

$$\mu \cos\tau = H / \{\alpha_1(1+\cos\theta) + \alpha_2(1-\cos 2\theta)\} .$$

The magnitude of the total magnetization is

$$N\mu_{z'} = N\mu\cos\tau = H/\{A_1(1+\cos\theta) + A_2(1-\cos 2\theta)\} ,$$

$$A_1 = \alpha_1/N, \quad A_2 = \alpha_2/N$$

so that the susceptibility is given by

$$\chi_{s\perp} = 1/\{A_1(1+\cos\theta) + A_2(1-\cos 2\theta)\} . \tag{41}$$

It might be remined that $\cos\theta = J_1/J_2 = A_1/4A_2$.

When $\boldsymbol{H}$ is applied in the spin plane, we have a different susceptibility, $\chi_{s//}$. In this case, we denote the angle between the equilibrium direction of $\boldsymbol{\mu}_n$ in the field and $\boldsymbol{H}$ itself by θ_n and similarly the angle between $-\boldsymbol{\mu}_{n'}$ and $\boldsymbol{H}$ by $\theta_{n'}$. Then we have

$$\begin{aligned} |\boldsymbol{\mu}_n \times (\boldsymbol{H}_n^{\mathrm{ex}} + \boldsymbol{H})| = -\alpha_1 \mu_n \{ & \mu_{n'} \sin(\theta_{n'} - \theta_n) \\ & - \mu_{n'-1} \sin(\theta_n - \theta_{n'-1})\} + \alpha_2 \mu_n \{\mu_{n+1} \sin(\theta_{n+1} - \theta_n) \\ & - \mu_{n-1} \sin(\theta_n - \theta_{n-1})\} - \mu_n H \sin\theta_n = 0 , \end{aligned} \tag{42}$$

and a similar equation for $\boldsymbol{\mu}_{n'}$. Here $\boldsymbol{H}_n^{\mathrm{ex}}$, given by (40), is different from that without external field since $\boldsymbol{\mu}_n$ and $\boldsymbol{\mu}_{n'}$ have changed, not only as regards their directions but also as regards their lengths. The latter is determined by

$$\mu_n = g\mu_B \langle S_\xi \rangle = g\mu_B S B_S(y_n)\,, \qquad y_n = (g\mu_B S/k_B T)|\boldsymbol{H}_n^{\text{ex}} + \boldsymbol{H}|\,, \tag{43}$$

and similar equations for $\mu_{n'}$, where $B_S(y)$ is the Brillouin function. When no external field is present, $\theta_{n+1}{}^{(0)} - \theta_n{}^{(0)}$ and $\theta_{n'}{}^{(0)} - \theta_n{}^{(0)}$ are given by

$$\theta_{n+1}{}^{(0)} - \theta_n{}^{(0)} = 2\theta, \qquad \theta_{n'}{}^{(0)} - \theta_n{}^{(0)} = \theta\,, \tag{44}$$

and all the μ_n and $\mu_{n'}$ are equal to

$$\mu = g\mu_B S B_S(y_0), \qquad y_0 = (g\mu_B S/k_B T)\mu(\alpha_1 \cos\theta - \alpha_2 \cos 2\theta - \gamma)\,.$$

If angular shifts, $\Delta\theta_n = \theta_n - \theta_n{}^{(0)}$, $\Delta\theta_{n'} = \theta_{n'} - \theta_{n'}{}^{(0)}$, and variations of μ_n and $\mu_{n'}$, denoted as $\mu\mathcal{E}_n$ and $\mu\mathcal{E}_{n'}$, due to the external field are considered to the first order in H, Eqs. (42) and (43) can be linearized, and the following difference equations are obtained for $\mathcal{E}_n$, $\mathcal{E}_{n'}$ and $\Delta\theta_n$, $\Delta\theta_{n'}$:

$$\begin{aligned}
&(\alpha_1/2)(\mathcal{E}_{n'} - \mathcal{E}_{n'-1}) \sin\theta - (\alpha_2/2)(\mathcal{E}_{n+1} - \mathcal{E}_{n-1}) \sin 2\theta \\
&\quad + (\alpha_1/2)(\Delta\theta_{n'} + \Delta\theta_{n'-1} - 2\Delta\theta_n) \cos\theta - (\alpha_2/2)(\Delta\theta_{n+1} + \Delta\theta_{n-1} - 2\Delta\theta_n) \cos 2\theta \\
&\quad - (H/\mu) \sin(2n\theta + \theta_0{}^{(0)}) = 0\,,
\end{aligned} \tag{45}$$

$$\begin{aligned}
&-(\alpha_1/2)(\mathcal{E}_{n'} + \mathcal{E}_{n'-1}) \cos\theta + \{t\mathcal{E}_n + (\alpha_2/2)(\mathcal{E}_{n+1} + \mathcal{E}_{n-1}) \cos 2\theta\} \\
&\quad - (\alpha_1/2)(\Delta\theta_n - \Delta\theta_{n'-1}) \sin\theta + (\alpha_2/2)(\Delta\theta_{n+1} - \Delta\theta_{n-1}) \sin 2\theta \\
&\quad + (H/\mu) \cos(2n\theta + \theta_0{}^{(0)}) = 0\,,
\end{aligned} \tag{46}$$

where

$$t = k_B T\{(g\mu_B)^2 B_S'(y_0)\}^{-1} + \gamma$$

The following solutions are easily found from these difference equations:

$$\begin{aligned}
\Delta\theta_n &= -d_1 \sin(2n\theta + \theta_0{}^{(0)}), & \Delta\theta_n &= d_1 \sin\{(2n+1)\theta + \theta_0{}^{(0)}\}\,, \\
\mathcal{E}_n &= d_2 \cos(2n\theta + \theta_0{}^{(0)}), & \mathcal{E}_n &= -d_2 \cos\{(2n+1)\theta + \theta_0{}^{(0)}\}\,,
\end{aligned} \tag{47}$$

where

$$Nd_1 = (H/\mu)(V - W)/(UV - W^2), \qquad Nd_2 = (H/\mu)(U - W)(UV - W^2),$$

$$U = (t/N) + A_1 \cos^2\theta + A_2 \cos^2 2\theta, \qquad V = A_1 \cos\theta(1 + \cos\theta) - A_2 \cos 2\theta(1 - \cos 2\theta),$$

$$W = A_1 \sin^2\theta + A_2 \sin^2 2\theta,$$

The magnitude of the total magnetization is

$$(N/n_z)\{\sum_n \mu_n \cos\theta_n - \sum_{n'} \mu_n \cos\theta_{n'}\} = (N\mu/2)(d_1 + d_2)\,,$$

so that the susceptibility is given by

$$\chi_{s//} = (1/2)(U + V - 2W)/(UV - W^2)\,. \tag{48}$$

This $\chi_{s//}$ has a finite value at absolute zero. For $T \to 0$, t becomes infinite and so $U \to \infty$, so that

$$(\chi_{s//})_{T=0} = 1/(2V) = (1/2)\{A_1 \cos\theta(1 + \cos\theta) - A_2 \cos 2\theta(1 - \cos 2\theta)\}^{-1}. \tag{49}$$

The ratio of $\chi_{s//}$ to $\chi_{s\perp}$ at absolute zero is a function of θ only (see Fig. 8), and is given by

$$(\chi_{s//})_{T=0}/\chi_{s\perp}=(1/2)\{(1+\cos\theta)+(A_2/A_1)(1-\cos 2\theta)\}$$
$$\times\{\cos\theta(1+\cos\theta)-(A_2/A_1)\cos 2\theta(1-\cos 2\theta)\}^{-1}, \tag{50}$$

where

$$\cos\theta=A_1/(4A_2)\ .$$

$\chi_{s//}$ increases monotonically with rising temperature up to T_N. At $T=T_N$, t becomes

$$(t/N)_{T=T_N}=A_1\cos\theta-A_2\cos 2\theta,$$

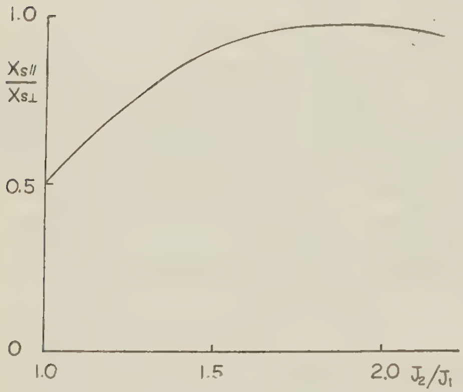

Fig. 8. Variation of $\chi_{s//}/\chi_{s\perp}$ against J_2/J_1.

and it can be shown that $\chi_{s//}$ coincides with $\chi_{s\perp}$.

When the anisotropy of the g-factor and the anisotropic crystalline field are taken into consideration, Eq. (39) will be replaced by

$$\boldsymbol{\mu}_n\times(\boldsymbol{H}_n^{\mathrm{ex}}+\boldsymbol{H}_n^{\mathrm{c.a}}+\boldsymbol{H}^*)=0\ ,$$

and y_n in Eq. (43) by

$$y_n=(g\mu_B S/k_B T)|\boldsymbol{H}_n^{\mathrm{ex}}+\boldsymbol{H}_n^{\mathrm{c.a}}+\boldsymbol{H}^*|\ .$$

Here $\boldsymbol{H}_n^{\mathrm{c.a}}$ (effective field due to crystalline anisotropy) is given, corresponding to (35), by

$$\boldsymbol{H}_n^{\mathrm{c.a}}=-(D'/\mu)\beta_{3n}(\boldsymbol{c}/c)-(E'/\mu)(\beta_{2n}\boldsymbol{a}/a+\beta_{1n}\boldsymbol{b}/a)\ ,$$

and $\boldsymbol{H}^*$, $\boldsymbol{H}^{*\prime}$ are defined by

$$\boldsymbol{g}^2\boldsymbol{H}=g^2\boldsymbol{H}^*,\qquad \boldsymbol{g}'^2\boldsymbol{H}=g^2\boldsymbol{H}'^*,$$

where $\boldsymbol{g}$ and $\boldsymbol{g}'$ are g-tensors for the corner and body-center cations, respectively. Their principal values will be denoted as g_1, g_2, g_3 corresponding to the axes [110], [1$\bar{1}$0], [001] for the corner sites and [1$\bar{1}$0], [$\bar{1}\bar{1}$0], [001] for the body-center sites. Assuming the proper screw-type structure, we obtain, in place of $\chi_{s\perp}$ and $\chi_{s//}$,

$$\chi_c=(g_3/g)^2\{A_1(1+\cos\theta)+A_2(1-\cos 2\theta)+(D'/\mu^2)(2/N)\}^{-1}, \tag{51}$$

$$\chi_a=(1/2)\{(g_1^2+g_2^2)/2g^2\}(U+V-2W)/(UV-W^2)\ . \tag{52}$$

At absolute zero, χ_a reduces to

$$(\chi_a)_{T=0}=(1/2)\{(g_1^2+g_2^2)/2g^2\}(1/V)\ . \tag{53}$$

We shall calculate the principal susceptibilities for the proper screw-type structure of pitch 7/2 and compare them with those measured by Bizette[2] with a single crystal of MnO_2. As $4A_2/A_1=J_2/J_1=1.60$ for this pitch, we obtain $(\chi_{s//})_{T=0}/\chi_{s\perp}=0.94$ from (50), neglecting the anisotropy of the g-factor and $\boldsymbol{H}_n^{\mathrm{c.a}}$. However, the experimental value of $(\chi_a)_{T=0}/(\chi_c)_{T=0}$ is 0.79. Furthermore, χ_a is smaller than χ_c above the Néel temperature according to Bizette. These discrepencies may perhaps be explained by the anisotropy of the g-factor, crystalline anisotropy field and dipolar interaction.

It was already pointed out by Yosida[1] that an observed value of χ_a/χ_c larger than 1/2 at absolute zero can be qualitatively accounted by the B.E.Y.-structure and the anisotropic property of the susceptibility above the Néel temperature by dipolar interaction. However, the dipolar interaction does not seem to be suficient to account for the latter quantitatively.

If we assume $g_1/g_3\approx 0.84$ (putting $g_1=g_2$ for simplicity and neglecting D' in expression (51) for χ_c), we can account for the difference between 0.94 and 0.79 for $(\chi_{s//})_{T=0}/\chi_{s\perp}$. D is related with g-values by

$$D\sim\lambda(g_3-g_1)/2\ ,$$

where λ is the spin-orbit coupling constant and is $140\,\mathrm{cm}^{-1}$ 7) for the free Mn^{4+}. Since $g_3 > g_1$, D is positive, which means that the crystalline anisotropy energy, in addition to the dipolar energy, stabilizes the proper screw-type structure. This is consistent with our assumption made at the beginning. If we adopt 1.49 for the value of $\{(2g_1^2+g_3^2)/3\}^{1/2}$, as Bizette and Tsai5) found from their powder susceptibility measurments above the Néel temperature assuming $S=3/2$ for Mn^{4+}, we find $D \sim 9\,\mathrm{cm}^{-1}$. This is somewhat too large to be expected from data on other salts and may not be reliable, but the positive sign of D will be certain.

Finally, it may be noted that, when a strong field is applied in the c-plane for the proper screw-type structure, we expect flopping of the spin direction as in the usual antiferromagnet. Namely, above a certain critical field, spins as a whole will turn and become perpendicular to the applied field, in other words, the proper screw-type structure will change to a cycloidal structure. This critical field can easily be derived from (33) and (38), as

$$H_c^2=\{ND'-3\varphi_A(\theta)(N\mu/2)^2\}/(\chi_{s\perp}-\chi_{s//}) \, .$$

H_c is about 10^6 oe at absolute zero for the above value of D ($D'=3D/2$ for $S=3/2$).

§ 5. Spin Waves and Antiferromagnetic Resonance in the Proper Screw-type Structure

We start with the exchange Hamiltonian (1). First, we perform an orthogonal coordinate transformation for spin components which is different for different positions of the spin:

$$\begin{aligned} S_{ix}&=S_{i\xi}\cos(kz_i)-S_{i\eta}\sin(kz_i), & S_{iy}&=S_{i\xi}\sin(kz_i)+S_{i\eta}\cos(kz_i), \\ S_{i'x}&=-S_{i'\xi'}\cos(kz_{i'})+S_{i'\eta'}\sin(kz_{i'}), & S_{i'y}&=-S_{i'\xi'}\sin(kz_{i'})-S_{i'\eta'}\sin(kz_{i'}) \, . \end{aligned} \tag{54}$$

ξ and ξ' are the equilibrium directions of the spins at the corner sites and body-center sites, respectively. Quantizing the spins along ξ and ξ' and using Holstein-Primakoff's technique8), we can derive the following spin-wave Hamiltonian:

$$\begin{aligned} H_{\mathrm{sw}}=&-N8J_1S^2\cos\theta+N2J_2S^2\cos 2\theta+N4J_3S^2 \\ &+2J_1S\sum_{<ii'>1}[(a_i^*a_i+b_{i'}^*b_{i'})\cos\theta+(a_i^*b_{i'}+a_ib_{i'}^*) \\ &\times(1-\cos\theta)/2-(a_ib_{i'}+a_i^*b_{i'}^*)(1+\cos\theta)/2] \\ &+2J_2S[\sum_{<ij>2}\{-(a_i^*a_i+a_j^*a_j)\cos 2\theta+(a_i^*a_j+a_ia_j^*) \\ &\times(1+\cos 2\theta)/2-(a_ia_j+a_i^*a_j^*)(1-\cos 2\theta)/2\} \\ &+\sum_{<i'j'>2}\{-(b_{i'}^*b_{i'}+b_{j'}^*b_{j'})\cos 2\theta+(b_{i'}^*b_{j'}+b_{i'}b_{j'}^*) \\ &\times(1+\cos 2\theta)/2-(b_{i'}b_{j'}+b_{i'}^*b_{j'}^*)(1-\cos 2\theta)/2\}] \\ &+2J_3S[\sum_{<ij>3}\{-(a_i^*a_i+a_j^*a_j)+(a_ia_j^*+a_i^*a_j)\} \\ &+\sum_{<i'j'>3}\{-(b_{i'}^*b_{i'}+b_{j'}^*b_{j'})+(b_{i'}^*b_{j'}+b_{i'}b_{j'}^*)\}] \, , \end{aligned}$$

where a_i, $b_{i'}$, a_i^*, $b_{i'}^*$ are the annihilation and creation operators and are connected with the spin operators by the following equations:

$$S_{i\xi}=S-a_i^*a_i\,, \qquad S_{i\eta}+iS_{iz}=(2S)^{1/2}\{1-(a_i^*a_i/2S)\}^{1/2}a_i\approx(2S)^{1/2}a_i\,,$$

$$S_{i'\xi'}=S-b_{i'}^*b_{i'}\,, \qquad S_{i'\eta'}+iS_{i'z}\approx(2S)^{1/2}b_{i'}\,.$$

We perform Fourier transformations on a_i and $b_{i'}$:

$$a_{\boldsymbol{q}}=(2/N)^{1/2}\sum_i a_i\exp(i\boldsymbol{q}\cdot\boldsymbol{r}_i)\,, \qquad b_{\boldsymbol{q}}=(2/N)^{1/2}\sum_i b_{i'}\exp(i\boldsymbol{q}\cdot\boldsymbol{r}_{i'})\,,$$

where $\boldsymbol{q}$ runs over the $N/2$ wave vectors in the Brillouin zone, referred to the chemical unit cell. Furthermore, the following new operators, $A_{q\mathrm{I}}$ and $A_{q\mathrm{II}}$, will be introduced:

$$\begin{aligned} A_{q\mathrm{I}} &= (1/8)[\{(A^-/B^+)^{1/4}+(B^+/A^-)^{1/4}\}(a_q+b_q) \\ &\qquad +\{(A^-/B^+)^{1/4}-(B^+/A^-)^{1/4}\}(a_q{}^*+b_q{}^*)] , \\ A_{q\mathrm{II}} &= (1/8)[\{(A^+/B^-)^{1/4}+(B^-/A^+)^{1/4}\}(a_q-b_q) \\ &\qquad +\{(A^+/B^-)^{1/4}-(B^-/A^+)^{1/4}\}(a_q{}^*-b_q{}^*)] , \end{aligned} \tag{56}$$

where

$$\begin{aligned} A^\pm &= 16J_1S\cos\theta(1\pm\gamma_{q1})-4J_2S\cos 2\theta(1-\gamma_{q2})-8J_3S(1-\gamma_{q3}) , \\ B^\pm &= 16J_1S(\cos\theta\pm\gamma_{q1})-4J_2S(\cos 2\theta-\gamma_{q2})-8J_3S(1-\gamma_{q3}) , \end{aligned} \tag{57}$$

$$\begin{aligned} \gamma_{q1} &= \cos(q_xa/2)\cos(q_ya/2)\cos(q_zc/2) , \\ \gamma_{q2} &= \cos(q_zc), \qquad \gamma_{q3}=\{\cos(q_xa)+\cos(q_ya)\}/2 , \end{aligned} \tag{58}$$

(see (3)). Using these operators, we can derive the diagonalized spin wave Hamiltonian:

$$\begin{aligned} H_{\mathrm{sw}} &= -N8J_1S(S+1)\cos\theta+N2J_2S(S+1)\cos 2\theta \\ &\quad +N4J_3S(S+1)+\sum_q \hbar\omega_{q\mathrm{I}}(N_{q\mathrm{I}}+(1/2))+\sum_q \hbar\omega_{q\mathrm{II}}(N_{q\mathrm{II}}+(1/2)) , \end{aligned} \tag{59}$$

where

$$\begin{aligned} N_{q\mathrm{I}} &= A_{q\mathrm{I}}{}^*A_{q\mathrm{I}} , \qquad N_{q\mathrm{II}}=A_{q\mathrm{II}}{}^*A_{q\mathrm{II}} , \\ \hbar\omega_{q\mathrm{I}} &= \{A^-B^+\}^{1/2}, \qquad \hbar_{q\mathrm{II}}=\{A^+B^-\}^{1/2} . \end{aligned} \tag{60}$$

As can be seen from (57), (58) and (60), $\omega_{q\mathrm{I}}$ vanishes at $\boldsymbol{q}=0$ and $\omega_{q\mathrm{II}}$ vanishes at $\boldsymbol{q}=\pm\boldsymbol{k}$ (where $\boldsymbol{k}$ is the wave vector of the screw). In the neighborhood of these points, $\omega_{q\mathrm{I}}$ and $\omega_{q\mathrm{II}}$ can be expanded as

$$\begin{aligned} (\hbar\omega_{q\mathrm{I}})^2 &= 8S^2\{4J_1(1+\cos\theta)-J_2(1-\cos 2\theta)\}\{(J_1\cos\theta-J_3)(q_x{}^2+q_y{}^2)a^2 \\ &\qquad +(J_1\cos\theta-J_2\cos 2\theta)q_z{}^2c^2\} , \\ (\hbar\omega_{q\mathrm{II}})^2 &= 8S^2\{4J_1\cos\theta(1+\cos\theta)-J_2\cos 2\theta(1-\cos 2\theta)\} \\ &\qquad \times\{(J_1\cos\theta-J_3)(q_x{}^2+q_y{}^2)a^2+(J_1\cos\theta-J_2\cos 2\theta)(q_z\mp k)^2c^2\} . \end{aligned} \tag{61}$$

A sketch of the variation of these frequencies against q_z is shown in Fig. 9.

The modes of oscillation of the spins in branch I at $\boldsymbol{q}=0$ and branch II at $\boldsymbol{q}=\pm\boldsymbol{k}$, are illustrated by Fig. 10. They must be detectable by antiferromagnetic resonance at zero field, as the matrix elements of $\sum_i S_{iz}+\sum_{i'} S_{i'z}$ and $\sum_i S_{ix}+\sum_{i'} S_{i'x}$, for branch I and II respectively, do not vanish. The first mode can be excited when an oscillating field is applied along the the c-axis, and the second doubly degenerate modes by an oscillating field in the c-plane. Taking into account the crystalline anisotropy energy, (36), as well as the dipolar interaction, the frequency of the doubly degenerate modes for $\boldsymbol{q}=\pm\boldsymbol{k}$ is calculated to be as follows:

$$(\hbar\omega_{\mathrm{II}})^2=4S^2\{4J_1\cos\theta(1+\cos\theta)-J_2\cos 2\theta(1-\cos 2\theta)\}\{(D/2)-(3N/8)\varphi_A(\theta)g^2\mu_{\mathrm{B}}{}^2\} , \tag{62}$$

$$(\omega_{\mathrm{II}}/\gamma)^2=2D_1/\chi_{s//} ,$$

where $\chi_{s//}$ is given by (49), and D_1 is defined by the total anisotropy energy, E_a,

$$E_a=D_1\sin^2\Theta=\{N(D'/2)-(3/2)\varphi_A(\theta)(N\mu/2)^2\}\sin^2\Theta .$$

In the case of $\mathrm{MnO_2}$, the wavelength corresponding to the frequency of this mode is calculated to be about 200 μ, assuming $16J_1\sim 90\ \mathrm{cm}^{-1}$, $J_2/J_1\approx 1.60$ (see section 2) and $D\sim 90\ \mathrm{cm}^{-1}$ (see section 4), thus it comes into the far infra-red region.

The mode of $q=0$ belonging to branch I is such that the spins oscillate as illustrated in Fig. 10 (A); the spins make a small oscillation as a whole in the c-plane, as well as out-of plane motions. Hence, its frequency is expected to be proportional to the geometrical mean between $1/\chi_{s\perp}$ and the anisotropy constant in the c-plane. The anisotropy energy in the c-plane may be very small, as discussed in section 3 (B), so that frequency of this mode may also be very low.

§ 6. Neutron Diffraction Pattern

The scattering cross-section of neutrons from the screw-type structure is calculated from the standered formula[9)] as

$$d\sigma/d\Omega \propto f(\kappa)^2\{1+(\kappa_\perp/\kappa)^2\}(<S^\xi>/S)^2\{\Delta(\kappa-\boldsymbol{k}+\boldsymbol{K})+\Delta(\kappa+\boldsymbol{k}+\boldsymbol{K})\}\sin^2\{((K_1+K_2)a+K_3c)/2\}\,, \qquad (63)$$

where $d\sigma/d\Omega$ is the differential cross-section, $f(\kappa)$ the form factor, κ the scattering vector, $\kappa_\perp$ the component of κ perpendicular to the plane to which the spins are parallel, $\boldsymbol{K}$ the reciprocal lattice vector referred to the chemical unit cell, K_1, K_2, K_3 are its components, and

Table II.

Indices	$\kappa=4\pi\sin\theta_B/\lambda$ (A^{-1})	$1+(\kappa_z/\kappa)^2$	$f(\kappa)^2$ *	I/I_{005}

225	4.29	1.13	.04	.03

* The normalized form factor for Mn^{2+} (not for Mn^{4+}) by Shull et al. used. (C. G. Shull, W. A. Strauser, and E. O. Wollan: Phys. Rev. **83** (1951) 334).

$$\Delta(\boldsymbol{X})=(2/N)|\sum_i \exp(\mathrm{i}\boldsymbol{X}\cdot\boldsymbol{r}_i)|^2, \qquad |X_x|,\ |X_y|<\pi/a, \qquad |X_z|<\pi/c.$$

As easily seen from (63), the Bragg condition for the magnetic reflection is that κ is equal to $\boldsymbol{K}\pm\boldsymbol{k}$ and $\{(K_1+K_2)a+K_3c)\}/\pi$ is odd. Hence, if p is the reciprocal of the screw pitch in units of c, we expect reflections $1, 0, p$, $0, 0, 1\pm p$, $1, 1, 1\pm p$, $2, 0, 1\pm p$, etc..

Through private correspondences the writer has been informed by Prof. Erickson[6] of his experiment of neutron diffraction with a single crystal of polianite. He has observed five relations 102, 005, 115, 009, and 205, at 80°K, where his indices refer to the magnetic unit cell which is seven times large along the c-axis compared with the chemical unit cell. These reflections are just what we expect for the screw-type structure of pitch 7/2. The calculated relative intensities of the reflections expected for the proper 7/2-pitch-structure are shown in Table II.

§ 7. Concluding Remarks

By a Fourier method, possible arrangements of classical vector spins in rutile-type crystal were studied, and it was found that the screw-type structure is energetically favorable under certain conditions imposed on the values of J_2/J_1 and J_3/J_1. A similar method of "the normal mode" has been independently used by Gersch and Koehler[10] in their study of the spin arrangement in some simple lattices, but they assumed scalar spins which have only two discrete values, $+S$ and $-S$, so that they could not find a configuration in which the spin direction varies gradually in space.

The stability conditions for the screw-type structure with a pitch of 7/2, which seems to be realized in polianite, are that $J_2/J_1=1.60$ and $J_3/J_1<0.31$, as described in section 2. The range of J_2/J_1, in which the 7/2-pitch-structure is stabilized by the crystalline field anisotropy, is extremely narrow, as discussed in section 3. It would therefore be accidental that the pitch of the screw in polianite at 80°K be exactly 7/2; to account for the neutron diffraction data, the pitch can be approximately 7/2. The pitch can vary in the neighborhood of 7/2 if J_2/J_1 varies due, for instance, to thermal expansion or an applied stress. It might be interesting to perform a neutron diffraction experiment at lower temperatures or under stress to detect such a variation in pitch.

If $J_3/J_1>0.31$, the 7/2-pitch screw-type structure cannot be realized, and the theoretical value of Θ_p/T_N cannot exceed 2.8. If we determine J_3/J_1 using Eq. (24) from the observed ratio of Θ_p (316°K) to T_N (84°K), that is, $\Theta_p/T_N=3.8$, we obtain $J_3/J_1\sim 0.56$. This discrepancy may partly be due to a crude approximation of the molecular field theory.

If θ is put equal to zero in (57), (60) and (61), we have the frequencies of the spin waves in the $\mathrm{MnF_2}$-type structure. According to these frequency formulae, some modes with small $\boldsymbol{q}$ have imaginary frequencies when J_2 is greater than J_1, as clearly seen from (61). This situation has been pointed out by Nagai and Nakamura[11]. However, the $\mathrm{MnF_2}$-type structure is less stable than the screw-type structure for $J_2>J_1$. Therefore we see that, as soon as the spin superstructure becomes energetically unstable, some of the spin wave excitations become also unstable. This statement is also true when the screw-type structure becomes less stable than the B.E.Y.-structure ($2J_2J_3>J_1^2$, $J_2/J_1>1$), in which case the frequencies of modes with $\boldsymbol{q}$ in the neighborhood of $q_x, q_y=\pm\pi/a$, $q_z=\pm\pi/c$ become imaginary. It can be shown that if only exchange energy is considered, the stability boundaries in the J_2/J_1, J_3/J_1-plane derivable from the instability of the spin waves are the same with those which can be derived by comparing the energy values of the various spin superstructures. When the anisotropy energy is also taken into consideration, this becomes no longer true; for example, in the region where the $\mathrm{MnF_2}$-type structure has just become unstable, all the spin waves of the same structure remain still stable.

The writer would like to express his deep thanks to Professor T. Nagamiya of Osaka University for suggesting this study as well as his continual advice in the course of the work and to Dr. J. Kanamori of Osaka University and Mr. Y. Kitano of University of Osaka Prefecture for their helpful discussions.

He is also indebted to Professor R. A. Erickson of Ohio State University for kindly supplying his experimental data prior to publication.

Oscillations in Plasma II

By Shoji KOJIMA, Kiyoe KATO, Shigeo HAGIWARA
and Ri'ichi MATSUZAKI

Tokyo University of Education, Otsuka, Tokyo

(Received March 2, 1959)

As previously reported, two or three plasma-electron oscillations of slightly different frequencies are simultaneously generated in a hot cathode discharge. The filled gas is mercury vapour at pressures of order of 1 micron. These oscillations can be observed by a Yagi antenna set apart from the discharge tube as well as by a probe in it. In the discharges the primary electrons form convergent and divergent beams. The oscillation of the highest frequency is generated by the convergent beam in the central part of the tube and this is that observed by many authors. The oscillation of the lowest frequency seems to be generated near the wall of tube by the divergent beam. Another oscillation having a middle frequency is often observed. This is generated at the periphery of the convergent beam.

§ 1. Introduction

In a previous paper[1], hereafter refered to as **I**, it was reported that a discharge at low pressure generates simultaneously two or three plasma oscillations of different frequencies. The frequency of plasma-electrons oscillation, f_p, is related to the concentration of electrons, N, by the well known expression

$$f_p=\sqrt{Ne^2/\pi m}\,, \tag{1}$$

where e is the charge and m the mass of electron. Therefore the oscillation of unique frequency will be expected. If the concentration of electrons is not uniform, frequencies of oscillations will be distributed continuously. The observation, however, indicated that there are discrete oscillations having different frequencies. In the present work the origin of the oscillations has been studied.

An experiment described in **I** showed that the plasma oscillation could be observed outside a discharge tube by a small antenna. Since the plasma oscillation is a longitudinal wave, it will give rise to no electromagnetic wave. In the preliminary experiment the antenna received the oscillation by electrostatic interaction because of small range of investigated distance whose maximum was less than a wave length. In the present work the investigation has been extended to a region where the induction field would vanish.

§ 2. Procedure of Experiments

In the previous work three types of discharge tube were used. The types A and C were similar to that described by Merrill and Webb[2)] and to that by Looney and Brown[3)] respectively. The type B was same as the type A except having no probe. In the present work somewhat modified tubes are used. However, the types are essentially same as before. All the discharge tubes are hot cathode tubes filled with mercury vapour at pressures of the order of 10^{-3} mm Hg.

The oscillations whose frequencies are in a region between 500 Mc and 1000 Mc are detected by a super-regenerative detector through a probe inserted in the discharge tube or through an antenna set outside the tube. The frequency of the detector can be controlled by changing the plungers of coaxial cavities as described in **I**. In most of the experiments, however, the detector is used at a fixed frequency and the frequency of oscillation is adjusted to it by changing a discharge current.

By means of superimposing an a.c. current of a suitable amplitude on a d.c. discharge current, generation of the oscillation whose frequency agrees with that of detector is visualized with an oscilloscope. A block diagram of this experimental method is shown in Fig. 1. The oscilloscope display which was obtained for the tube described below (§ 5) is reproduced in Fig. 2.

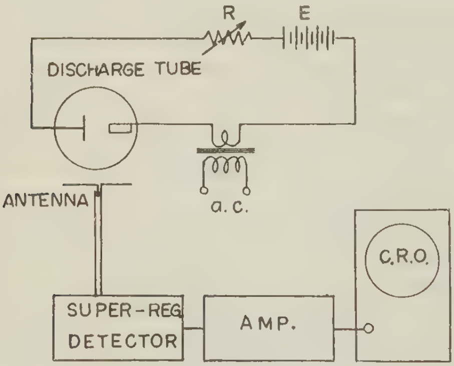

Fig. 1. Block diagram illustrating the method of displaying plasma oscillations on a cathode-ray oscilloscope.

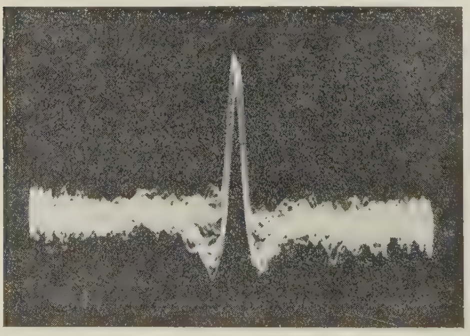

Fig. 2. A typical oscillogram. The time base of the oscilloscope runs in synchronism with the discharge current. The frequency of the detector is 833 Mc. The d.c. discharge current is 21 mA, on which a.c. current of 6 mA is superimposed.

A Yagi antenna which consists of five guiding elements and one reflector is used for receiving. The construction is shown in Fig. 3.

§ 3. Oscillations in a Tube having Two Cathodes

In **I** it was shown that the auxiliary electron beam in the discharge tube of type C was not essential to generate the oscillations. The discharge tubes used here were same as the type C in **I**, but they had no auxiliary electron gun. A diagram of the tube is shown in Fig. 4. As previous experiments a relation between the frequency and the discharge current was studied. The obtained plots of frequency of oscillation *vs*. the discharge current are shown in Fig. 5. In this case too, three groups of oscillations, *a*, *b* and *c* groups were observed. The oscillations of the *c* group were very weak compared with those of other groups. On this tube an effect of pair of cathodes could be studied by changing the currents through the each cathode independently. A circuit diagram of the experiments is shown in Fig. 6. In order to generate the oscillation of a fixed frequency there are some relations between the currents I_1 and I_2. Such relations were searched. The result is reproduced in Fig. 7. The points P_1 and P_2 in the figure correspond to the points indicated in Fig. 6 where the two cathodes were connected together. Even if one of the cathode currents is decreased, I_1 form P_1 to P_1' for example, the other cathode current I_2 is almost constant. This suggests that the origin of the oscillations of group *a* is related to the cathode C_2. Similary the origin of the oscillations of group *b* is related to the cathode C_1. It is interesting that both oscillations originated from the pair of cathodes are observed by a probe at the center of discharge tube. If the cathodes were made identically, the groups *a* and *b* would coincide with each other. On the group *c* a discussion will be given in the next section.

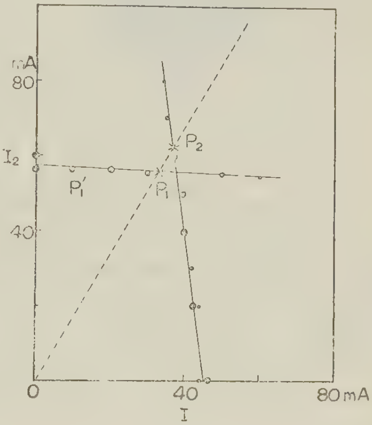

Fig. 7. Plots showing relation of two currents which generate the oscillation of 917 Mc. The intensity of oscillation is illustrated by the size of point.

§ 4. Detailed Characters of Oscillations

In order to determine the concentration of electrons a discharge tube was equiped with a pair of plane probes. Its diagram is shown in Fig. 8. In the discharge tube the primary electrons form two beams. One is converging and the other diverging*. The central region α where the convergent electron beam is present is brighter than the neighbouring plasma. The structure of discharge is also shown schematically in Fig. 8. In addition to the plane probes this tube has a pair of needle probes which are movable across the beam of electrons. From one of these probes the oscillations were picked up. A relation between the frequency of oscillation and the discharge current was studied. The result with a probe at the center of region α is shown in Fig. 9 with full circles. The plots form into two groups as the case shown in Fig. 4 in **I**. When the pick-up probe was set at the periphery of region α the oscillations mentioned above became somewhat weak and newly the third group appeared. These oscillations are shown in Fig. 9 with open circles. The results shown in Fig. 9 indicate that two or three oscillations with different frequencies can be generated simultaneously at a fixed discharge current.

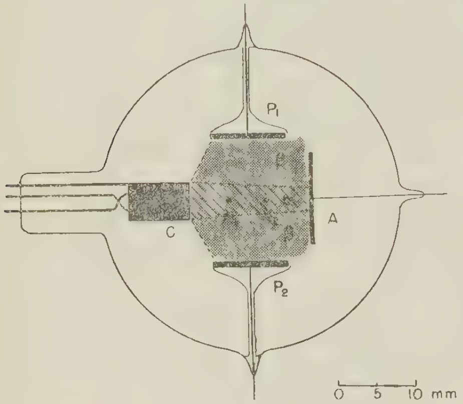

Fig. 8. Discharge tube having plane probes. A: Anode, C: Cathode, P_1 and P_2: Pair of plane probes, N_1 and N_2: Pair of needle probes, α: Bright region, β: Faint region.

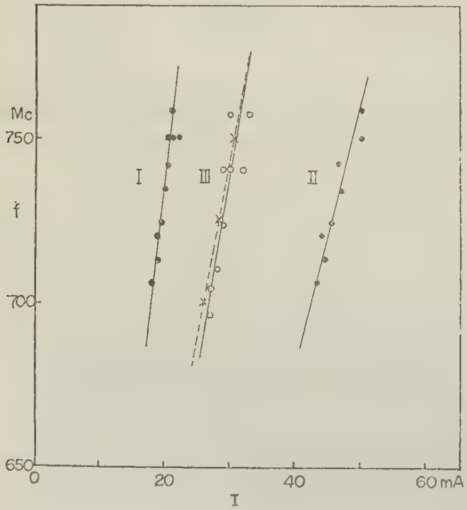

Fig. 9. Plots of frequencies of oscillations *vs.* discharge currents. Closed circles indicate the results with a probe at the center and open circles the results at the periphery of region α. Crosses represent the results calculated from measured densities.

The simultaneous generation of the oscillations was verified more directly with an experiment where two super-regenerative detectors working with different frequencies were used.

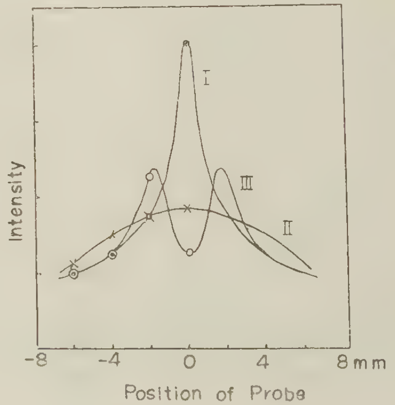

Fig. 10. Intensity as a function of position of the probe. The distance is measured from the center to the wall. I, II and III indicate the groups of oscillation shown in Fig. 9.

The concentrations of electrons were determined from measurements with the plane probes. An ion-saturation current of the probe, I_s, is expressed by Boyd[3] and Shultz-Brown[4] as follows:

$$I_s=0.61eN\sqrt{kT_e/M}\,S \tag{2}$$

where k is Boltzmann constant, T_e the electron temperature, M the mass of ion and S the area of the plane probe**. From the measurement of I_s the electron concentration N was determined by using Eq. (2) and then the frequency of the plasma oscillation was calculated by the aid of Eq. (1). The calculated frequencies are shown in Fig. 9 by crosses. The straight line through the calculated points agrees with the line representing the third group of the oscillations. Since the measured concentrations give certain average values, the agreement should not be interpreted strictly. It means only that all the observed oscillations are reasonable to attribute to the plasma electron oscillation.

---

* The convergent and divergent beams start from near the cathode. In the present case the meniscus which is described by Allen et al. (British J. Appl. Phys. **6** (1955) 320) was not seen.

** In I, the usual expression $I_s=\frac{1}{4}eN\sqrt{8kT_p/\pi M}\,S$ was used, where T_p is the ion temperature. In the present case at which the pressure is low enough the expression (2) seems to be more adequate.

When the pick-up probe was moved from the center to the wall, the intensity of the oscillations of each group varied in different manner as shown in Fig. 10. Since the oscillations belonging to the third group have a maximum intensity at the boundary between the regions α and β, they seem to be generated at this boundary. The oscillations of the first group, which are generated strongly at the center of plasma, seem to be the main plasma oscillations that are reported by many authors[2),3)]. The oscillations of the second group are observed in a very wide region which extends to the wall. The convergent and divergent beams presumably play roles analogous to those from two cathodes mentioned in the last section. Then, the oscillation of the second group seems to be a plasma oscillation which is generated by the divergent electron beam.

The frequencies of oscillations of the first and the second groups may be determined from the electron concentration in the regions α and β respectively. The Eq. (1) yields the following frequencies:

$$f_1=\sqrt{e^2N_\alpha/\pi m} \text{ and } f_2=\sqrt{e^2N_\beta/\pi m}\,, \qquad (3)$$

where N_α and N_β are the concentrations in the regions α and β. By using needle double probes the concentrations were measured. The obtained values were not accurate in absolute scale because of the effect of sheath around the probes, but useful for comparison between them. The results supported above relations.

In view of the location of oscillation the third group may attribute to the sheath resonance which occurs at the boundary between the regions α and β. If a discontinuity in concentration is assumed, the frequency of the resonance is expressed by

$$f_3=\sqrt{f_1^2-f_2^2}\,. \qquad (4)$$

The results shown in Fig. 9 give the ratio $f_1 : f_2 : f_3$ to be about $\sqrt{54} : \sqrt{23} : \sqrt{35}$ which satisfy the relation expressed by Eq. (4) approximately.

The groups a and b in the discharge tube having two cathodes which are mentioned in the last section correspond to the first group in the present case. The group c to which belonging oscillation is very weak, corresponds probably to the second group in the present case.

§ 5. Radiation having the Frequency of Plasma Oscillation

The oscillations of the three groups mentioned in the last section were also observed outside the discharge tube by a Yagi antenna. In this case the probe is unnecessary. Sometimes, however, the probe affected the oscillations. When the probe was inserted at the periphery of region α, the oscillations of the third group became strong. It may be considered that the probe works as a sending antenna. It was tested with a discharge tube whose probe was made from non-conducting material. The effect of the probe, however, was same as the case of conducting probe. So that the action of probe is to disturb the plasma and to strengthen the oscillation.

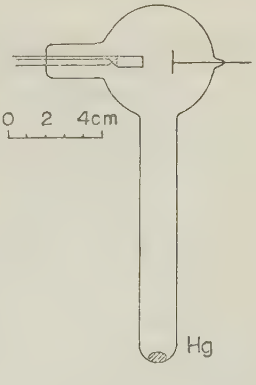

Fig. 11 Discharge tube having no probe.

Radiation was further studied with a tube having no probe. A diagram of the used tube is shown in Fig. 11. Since the Yagi antenna had large gain, the oscillation could be detected at a distance of 300 cm from the tube. The decrease of the observed intensity was less than that given by the inverse square law. As shown in Fig. 12, the field strength was almost inversely proportional to the distance. This suggests that the oscillation propagates as an electromagnetic radiation. The intensity of radiation depended on its direction. The curve shown in the figure was a result when the direction of antenna was set at perpendicular to the axis of the discharge tube and the plane of the antenna was parallel to the axis.

The angular dependency of the radiation was measured by changing the direction of antenna. The results in two cases where the elements of Yagi antenna are parallel and perpendicular to the axis of discharge tube are shown in Fig. 13. On the direction perpendicular to the axis of tube the intensity of radiation was very different in the two cases. Such polarization effect was studied by rotating the antenna around its axis. The results of measurements are shown in Fig. 14.

The angular distribution and polarization are not same for three groups of oscillations. The results mentioned above are refered to the first group of the oscillations. The oscillations of the second and third groups did not show remarkable polarization as those of the first group*.

Since the super-regenerative detector emits oscillations from itself, it may receive change of impedance of distant plasma. In order to prove the presence of radiation a detector of pure absorption type is preferable. Fortunately, when the a.c. modulation of the discharge current was applied, a method of crystal detector and amplifier was usable. The radiation from the oscillation of the first group could be verified by this method.

§ 6. Conclusion

In **I**, many plasma oscillations having slight different frequencies were detected. In the present work details of the oscillations are studied. Generally, a discharge tube yields two plasma oscillations. One is generated in the central region of discharge tube by a convergent electron beam from the cathode. The other is generated in the region near the wall by a divergent electron beam from the cathode. The frequency of the latter is lower than that of the former. When the main electron beam has a clear boundary, another oscillation is generated.

---

* The third group of oscillations was scarcely observed for the tube having no probe. Only when the convergent beam had sharp periphery, it appeared.

These plasma oscillations can be radiated as electromagnetic waves.

This work was financed by the Scientific Research Fund of the Ministry of Education.

Experimental Studies on the Hypersonic Flow past Plane, Convex and Concave Wedges

By KIM, Chul-Soo*

Department of Physics, Faculty of Science,
University of Tokyo

(Received January 30, 1959)

In this paper, the phenomena of viscous-inviscid interaction effects at $M_\infty=6.2$ over the front part of bodies have been investigated. The models tested are a flat plate and wedges having a plane, a convex or a concave surface, respectively. A uniform flow of $R_\infty=2.0\times10^5$ per cm was established using a divergent shock tube. The measurements of the flow field were made by optical methods (interferometer and schlieren photograph), and in order to supplement the data the X-ray technique was employed near the leading edge of the model.

The results are as follows. (1) For a flat plate: i) the pressure distribution on the sharp-nosed plate is about 5 per cent higher than Nagakura-Naruse's theoretical values; ii) the boundary layer thickness agrees almost perfectly with Naruse's theoretical values; iii) the shock wave location is in good agreement with the empirical formulae of Kendall and of Bogdonoff and Hammitt. (2) For wedges: i) near the leading edge, the boundary layer growth on a concave wedge is more rapid than that either on a plane or a convex wedge; ii) except in the region close to the leading edge, the influence of leading edge bluntness on boundary layer growth is significant in the order of convex wedge, plane wedge and concave wedge; iii) except in the region very close to the leading edge, the pressure distributions at the front parts of the plane and convex wedges are in fairly good agreement with the values predicted by inviscid theories (characteristic method, tangent-wedge approximation, Newtonian-plus-centrifugal-force approximation and hypersonic small disturbance theory), but considerable discrepancies are found at the rear parts; iv) for the concave wedge, agreement is rather better at the rear part of the body than at its front part.

§ 1. Introduction

When the flight Mach number greatly exceeds unity, linearized theory breaks down for a very slender body because non-linearity becomes an essential feature of the flow. This is due to the fact that the kinetic energy of the hypersonic flow is much larger than that of the subsonic or the supersonic flow. Therefore, the exact equations are in general very difficult to be handled even when the viscosity and the real gas effects associated with the hypersonic flow are neglected. Approximate solutions were obtained by Van Dyke1) and Cole2) on the assumption that the entire flow field involves only small disturbances. But, for slender or thin bodies, the shock wave lies relatively close to the surface of the body and the so-called viscous-inviscid interaction may be generally more significant than that for blunt bodies. When this interaction is strong3)–4) or weak6)–9), many theoretical studies have been performed assuming that the flow between the shock wave and the body surface consists of the boundary layer and the inviscid external flow. Quite recently, Nagakura and Naruse10) obtained an excellent approximate solution which covers the whole region including strong and weak interaction regions, in the case of the flow over a flat plate.

---

* Present address: Department of Physics, National Seoul University, Tongsung-Dong, Seoul, Korea.

Theoretical studies are mostly limited to the sharp-nosed simple bodies, so far as the present author is aware, but it is, in practice, impossible to make such a sharp nose. Thus, in particular, the interest of an experimental study seems to be in the problem of the effect of leading edge bluntness on the hypersonic flow field over the body. For the hypersonic flow over a flat plate, several experiments were carried out by Bogdonoff and Hammitt11), by Kendall12) and by Bertram13). In these experiments, blunt leading edges of various thickness were obtained by cutting the leading edge of the wedge normal to the plane surface. They emphasized that the Reynolds number R_t based on the thickness of the leading edge behaved as a very important parameter in the study of viscous-inviscid interaction of the hypersonic flow.

The main aim of the present experiment is to study how the small disturbances propagate in the hypersonic flow. For this purpose, three groups of models are used: plane wedge, convex wedge and concave wedge (see Fig. 2). The choice of these models is physically significant in the following respects. For the plane wedge and the convex wedge, disturbances due to the boundary layer add a negative pressure gradient to the pressure for the inviscid flow past a plane wedge, whereas for the concave wedge it adds a positive pressure gradient. Therefore, the former has a tendency to make the boundary layer thin and the latter has an opposite tendency. What has prompted this experiment is, in short, the expectation that there will be different modes of the viscous-inviscid

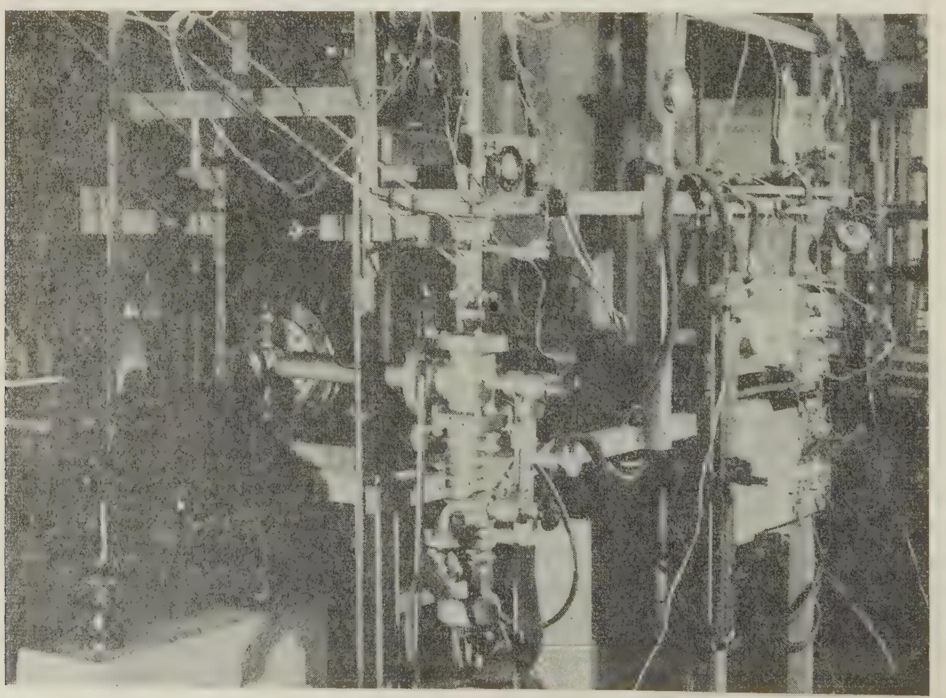

Fig. 1. Photograph of apparatus.

interaction in the accelerating (for plane wedge and convex wedge) and the decelerating (for concave wedge) hypersonic flow. For the detailed study of the problem, the effects of leading edge bluntness were also investigated. All the experiments were carried out at the free stream Mach number of $M_\infty=6.2$, utilizing the shock tube. The Reynolds number of the uniform flow was $R_\infty=2.0\times10^5$ per cm, and the duration of the uniform flow was about 1 milli-second. The measurements of the flow field were made by optical methods (interferometer and schlieren photograph), and near the leading edge of the model, the X-ray technique was employed for determining the air density. Experimental results will be compared with Van Dyke's hypersonic small disturbance theory[1] which assumes ideal gas flow. Experiments for the flat plate will also be compared with those of Bogdonoff and Hammitt[11] and of Kendall[12].

§ 2. Apparatus

Full explanation of the divergent shock tube, optical apparatus and X-ray tube has already been made by Professor F. Tamaki and the present author in Refs. 14, 15 and 16. Accordingly, only a photograph of the essential parts of the apparatus will be presented in Fig. 1. Divergent nozzle used in the present experiments has a throat section of 5 mm × 58 mm and a test section of 230 mm × 58 mm. Models tested are shown in Fig. 2. For the sake of convenience, each model is called $W_{P2.5}$, W_{E1}, W_{C0}, etc. First subscripts P, E and C denote plane, convex (expansion) and concave wedge, respectively, and second subscripts 0, 1 and 2.5 represent the cutting distance L from the sharp leading edge in millimeter scale.

In order to make the comparison of the experimental results with Van Dyke's hypersonic small disturbance theory, the leading edge of W_{P0}, W_{E0} and W_{C0} are sharpened as sharp as possible, and they are examined several times throughout the experiments to keep R_t $(=\rho_\infty u_\infty t/\mu_\infty$, t being the thickness of the leading edge) below 200. For these

models, the hypersonic similarity parameter defined by $k = M_\infty \tau$ is of the order of unity, where M_∞ is the Mach number of the uniform flow and τ expresses either the thickness of the model or the inclination of the shock wave emanating from the leading edge of the model. For the study of the effects of the leading edge bluntness on the propagation of small disturbance in the hypersonic flow, W_{P1}, $W_{P2.5}$, W_{E1} and W_{C1} are made by cutting the leading edges of W_{P0}, W_{E0} and W_{C0} normal to their flat surfaces. All the models are made of stainless steel. The span is 58 mm and the length of the uncut models is 80 mm.

§ 3. Results and Discussions

3.1) *Uniform flow*

If one uses a continuously running wind tunnel, the aerodynamic heating due to the hypersonic flow is much more significant at the front part of the body than at its rear part. Therefore, in order to keep the uniform temperature over the entire surface of the body, the surface must be partly heated or cooled. Thus, it is rather difficult to obtain the uniform surface temperature in actual experiments, although this condition makes theoretical analysis easy. Since a shock tube runs in a short time interval (about 1 millisecond) this difficulty dissolves itself. The shock tube was operated under the initial condition of $p_0/p_1 = 10$ atms/2 mm Hg and $T_0/T_1 = 325°\text{K}/295°\text{K}$, where p_0, T_0 and p_1, T_1 denote the initial pressures and temperatures in the high and the low pressure chamber respectively. The Mach number M_∞ of the free stream at the test section was 6.2. This value was determined by observing Mach waves generated by small disturbing elements attached to the divergent walls of the shock tube. Temperature of the free stream was estimated to be about 37°K, and Reynolds number R_∞ of the free stream was 2.0×10^5 per cm.

3.2) *X-ray technique: radiographic method*

Except Bogdonoff-Hammitt's experiment, most of the measurements of the hypersonic flow past a flat plate were carried out with static pressure holes and Pitot tubes. However, the probe methods encounter an unavoidable difficulty in bringing the probe very close to the leading edge without disturbing the surrounding flow. In our experiments, measurements of the flow field were made mainly by optical methods. Even with these methods the accuracies of the measurements were not satisfactory near the leading edge of the model, because of the indistinctness of the interferogram and the schlieren photograph, and of the decrease in accuracy due to the refraction of light rays near the leading edge. Accordingly, the soft X-ray radiography described in the previous report (Ref. 16) was used in order to supplement the density data near the leading edge.

The same flash X-ray tube as in Ref. 16 was used in the present experiments. The anode voltage was 1800 volts, and the potential for the triggering discharge was 2400 volts. In order to sensitize the X-ray film it was exposed to three flashes of X-rays at the initial condition of the low pressure chamber of the shock tube ($p_1 = 2$ mm Hg, $T_1 = 295°\text{K}$) before experiments. Then it was exposed to three flashes by repeating three times the operation of the shock tube.

Fig. 3 shows the typical radiograph of the flow near the leading edge of the model W_{P1} whose leading edge thickness is about 10 microns. As seen in this photograph, the shock wave coincides with the outer edge of the boundary layer in the immediate neighbourhood of the leading edge. Such a distinct flow pattern cannot be observed by ordinary optical methods, as shown in Fig. 4. Quantitative results obtained from these radiographs will be presented in the following subsections.

3.3) *Boundary layer*

Interferograms and schlieren photographs of the flow past a plane wedge, a convex wedge and a concave wedge are shown in Figs. 4a, 4b and 4c, respectively.

Let us consider first the boundary layer growth on the surface of the flat plate. As seen from these photographs, the region between the plate surface and the shock wave except in the neighbourhood of the leading edge is distinctly separated into the boundary layer and the isentropic external flow, when the Reynolds number R_t based on the leading edge thickness t is 200 approximately. Boundary layer having finite thickness already exists at the leading edge of the body. Thus, in its immediate neighbourhood, the outer edge of the boundary layer coincides with the shock wave. Because of this abrupt growth of the boundary layer even with such a small value of R_t, the shock wave is slightly curved near the leading edge. In this region, the flow field between the shock wave and the boundary layer is not isopicnal laterally, i.e. in the direction normal to the surface of the flat plate. This phenomenon seems to be due not to the bluntness of the leading edge but to the viscous effect (see 3.5)).

Fig. 4a shows that the flow region affected by the leading edge increases with increasing R_t. At R_t of approximately 6400, the bound-

ary layer cannot be distinguished from external flow with an interferogram. Here, the measurements of the boundary layer thickness δ were made by tracing the sharp bents of the interferometer fringes. Boundary layer thickness along the flat plate at various R_t is shown in Fig. 5. Utilizing the helium tunnel at Princeton, Bogdonoff and Hammitt carried out similar experiments for the flat plate of various leading edge thicknesses t with an interferometer. The influence of bluntness upon the boundary layer growth in their experiments appears much stronger than that of the present experiments. Although this may be mainly due to the larger values of M_∞ in their experiments, it may be partly due to the use of helium as a working gas.

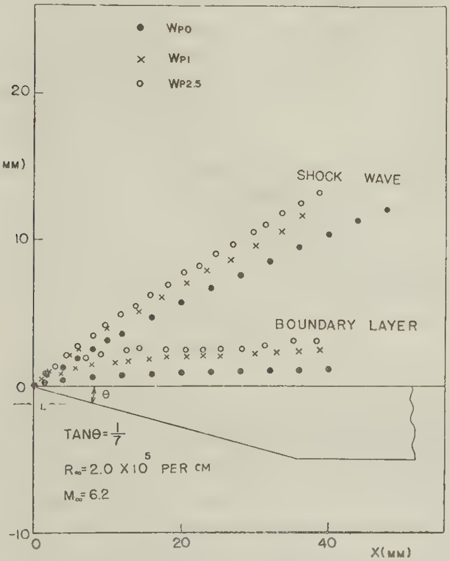

Fig. 5. Shock wave and boundary layer for the flat surface.

In Fig. 6, the boundary layer thickness δ on the flat plate for $R_t=200$ is given by a chain line, and the theoretical values δ_{N-N} calculated by the following formula of Nagakura and Naruse are given by a dotted line:

$$\delta^2_{N-N}\approx\delta^{*2}=K\left(\frac{p}{p_\infty}\right)^{-\alpha}\int_{x_J}^{x}\left(\frac{p}{p_\infty}\right)^{\alpha-1}dx+\text{const}\,,$$

where K and α are constants. Difference between the thickness δ and the displacement thickness δ^* is neglected in the present comparison, since it is of the order of M_∞^{-2} in the hypersonic region. The values of p/p_∞, the ratio of static pressure on the plate to that of the free stream, are determined from interferograms and radiographs (see 3.5)). These two curves show similar shapes in boundary layer growth along the x-axis, the ratio δ/δ_{N-N} being about 1.3 throughout the entire surface. It was revealed through a private communication from H. Naruse to the author that he obtained a more precise theoretical formula for the boundary layer thickness without neglecting the order of M_∞^{-2}. When his refined formula is applied, our experimental values are found to agree almost perfectly with the theoretical ones (see double-dotted chain line in Fig. 6).

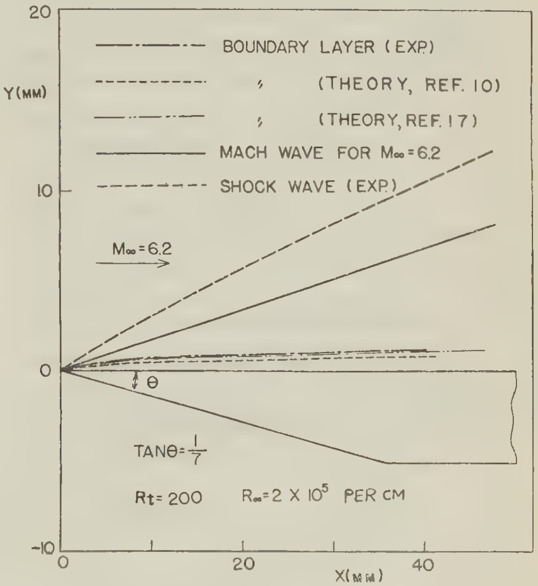

Fig. 6. Boundary layer growth along the flat surface.

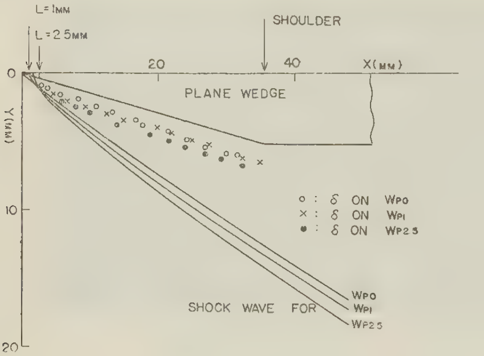
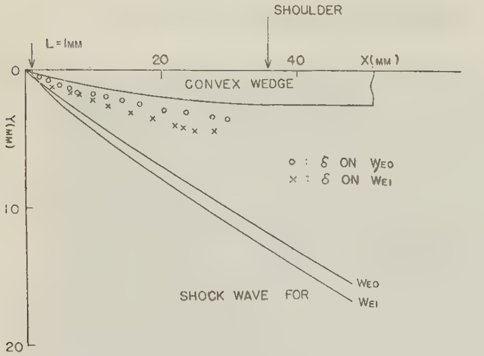
The shapes of the boundary layer on a plane wedge, a convex wedge and a concave wedge are shown in Figs. 7a, 7b and 7c, respectively. Compared with the boundary layer shapes on W_{P0} and W_{E0}, a boundary layer of a different shape grows on W_{C0}: 1) boundary layers of parabolic shapes grow on W_{P0} and W_{E0}, while in the case of W_{C0}, the boundary layer growth is more rapid near the leading edge and is more gradual in the rear part; 2) the boundary layer grown on the front part of W_{C0} has the effect to fill up the cave of the surface; 3) in the neighbourhood of the shoulder, the boundary layer thicknesses on W_{P0}, W_{E0} and W_{C0} are nearly the same. These phenomena seem to depend on the effects of Reynolds number, stability of boundary layer, leading edge bluntness and others. However, it seems to the author that: 1) the fundamental feature of the leading edge effects for plane, convex and concave wedges is the same as for the flat plate; 2) except in the region close to the leading edge, the influence of R_t on boundary layer growth is significant in the order: convex wedge, plane wedge and concave wedge.

3.4) *Shapes of shock waves*

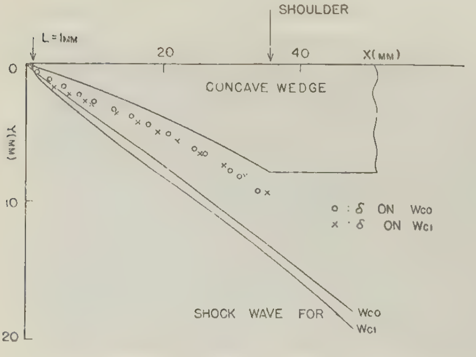
Since the shock wave location is closely related to the effective shape of the body (the geometrical shape of the body plus the boundary layer displacement thickness), it is as important as the boundary layer on body surface for the study of viscous-inviscid interaction. Here, the author considers only the front portion of the shock wave which is not influenced by the shoulder of the model.



(a) plane wedge.



(b) convex wedge.



(c) concave wedge.

Fig. 7. Shock wave and boundary larger for wedge surfaces.

Fig. 6 and Fig. 8 show the shapes of shock wave originating from the flat plate and from W_{P0}, W_{E0} and W_{C0}. In Fig. 8, the dotted lines show the shapes of theoretical shock waves obtained by characteristic method[17], neglecting the reflection at the shock wave of the waves generated from the body surface (compression and expansion waves). The chain lines in the same figure show those calculated according to the hypersonic small disturbance theory[1], considering only the first order of the body curvature. In the present experiments, optical methods (interferometer and schlieren method) are mainly employed for determining the shapes of the shock waves, but near the leading edge where they become not clear, X-ray technique is employed. The steepness of the experimental shock location compared with the above theoretical curves is, of course, due to the growth of the boundary layer. It is interesting, however, that shock waves for W_{E0} and W_{C0} are very close to that for W_{P0}, though the geometrical shapes of these bodies are fairly different. This fact seems to show the importance of the leading edge effect in the hypersonic flow.

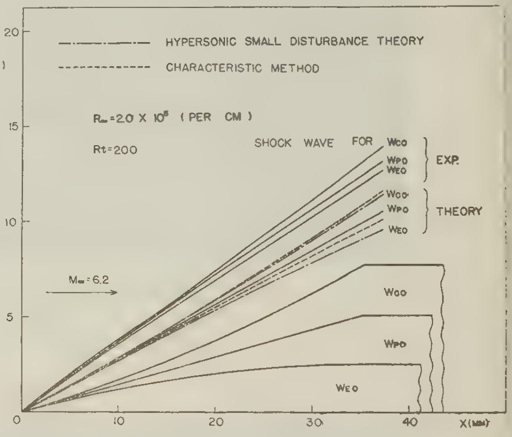


Fig. 8. Shock shapes.

As the thickness of the leading edge increases, the shapes of the shock waves become increasingly fat. The corresponding shock shapes for a flat plate, a plane wedge, a convex wedge and a concave wedge are shown in Figs. 5, 7a, 7b and 7c, respectively. The characters of the shock shapes are listed in the following Table.

	Flat plate	Plane wedge	Convex wedge	Concave wedge
$L=0$ mm	×	×	×	○
$L=1$ mm	×	○	×	○
$L=2.5$ mm	×	○		

○: with inflection point
×: without inflection point

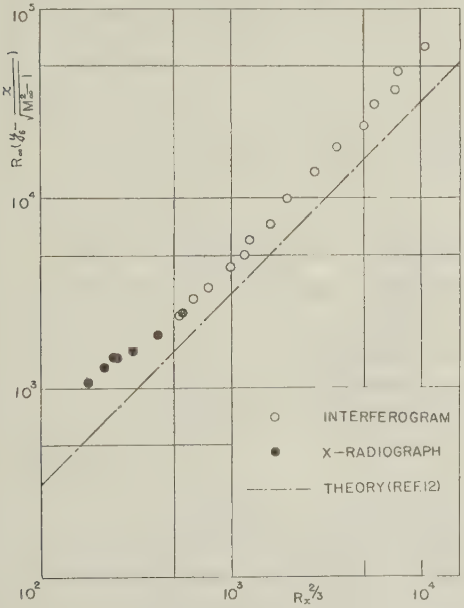

Fig. 9. Relation between $R_x^{2/3}$ and $R_\infty(y_s - x/\sqrt{M_\infty^2-1})$.

The appearance of an inflexion point in the shock wave for W_{C0} even when the leading edge is the sharpest in our experiments, i.e. as sharp as $R_t=200$, seems to be due to the peculiar boundary layer growth on the front part of the body (see 3.3)).

For the comparison with Kendall's theoretical shock shapes[12] for a flat plate, the experimental values shown in Fig. 6 are replotted in Fig. 9, representing the relation between $R_x^{2/3}$ and $(y_s - x/\sqrt{M_\infty^2-1})$, where y_s is the ordinate of the shock wave.

It should be remarked here that the shock location in Fig. 6 is also represented as $R_{ys} \sim R_x^{0.91}$, where R_{ys} is the Reynolds number based on y_s. It is shown in Ref. 12 that the shock locations for a flat plate with $R_t=119$ $(M_\infty=14)$[11], and with $R_t \doteqdot 100$ $(M_\infty=5.8)$[12] may be expressed as $R_{ys} \sim R_x^{0.88}$ and $R_{ys} \sim R_x^{0.90}$, respectively. The agreement of the shock shapes in the present experiments with those in Refs. 11 and 12 is very good.

3.5) *Pressure distribution*

The distribution of the non-dimensional pressure p/p_∞ over a flat plate for various R_t is plotted against x in Fig. 10, and against the hypersonic interaction parameter $s=(c\mu_\infty/\rho_\infty u_\infty)^{1/2} M_\infty^3 x^{-1/2}$ in Fig. 11, where c is a constant related to temperature ratio T/T_∞ and viscosity ratio μ/μ_∞, ρ is the density, and ∞ denotes the free-stream condition. In order to determine the pressure from the density measured by the interferometry, it is necessary to assume the entropy change across the shock wave. For the cases of $L=0$ and 1 mm, the entropy change was estimated from the mean value of the inclinations of the shock wave at the leading edge and the shoulder, while for the case of $L=2.5$ mm, it was estimated from the normal shock relation.

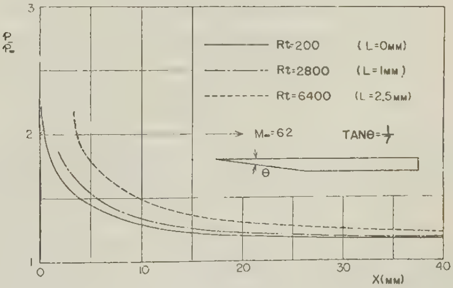

Fig. 10. Pressure distribution on flat plate (leading edge effect).

The pressure rise at the leading edge is evident even in the case of sharp-nosed flat plate ($L=0$ mm), for which inviscid theory predicts no pressure rise (see Fig. 10). This pressure rise at the leading edge may be caused either by the bluntness of the edge or by the viscous effects. Therefore, it seems to be desirable to determine, if possible, the relative importance of these effects under the various flow conditions. It is thus necessary to investigate the flow in the neighbourhood of the leading edge. But the investigation is very difficult by using the static pressure holes or the interferometer, as already mentioned in 3.3). Here, the pressure distribution near the leading edge (to the distance of 1 mm from the leading edge) was measured by the X-ray technique. In this case, the entropy change for the derivation of the pressure distribution p/p_∞ from the measured values of ρ/ρ_∞ was determined by the shock wave inclination at the leading edge in the radiograph.

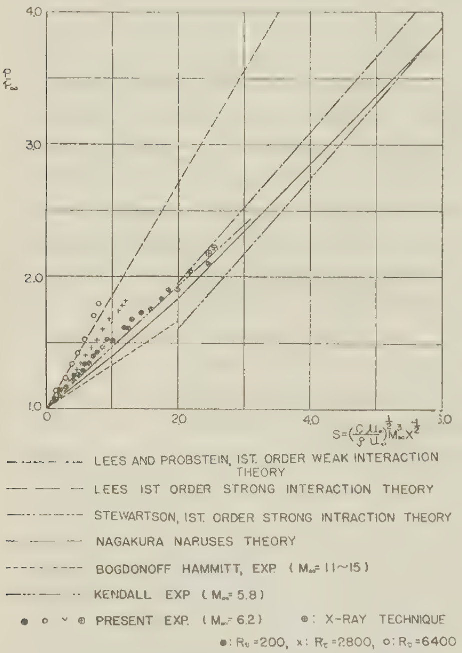

Fig. 11. Relation between p/p_∞ and hypersonic interaction parameter s.

As seen in Fig. 10, the leading edge thickness of the flat plate causes a pressure rise but not seriously. For instance, at the forward part of the flat plate (in the region of about 8 mm from the leading edge), the values of p/p_∞ become merely 1.4 times, as the leading edge thickness t increases from 10 microns ($L=0$ mm) to 320 microns ($L=2.5$ mm). Since the value of t in cases of W_{P0}, W_{E0} and W_{C0} did not exceed 10 microns, the pressure rise due to the leading edge thickness is small, and thus, the leading edge thickness cannot be considered as a major cause for the pressure rise. The pressure rise seems mainly due to the viscous effects near the leading edge of the flat plate. This fact is also confirmed by Bertram's calculation[13].

Fig. 12 presents experimental values of pressure for plane, convex and concave wedges of $L=0$ and 1 mm. In the same figure are also included theoretical values for these wedges with infinitely sharp nose, assuming inviscid flow. The full lines, the chain lines and the dotted lines denote the values calculated by characteristic method[17], tangent-wedge approximation[5] and Newtonian-plus-centrifugal force approximation[18], respectively. The broken lines show the value calculated by Van Dyke's first order approximation of the hypersonic small disturbance theory (considering only the first order of the curvature of the body). The pressure distribution on the surface of W_{C0} is somewhat different from that for W_{P0} and W_{E0}, that is: 1) at the front part of W_{C0}, values of p/p_∞ are nearly the same over a fairly wide range, whereas they decrease gradually on W_{E0} and more gradually on W_{P0}; 2) approaching the shoulders of W_{P0} and W_{E0} there are considerable discrepancies between the theoretical and the measured values of p/p_∞, but these discrepancies become small on the surface of W_{C0} as the distance from the leading edge increases; 3) the pressure rise due to the leading edge thickness is not so severe on the concave wedge as on the plane and the convex wedge (see Fig. 12). These facts are, of course, closely related to the boundary

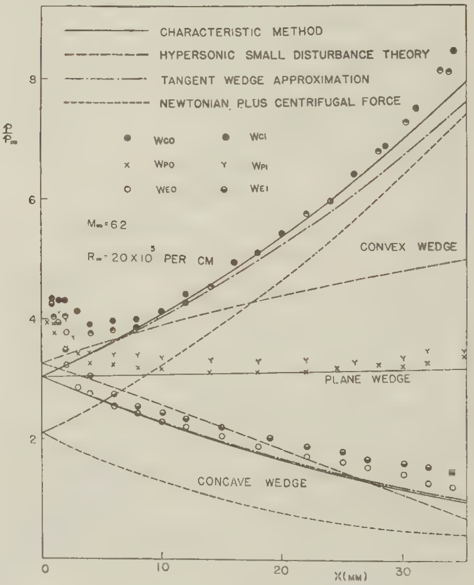

Fig. 12. Pressure distribution on wedge surfaces.

layer growth on the models.

The author wishes to express his sincere gratitude to Professor Fumio Tamaki for the valuable guidance and advice in conducting the experimental work. The author expresses his cordial thanks to Professor Isao Imai for his continual encouragement throughout this work. His cordial thanks are also due to Dr. M. Kawaguti and Mr. H. Naruse for their kind informations and eager discussions.

The Drag of Lattice of Many Parallel Circular Cylinders at Low Reynolds Number

By Takashi SAWADA

Department of Physics, Asahigawa College, Hokkaido Gakugei University, Asahigawa, Hokkaido, Japan

(Received January 29, 1959)

The relations between the drag coefficient C of lattice of many parallel circular cylinders and Reynolds number R were studied experimentally. The drag of the specimen falling in a tower was measured in the region of R=ca 0.25~1.0. If C vs R curve of a cylinder by Wieselsberger is used as standard, C vs R relations of lattice are approximately the same as Wieselsberger's, when $h/d=250$ and 125, with d being the diameter of the cylinder, and h the distance of the centers of the two cylinders. Accordingly it is seen that Imai's formula on the basis of the combination of Stokes' and Oseen's approximations is better than Tomotika and Aoi's formula on the basis of Oseen's. The C vs R relations of lattice, when $h/d=50$, 25 and 12.5, are somewhat similar to Fujikawa's C vs R curves of two parallel cylinders.

§ 1. Introduction

In nature we can see some hairy bodies such as pappi of dandelion or thistle. Formerly the properties of drag of these bodies falling in air were studied by the author[1]. The pappi are assemblages of many thin cylinders in spatial configurations, so the hydrodynamical analysis of their drag should be very complicated. But the simplest of them may be subjected to theoretical analysis. Some years ago, H. Fujikawa[2] calculated the drag of two parallel circular cylinders on the basis of Oseen's approximation. The drag of lattice of infinitely many parallel circular cylinders was studied by K. Tamada and H. Fujikawa[3] on the same basis, and by T. Miyagi[4] on the basis of Stokes'. In this paper the author presents the results of experimental study on the drag of lattice of many parallel circular cylinders of finite length arranged in a plane. Further, he can determine the most credible curve of drag coefficient C vs Reynolds number R relation of an isolated cylinder at low Reynolds number.

§ 2. Specimens and Experimental Method

To make specimens of lattice of parallel cylinders, the author used thin glass filaments of ca 20 μ in diameter. They were measured by the optical microscope with the dissolving power of 0.2 μ and therefore the accuracy of measurement was not so good with regard to each one filament, but the mean value of many may be fairly accurate. For example, if the number of filaments is 10, then the probable error may be 0.06 μ.

To set the specimen, a square-shaped framework made of glass filaments of 30~70 μ in diameter was used, the length of its one side being 6 cm. The drag of the specimen was calculated from its final falling velocity in a tower of square cross section whose height and side length are respectively 420 cm and 50 cm. The effective length of the tower to measure velocity is 250 cm. Because the plane of specimen must be kept horizontal in falling, at eace corner of the framework was attached a filament of 8.0 cm in length and 30~70 μ in diameter, and their opposite ends were joined together at one point. Furthermore, to protect the thin filaments of lattice, 1~3 supporting filaments are attached perpendicular to them. The distances between centers of adjacent filaments, h, were varied as 5.0, 2.5, 2.0, 1.5, 1.0, 0.5 and 0.25 mm. As the diameter of filament, d, is 20 μ, the ratios h/d are respectively 250, 125, 100, 75, 50, 25 and 12.5. The coefficient of viscosity of air was calculated by Sutherland's formula:

$$\eta=\eta_0\left(\frac{T}{T_0}\right)^{3/2}\frac{C+T_0}{C+T},$$

where $\eta_0=1.722\cdot10^{-4}$ poise, $T_0=273.15°\text{K}$ and $C=105.6°\text{K}$.

The density of air was calculated taking into consideration its humidity.

§ 3. Determination of Standard C vs R Curves of Isolated Cylinder Set Perpendicular or Oblique to Uniform Flow

If the drag of the framework, legs and supporting filaments is subtracted from the total drag of the specimen, then we can obtain the drag of lattice, from which we can find the mean drag coefficient of each cylinder per unit length. The drag of the framework and supporting filaments is calculated by means of the drag coefficient of a circular cylinder perpendicular to uniform flow. In our experiments, the Reynolds number used in the above calculation lies between ca 0.3 and 3.0. In this region, C vs R relations are given by several authors. S. Tomotika and T. Aoi[5] gave theoretical formula according to Oseen's approximation, and I. Imai[6] by suitable combination of Oseen's and Stokes' approximations. Further F. Eisner[7] and C. Wieselsberger[8] gave respectively semiempirical curves. Lately R. Finn[9] reported numerous experimental data, in which are to our regret considerable fluctuations. See Fig. 1.

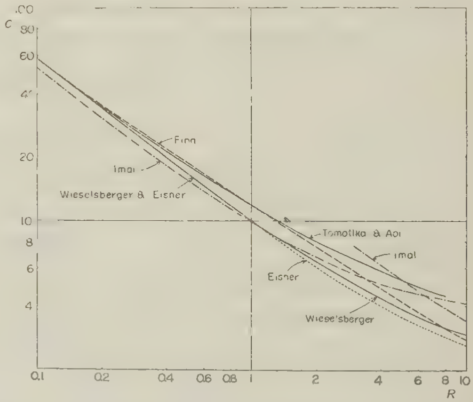

Fig. 1. Theoretical or experimental C vs R curves of an isolated circular cylinder by several authors.

But these curves are different from each other, so we could not decide definitely which of them is the best. Therefore the author determined the most suitable curve by the method of trial and error. It is as follows:

In case of large value of $h/d\geq125$, the interference of each cylinder may be negligibly small. Let us assume any curve of the above as standard, and by means of a suitable method which will be shown later, determine C vs R curve of a cylinder set oblique to the main flow. Next we calculate the drag of framework, supporting filaments and legs, then subtract them from the total drag of the specimen. Finally we obtain the C vs R curve of the lattice. If the latter coincides approximately with the assumed C vs R curve of a cylinder set perpendicular to the main flow, we can say that the assumed C vs R curve is true.

As shown later, it resulted that C vs R curves in the region $0.3<R<3.0$ by Eisner, Wieselsberger or Imai are better than that by Tomotika and Aoi or Finn, but the value of drag coefficient by Imai in the region $R<1$ is slightly less than reality. But the difference between Wieselsberger's and Eisner's curves is small in this region, so the author could not determine which of them is the better. In the present work, he adopted temporarily Wieselsberger's curve as standard and could obtain satisfactory results.

The force acting on a cylinder set obliquely in a uniform flow has been studied by Tomotika, Aoi and Yosinobu on the basis of Oseen's approximation. Let us represent the transverse and longitudinal components as

$$N=1/2\cdot\rho v^2 dC_N\ ,$$

$$L=1/2\cdot\rho v^2 dC_L\ .$$

Here ρ is the density of fluid, v the velocity of the uniform flow, and C_N and C_L are non-dimensional force coefficients. Then the resultant drag on unit length of the cylinder in the direction of uniform flow is given by

$$D=1/2\cdot\rho v^2 d\sin i(C_N+C_L\cot i)\ ,$$

where i is the angle of incidence, i.e. the angle between the axis of the cylinder and the direction of the uniform flow. In our experiment, the angle of incidence is determined by the length of the leg of the specimen. Because the effective length of the leg was 7.8 cm, the angle of incidence was 33°. In Fig. 2 the values of $(C_N+C_L\cot i)$ are given against Reynolds number.

First we experimented on the specimens constructed of framework and legs only. As stated above, the drag of framework was calculated according to Wieselsberger's curve and was subtracted from the total drag. Then we obtain the drag coefficient of the leg; here the projected length of legs is taken as 17.2 cm. Because of difficulty in obtaining the exact values of mass and dimension of specimen, the number of data is only three. But as seen in Fig. 2 these data lie on one curve slightly above Wieselsberger's. Comparing this with theoretical curves by Tomotika, Aoi and Yoshinobu it is seen that there is a remarkable similarity between them. Thus we may assume that the absolute values of drag coefficient of a cylinder by Tomotika, Aoi and Yoshinobu are larger than reality, but the ratios between drag coefficients of a cylinder set perpendicular and oblique are correctly expressed. In our specimens there are 5 singular points, i.e. 4 corners of the square and the lower center. To determine the C vs R curve of a cylinder set oblique, we must take into consideration this singularity. Let us denote the ratios of drag coefficients of a cylinder for $i=90°$ and 33° at the same Reynolds number by A_0 and A, where the former is the theoretical value by Tomotika, Aoi and Yoshinobu and the latter the experimental value. The mean value of A/A_0 with regard to 3 experimental data was 1.037. We may suppose that the value 0.037 originated from the above singularity, but the exact meaning of this number cannot be explained by these experiments only.

The process of drawing the curve is as follows: At any Reynolds number the drag coefficient C_1 is read from Wieselsberger's curve. At the same Reynolds number the drag coefficients C_{10} at $i=90°$ and C_{20} at $i=33°$ are read from the theoretical curve by Tomotika, Aoi and Yosinobu. $A_0=C_{20}/C_{10}$ is multiplied by the factors 1.037 and C_1. The re-

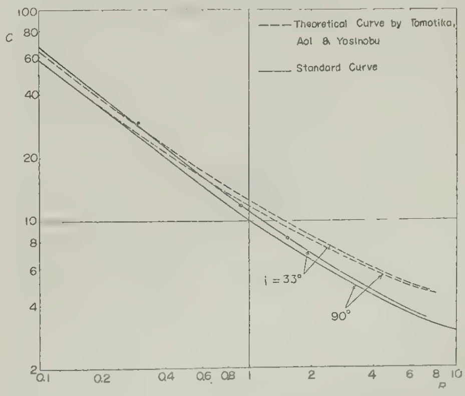

Fig. 2. C vs R curves of an isolated circular cylinder set perpendicular and oblique to main flow.

sult is C_2, which is considered to be the most reliable of the drag coefficient of the legs.

By this method we obtained the standard curves for calculation of drag of framework, supporting filaments and legs as shown in Fig. 2.

§ 4. Relation between Drag Coefficient and Reynolds Number of Lattice

The general method of experiment has already been mentioned. To vary the Reynolds number, a small weight of lead was hung at the lower ends of legs by means of a thin nylon filament. The drag of the weight is very small in comparison with the other parts of specimen, so we can neglect it. The symbols necessary to show experimental data are as follows:

$D_0=mg$	total drag of specimen
n	number of cylinders of lattice
l	length of cylinder
suffix 1	framework
2	legs
3	supporting filaments
4	lattice

1. $h/d=250$ ($h=5.0$ mm, $n=11$)

In this case the magnitudes of D_1, D_2 and D_3 are of the same order as D_4, so the errors by use of unsuitable standard curve may be quite large. But as shown in Fig. 4 we obtained quite satisfactory results. An example of experimental data is as follows:

Specimen No. V–4 (Fig. 3)

$d_1=5.31\cdot10^{-3}$cm $l_1=24.7$ cm
$d_2=5.13$ 〃 $l_2=32.0$
$d_3=2.0$ 〃 $l_3=6.2$
$d_4=2.00$ 〃 $l_4=67.9$
$v=36.54$ cm·sec^{-1} $D_0=3.548$ dyn
$R_1=1.270$ $C_1=8.58$ $D_1=0.890$
$R_2=1.227$ $C_2=9.61$ $D_2=0.670$
$R_3=0.478$ $C_3=17.35$ $D_3=0.170$
$R_4=0.478$ $C_4=16.9$ $D_4=1.82$

2. $h/d=125$ ($h=2.5$ mm, $n=23$)

To obtain the specimen as light as possible, we used the cylinders of nearly 2.0 μ in diameter as framework and legs. By use of this, we obtained data at very low Reynolds

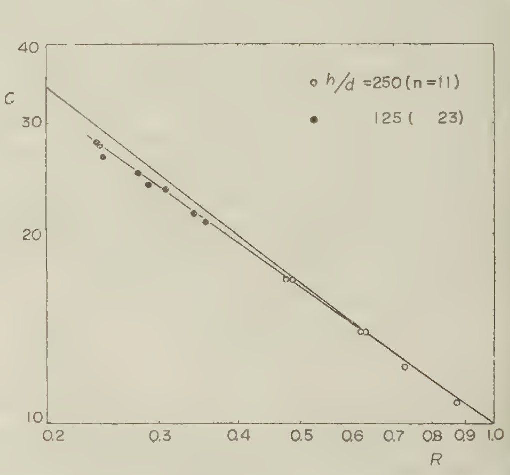

Fig. 4. Relation between C and R of lattice of parallel circular cylinders, in which h/d is 250 and 125.

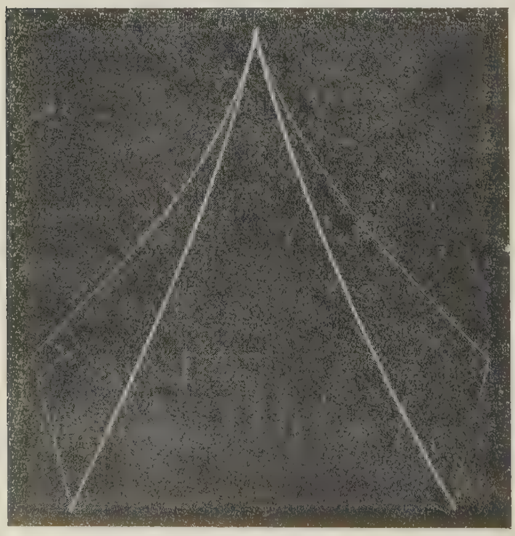

Fig. 3. Specimen of $h/d=250$. Side view.

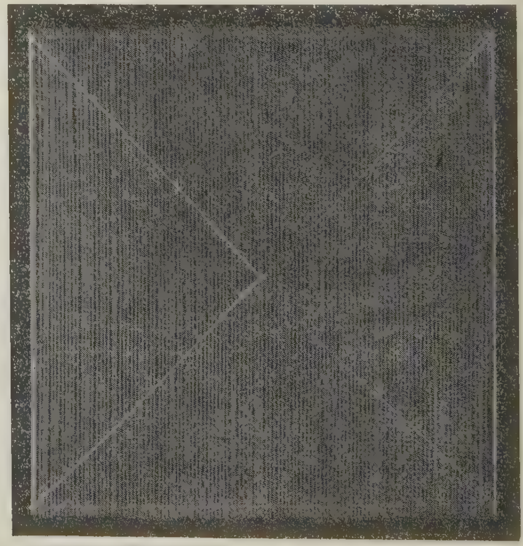

Fig. 5. Specimen of $h/d=25$. Plan view.

number, but data beyond $R=0.4$ were not accurate because of flexion of framework in falling. The C vs R relation is shown in Fig. 4, which on the whole is the same as in $h/d=250$.

3. $h/d=100$ ($h=2.0$ mm, $n=29$)
4. $h/d=75$ ($h=1.5$ mm, $n=39$)

In these two cases we could not perceive any distinct effects of interference of cylinders. The C vs R curves are nearly the same as in the previous cases.

5. $h/d=50$ ($h=1.0$ mm, $n=59$)

An example of experimental data is as follows:

Specimen No. V-3

$d_1=4.02\cdot10^{-3}$cm $l_1=24.8$ cm
$d_2=5.23$ 〃 $l_2=32.0$
$d_3=2.0$ 〃 $l_3=6.2$
$d_4=2.00$ 〃 $l_4=368$
$v=20.66$ cm·sec^{-1} $D_0=5.485$ dyn
$R_1=0.546$ $C_1=15.7$ $D_1=0.398$
$R_2=0.711$ $C_2=14.2$ $D_2=0.325$
$R_3=0.272$ $C_3=27.0$ $D_3=0.085$
$R_4=0.272$ $C_4=25.0$ $D_4=4.68$

The C vs R relation is shown in Fig. 6.

6. $h/d=25$ ($h=0.5$ mm, $n=119$)

In this case the effects of interference of cylinders are remarkable. An example of experimental data is as follows:

Specimen No. V-2 (Fig. 5)

$d_1=6.0\cdot10^{-3}$cm $l_1=24.7$ cm
$d_2=6.8$ 〃 $l_2=32.0$
$d_3=2.0$ 〃 $l_3=12.4$
$d_4=1.98$ 〃 $l_4=739$
$v=22.42$ cm·sec^{-1} $D_0=10.42$ dyn
$R_1=0.887$ $C_1=10.9$ $D_1=0.483$
$R_2=1.005$ $C_2=11.15$ $D_2=0.389$
$R_3=0.296$ $C_3=25.3$ $D_3=0.188$
$R_4=0.293$ $C_4=21.4$ $D_4=9.36$

On account of interference of cylinders, strictly speaking we ought not to use the standard curve of isolated cylinder to calculate the drag of framework and supporting filaments. But as seen above, D_1, D_2 and D_3 are small compared with D_4, so their errors may be neglected. The C vs R relation is shown in Fig. 6, in which the curve tends asymtotically to coincide with the standard curve of isolated cylinder at higher Reynolds number.

7. $h/d=12.5$ ($h=0.25$ mm, $n=239$)

An example of experimental data is as follows:

Specimen No. V-8

$d_1=6.9\cdot10^{-3}$cm $l_1=24.7$ cm
$d_2=7.6$ 〃 $l_2=32.0$
$d_3=2.0$ 〃 $l_3=18.4$
$d_4=2.00$ 〃 $l_4=1480$
$v=27.1$ cm·sec^{-1} $D_0=17.89$ dyn
$R_1=1.197$ $C_1=8.9$ $D_1=0.65$
$R_2=1.318$ $C_2=9.3$ $D_2=0.52$
$R_3=0.347$ $C_3=22.3$ $D_3=0.35$
$R_4=0.347$ $C_4=12.9$ $D_4=16.4$

The C vs R relation is shown in Fig. 6. The effects of interference of cylinders are very remarkable, so the apparent drag coefficient of lattice $C_{ap}=Cd/h$ cannot exceed the value of the drag coefficient of square plate, i.e. 1.16.

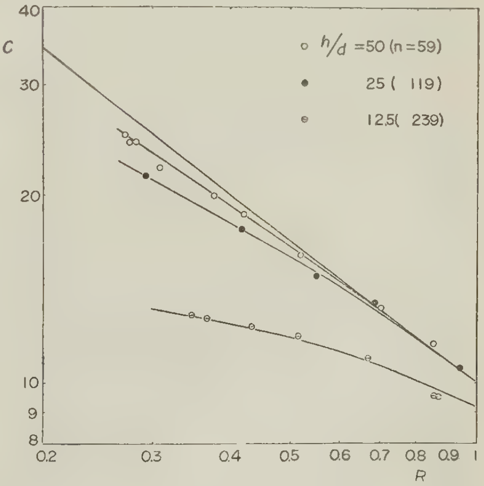

Fig. 6. Relation between C and R of lattice of parallel circular cylinders, in which h/d is 50, 25 and 12.5.

§ 5. Discussion of the Results

According to Fujikawa's calculation the C vs R curves of two parallel cylinders are as Fig. 7. The features of these are very similar to our results. In general the smaller the value of h/d, the more deviates the C vs R curve from that of the isolated cylinder, but the former approaches asymtotically to the latter at higher Reynolds number.

The C vs R curves of lattice of infinitely many parallel circular cylinders calculated by Tamada and Fujikawa are shown in Fig. 8. The relations between these curves and that for an isolated cylinder are in the opposite trend to our results. If, however, we use not the falling velocity of specimen but the actual velocity of flow through the lattice to calculate the drag coefficient, we would obttain the curves similar to Fig. 8.

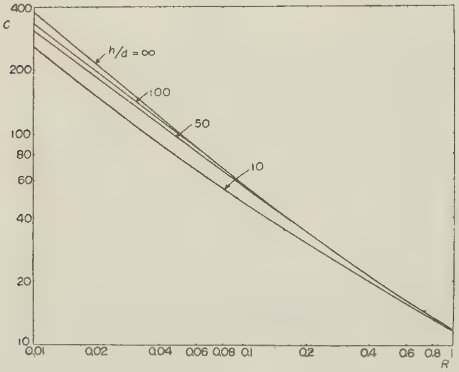

Fig. 7. C vs R curves of two parallel circular cylinders calculated by H. Fujikawa.

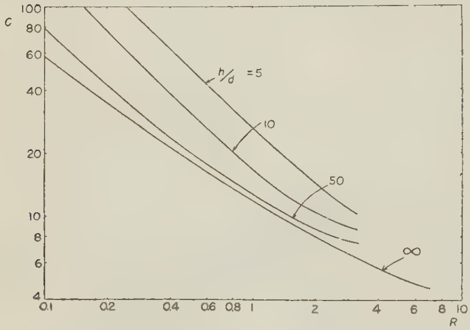

Fig. 8. C vs R curves of lattice of infinitely many parallel circular cylinders calculated by K. Tamada and H. Fujikawa.

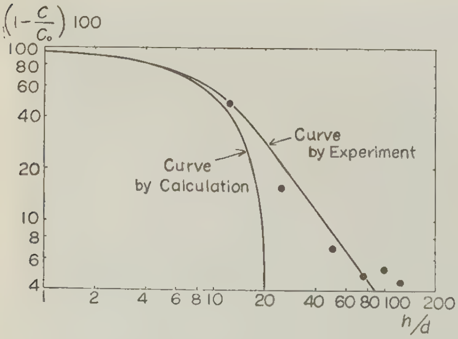

Fig. 9. Relation between $(1-C/C_0)\cdot 100$ and h/d, where C and C_0 represent respectively drag coefficient of a lattice and of an isolated circular cylinder at $R=0.3$.

The value of the drag coefficient of an isolated cylinder at $R=0.3$, C_0, is 25.0. Let us represent as C the experimental value of drag coefficient of lattice at the same Reynolds number. In Fig. 9 are shown the $(1-C/C_0)\cdot 100$ vs h/d relations, where the curve by calculation is as follows: We assume that the apparent drag coefficient of lattice cannot exceed 1.16, i.e. the value of the drag coefficient of square plate no matter how small the value of h/d is. The drag coefficient of lattice which gives $C_{ap}=1.16$, i.e. $C'=1.16h/d$ will become larger with increasing h/d, but cannot exceed 25.0, that is, the value of the drag coefficient of an isolated cylinder. If $h/d=21.55$, then $C'=25.0$. By means of the above formula we calculate C' for $h/d<21.55$, and plot $(1-C'/C_0)\cdot 100$ against h/d. Thus we obtain the curve by calculation. It may be supposed that the curve by experiment will approach asymtotically to it at smaller value of h/d.

Acknowledgement

The author wishes to express his sincere thanks to Prof. U. Nakaya for his continued encouragement throughout this work, and to Profs. I. Imai, K. Tamada, Y. Takaisi and H. Fujikawa for their kind interest and discussions.

Downstream Development of the Wakes behind Cylinders

By Sadatoshi TANEDA

Kobe University of Mercantile Marine

(Received March 4, 1959)

Wake development behind circular cylinders and flat plates was investigated in the research water tanks. The aluminium dust method was used to observe the flow patterns.

At the intermediate Reynolds number range the Kármán vortex streets are formed in the wakes behind cylindrical obstacles. But these primary Kármán vortex streets are not stable. They are more and more deformed as the distance from the obstacle is increased, and finally break down.

Thereafter, however, the wake in most cases begins to rearrange itself again into a configuration of the Kármán vortex street. The dimension of the secondary Kármán vortex street thus produced is much larger than that of the primary one. For the circular cylinder, when Reynolds number is lower than about 150, the ratio of the wave length of the secondary vortex street to that of the primary one is about 1.8 to 3.6, while it is about 10 when Reynolds number is higher than about 150.

Sometimes the secondary Kármán vortex street simply decays by viscous diffusion as it moves downstream, but in most cases it rearranges itself again to the next Kármán vortex street.

§ 1. Introduction

Since the time of Bénard[1)], the wake produced by a two dimensional body has been investigated by many experimenters. Especially the Kármán vortex street has long been a matter of interests to hydrodynamicians. All the observations, however, have been made only near the body, and we have no information relating to the flow at a great distance downstream from the body.

On the other hand, owing to the extreme mathematical difficulties of the problem, there has been little theoretical investigation of the wake, and the problem is still left unsolved, in spite of its importance.

In order to investigate the wake more closely, it seems to be necessary to observe the behaviour of the flow not only at the neighbourhood of the body but also at a great distance downstream.

In the present paper a description is given of the observations on the wake development far downstream behind circular cylinders and flat plates, at Reynolds numbers between 10^1 and 10^3 for the circular cylinder and between 10^3 and 10^5 for the flat plate. (The Reynolds number R is Ud/ν for the circular cylinder and Ul/ν for the flat plate, where U is the model speed, d is the cylinder diameter, l is the plate length and ν is the kinematic viscosity of the fluid.)

§ 2. Apparatus and Experimental Method

The experiments were made with the glass sided water tanks of three different sizes. They are 300 cm long, 20 cm deep and 20 cm wide; 400 cm long, 30 cm deep and 30 cm wide; and 2500 cm long, 150 cm deep and 200 cm wide respectively.

The carriage to which a model was fixed upright was moved uniformly along rails mounted horizontally over each water tank. Circular cylinders and thin flat plates of various size were used as models. All the flat plates were carefully tapered smooth to sharp edges. Sizes of the models used are given in Table I. The Reynolds number could be varied from 10^1 to 10^3 for the circular cylinder and from 10^3 to 10^6 for the flat plate.

In order to visualize the motion of water below the free surface, aluminium dust was suspended uniformly in the water. Then the movement of the suspended aluminium dust, which was illuminated horizontally from a side of the tank by a sheet of intense light from incandescent lamps behind a narrow slit, was photographed from above with a

t: Thickness of the flat plate.

camera. From these pictures, the wave length and the spacing ratio of the vortex street were determined.

On the other hand, it was attempted to use the hot wire technique for determing the frequency of the velocity fluctuations in the wake. Pt wire of 30 μ in diameter and about 5 mm in length, which was heated electrically by 250 cycle a. c., was used in the water as the hot wire. It was quite easy to determine the frequency of the velocity fluctuations in the primary Kármán vortex street with the hot wire, as was reported in the previous paper[2]. However, it was not easy to detect the frequency of the secondary Kármán vortex street, because the velocity of the flow in the secondary vortex street was extremely small. In the present experiments, therefore, the measurements of the secondary Kármán vortex street were made chiefly by means of photography.

§ 3. Results

In the first place, observations were made on the wake behind circular cylinders.

Many photographs of the wake were taken at various Reynolds numbers. From these photographs it was confirmed that, at the intermediate range of the Reynolds number, the wake behind a cylinder oscillates and arranges itself into a configuration corresponding to that of the Kármán vortex street some distance downstream.

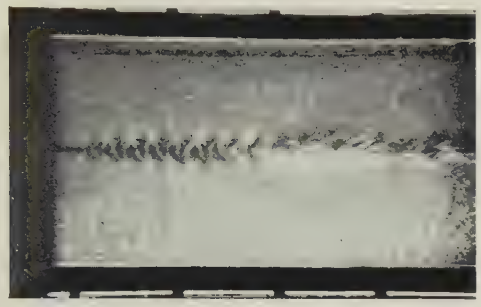
The Kármán vortex street thus produced, however, can not keep its regular arrangement for a long distance. It gradually changes its shape with the distance from the cylinder, and finally breaks down at a distance of about 50 diameters behind the cylinder. The point at which the breakdown of the Kármán vortex street occurs depends on the Reynolds number. The distance from the cylinder to the transition point seems to be decreased as R is increased. Moreover, it was found that the way in which the wake develops downstream is quite different in the two ranges, $R<150$ and $R>150$.

When R is lower than about 150, the flow is always the typical viscous flow and there is no further possibility for the fluid to become turbulent. After the primary Kármán vortex street breaks down, there follows at once a secondary Kármán vortex street, the wave length of which is much larger than that of the primary one. The secondary Kármán vortex street is always somewhat irregular at the beginning of its appearance. It, however, gradually becomes regular and is finally completed at about 10^3 diameters behind the cylinder.

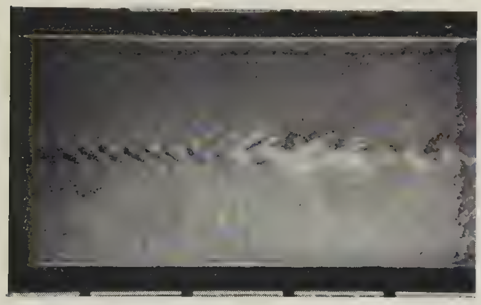
If λ_1 and λ_2 are the wave lengths of the primary and the secondary Kármán vortex street respectively, λ_2/λ_1 depends on the Reynolds number. The values of λ_2/λ_1 for various Reynolds numbers are shown in Table II. As is seen from the table, there seems to be a general relation that the lower is the Reynolds number, the larger is the value of λ_2/λ_1. At $R=60$ the value of λ_2/λ_1 is about 3.3, while at $R=125$ it is about 1.8.

When R is lower than about 50, it is rather difficult to determine the wave length of the secondary Kármán vortex street from the photographs, since the image of the secondary Kármán vortex street is not clear at such low Reynolds numbers. At $R<50$ the existence of the secondary vortex street is somewhat in doubt.

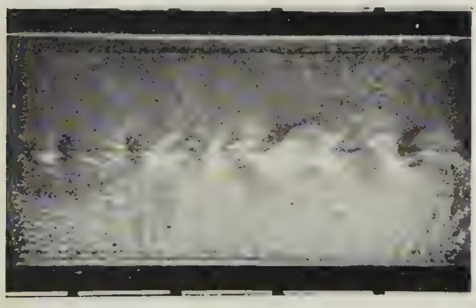
An example of the wake for $R<150$ is shown in the photographs of Fig. 1. They are the photographs of one part of the field, taken successively by a camera fixed to the water tank at a Reynolds number of 73.5, up to a distance of about 500 diameters behind the cylinder.



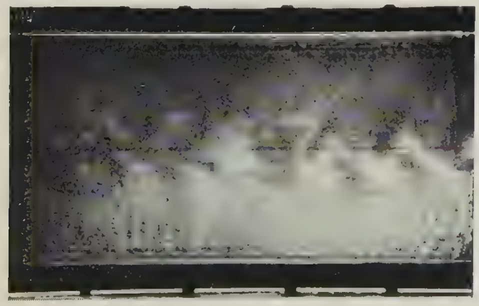
(a) Oscillating wake immediately behind the cylinder. $\lambda_1=19$ mm.



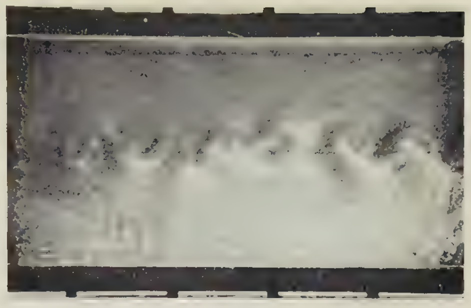
(b) about 10 cm to 50 cm behind the cylinder.



(c) about 30 cm to 70 cm behind the cylinder.



(d) about 70 cm to 110 cm behind the cylinder.



(e) about 110 cm to 150 cm behind the cylinder. $\lambda_2=56$ mm, $\lambda_2/\lambda_1=2.9$.

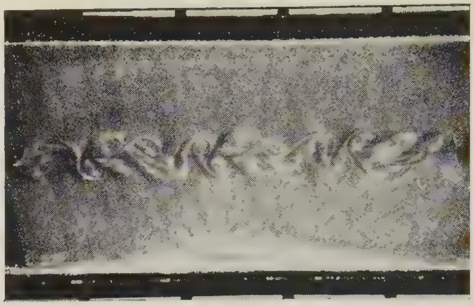
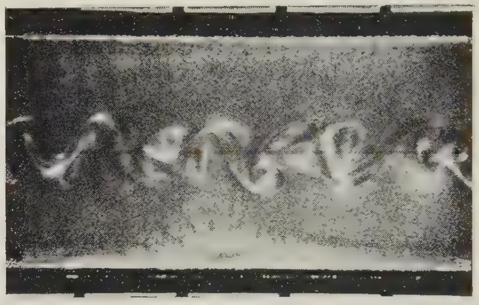
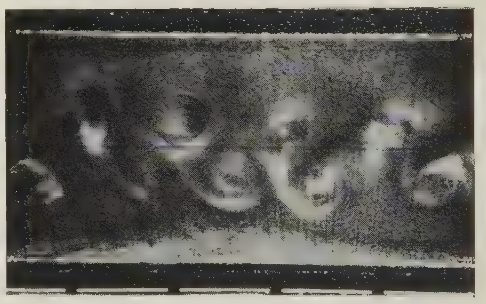
(b) about 20 cm to 60 cm behind the flat plate.



(c) about 50 cm to 90 cm behind the flat plate.



(d) about 100 cm to 140 cm behind the flat plate.



(e) about 200 cm to 240 cm behind the flat plate. $\lambda_2=80$ mm, $\lambda_2/\lambda_1=3.0$.

Fig. 3. Photographs showing downstream wake dovelopment behind a flat plate placed at zero incidence for $U=5.0$ cm/s, $l=140$ mm and $R=8150$.

On the other hand, when R is higher than about 150, the way in which the secondary vortex street is formed is quite different from that at R lower than about 150. At $R>150$, after the primary Kármán vortex street breaks down, the wake becomes turbulent, as was already pointed out by Roshko[3] in 1953. The turbulent wake continues to exist for a considerable distance, then there appear again a new Kármán vortex street. The ratio of the wave length of the new vortex street to that of the primary one scatters largely and cannot be determined precisely, but it is of order of magnitude of 10. This value is much larger than that for $R<150$.

d: Diameter of the cylinder.
U: Model speed.
R: Reynolds number (Ud/ν).
λ_1: Wave length of the primary vortex street.
λ_2: Wave length of the secondary vortex street.

Fig. 2 shows an example of the wake at $R=304$.

Sometimes the secondary Kármán vortex street is observed to decay simply by viscous diffusion as it moves downstream. But, in most cases, it breaks down at some distance downstream, then the formation of the next Kármán vortex street begins again, and in this way the formation and the breakdown of the vortex street are repeated alternately, the wave length becoming larger and larger with every transition from one vortex street to the next.

In the second place, the experiments similar to those described above were also made for the flat plate placed at zero incidence. And it was found that the manner of the formation of the secondary Kármán vortex street and the subsequent history are substantially similar to those for the circular cylinder. An example of the wake development behind a flat plate at $R=8150$ is shown in Fig. 3.

As is well known, the boundary layer of the flat plate is turbulent when R is larger than about 5×10^5. Even in this range of Reynolds number, however, the appearance of the primary and the secondary Kármán vortex street could be observed up to $R=10^6$ or more, although their periodicity was somewhat irregular.

§ 4. Discussion

It is believed that the Kármán vortex street is stable for the perfect fluid. However, the actual vortex street which appears in the wake of real fluid is not stable. It continuously changes its shape with the distance from the body and finally breaks down. After this, however, the wake shows a strong tendency to rearrange itself again into the configuration of the Kármán vortex street. In this way the formation and the breakdown of the regular vortex street occur alternately as the distance from the obstacle is increased, the wave length becoming larger and larger with every transition from one vortex street to the next. Even when the regular vortex street is not formed, the dimension of the predominant discrete vortices which appear in the wake always increases as the distance from the body increases.

These results show that the dimension of the Kármán vortex street which is formed in the wake is the function not only of the Reynolds number of the body but also of the distance from the body.

Thus, we are led to the following questions: (1) why the vortex street with a fixed wave length cannot exist for a long distance, (2) why the periodicity of the wake can appear again after it has broken down once. It appears that the answer lies in the hydrodynamical stability problem. A Kármán vortex street which is stable at one position in the wake may be no longer stable at the other position. Then the wake may begin to rearrange itself into the next Kármán vortex street which is stable in the new position. And in this way the formation and the breakdown of the vortex street may occur alternately. Further investigations on this possibility are being carried out.

In conclusion, the author wishes to express his thanks to Professor Hikoji Yamada of Research Institute for Applied Mechanics, for his valuable advice and encouragement in the course of this work. The present investigation was supported by the Scientific Research Grant of the Ministry of Education.

On the Anomalous Magnetoresistance Effect in n-InSb

By Wataru SASAKI and Chikako YAMANOUCHI
Electrotechnical Laboratory, Nagatacho, Tokyo

(Received May 1, 1959)

It has been pointed out by Broom[1] that n type InSb containing less than 10^{16} carriers per cc shows oscillatory magnetoresistance effect at liquid helium temperature. We have prepared various InSb crystals containing less than 10^{16} carriers per cc, and have measured the magnetoresistance effect in these crystals.

It has been found that the crystals containing nearly same amount of carriers show either oscillatory or non-oscillatory magnetoresistance such as observed in heavily doped n-Ge[2] or p-InSb[3], and that the oscillatory effect is found in crystals in which conduction electrons have higher mobility values.

Fig. 1 shows the distribution of the crystals in regard to their carrier concentration and the relaxation time determined from their conductivity and Hall constant at liquid helium temperature. △ represents the crystals which show non-soscillatory effect, while ⊙ and ● represent the crystals which show oscillatory effect at the magnetic field higher than 1 koe and 2 koe respectively. This figure contains the results obtained by Frederikse and Hosler[4] as well as those by us.

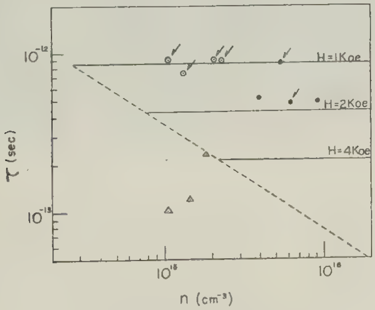

Fig. 1. Relaxation time τ and carrier concentration n of various crystals of n-InSb. △ represents crystals with non-oscillatory magnetoresistance, and ⊙ and ● represent crystals with oscillatory magnetoresistance at magnetic fields higher than 1 koe and 2 koe respectively. The points attached with small arrows represent the observation by Frederikse and Hosler.

If the oscillatory magnetoresistance effect is caused by the same origin as de Haas van Alphen effect, we can expect that this effect will occur when the relaxation time of conduction electrons is longer than the cyclotron period, $\tau_c = m^*c/eH$, and when the carrier concentration is large enough so that the Fermi energy is higher than the diamagnetic energy difference $\varepsilon_d = e\hbar H/m^*c$ for the magnetic field where the oscillatory effect is observable. We can define a region in Fig. 1 where these two conditions for de Haas van Alphen effect are satisfied. We draw horizontal lines at τ values equal to τ_c for various magnetic field strength with $m^* = 0.015\,\mathrm{m}$[5], and draw a broken line which consists of points on the horizontal lines where the Fermi energy corresponding to the concentration is equal to ε_d for each magnetic field strength. The conditions for de Haas van Alphen effect are satisfied for crystals represented by points on the right side of this broken line at the magnetic field with τ_c values shorter than their relaxation time.

As is seen in Fig. 1, the points representing crystals which do not show oscillatory effect are situated on the left side of the broken line, while the points for the oscillatory crystals are situated on the other side of the broken line, and the magnetic field where the oscillation begins corresponds to the parameter of the horizontal lines.

These facts show that the oscillatory magnetoresistance effect and de Haas van Alphen effect are caused by the same mechanism and that the assumed m^* value is well fitted for these InSb crystals.

Synthesis of Large CdS and ZnS Crystals

By Jiro NISHIMURA
Faculty of Art and Literature, Iwate University, Morioka, Japan
and Yasaku TANABE
Research Institute for Scientific Measurements, Tohoku University, Sendai, Japan

(Received May 11, 1959)

In spite of several outstanding methods,[1][2][3] it is not easy to synthesize large CdS and ZnS crystals. We have succeeded, with sufficient reproducibility, in synthesizing large single crystals from a charge of sulfide powder by the following procedure.[4] Polycrystals of easy grain growth are first prepared from a charge of powder by sublimation and recrystallization process. Special lattice plane of these polycrystals is prevailing at their growth front when the vapor of CdS and ZnS is cooled and recrystallized in the zone with large temperature gradient. These polycrystals are a bundle of needle like or rod-like grains with the growth plane of the same Miller index. C-axis of these grains are all parallel in the case of CdS to and make an angle of 25° in the case of ZnS with the normal direction of the substrate surface. Single crystals are then grown from these polycrystals by heat treatment under saturated vapor. The above-mentioned procedure, namely, recrystallization and grain growth, can be done by a single run of the furnace.

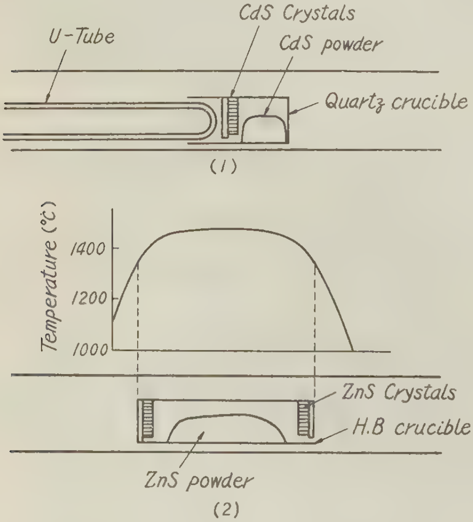

Fig. 1. Furnaces with contents in place.

Experimental furnaces are shown in Fig. 1. A charge of CdS powder is placed in a quartz tube 30 mm in diameter with cups at its both ends (Fig. 1, (1)). One end of the tube is situated in the sublimation zone. The cup of the other end serves as substrate upon which single crystals are formed. It has a small hole for exchanging the ambient gas and is attached to the head of U tube by which steep temperature gradient is formed there. CdS vapar produced in the sublimation zone is cooled and recrystallized on the substrate, and one or several single crystals are synthesized by grain growth. In the case of ZnS, another furnace with steep temperature gradient is used without U-tube (Fig. 1, (2)), and H. B. combustion tube (>57% Al_2O_3) together with S. S. A. crucible (>95% Al_2O_3) are inserted in it.

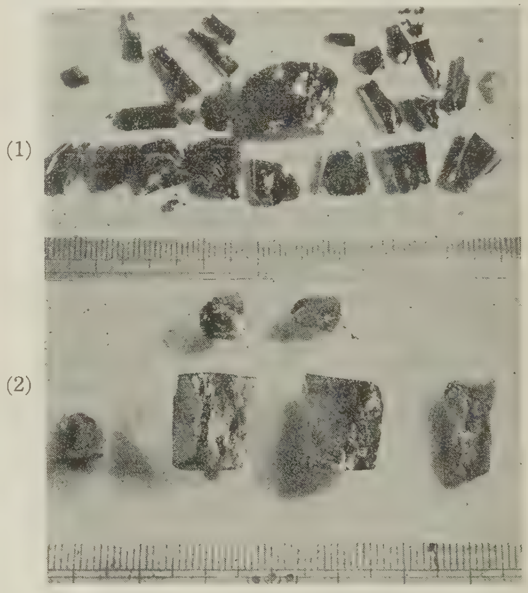

Fig. 2. (1) CdS single crystals cleaved from a polycrystal.
(2) ZnS single crystals cleaved from a polycrystal.

Table 1. Conditions for growing CdS and ZnS Crystals.

	CdS	ZnS
A charge of powder (g)	40	60
Temperature of sublimation zone (°C)	1150	1430
Temperature of recrystallization zone (°C)	1050	1350
Temperature gradient (°C cm⁻¹)	20	50
Time of treatment (hr)	70	80

Fig. 2 and Table 1 show some examples of CdS and ZnS crystals and their growing conditions. Large CdS block in the center consists of several single crystals of about 3×3×12 mm³ which grow parallel to one another. The other CdS blocks are separate single crystals. Two large ZnS crystals in the center, cleaved from the middle part of one single crystal are both about 5 g in weight and their crystal structure is of Wurtzite type and have stacking faults. The larger the quantity of a charge and the higher the furnace temperature, the larger single crystals may grow. Remarkable grain growth in ZnS was observed when the temperature of recrystallization zone was higher than 1400°C.

A detailed description will be published later.

Double Proton Magnetic Resonance by a Side Band Method

By Junkichi ITOH and Siro SATO
Department of Physics, Osaka University

(Received March 28, 1959)

If, in an organic liquid, the chemical shifts of NMR lines from equivalent protons in atomic groups A and B differ considerably from each other, well-resolved two lines will be observed in high resolution spectrum, each of which will split further into several multiplet components in the presence of an indirect spin-spin coupling between these protons.

Suppose we are observing the A resonance by an usual method, and an additional rf field with amplitude H_{1B} is applied, whose frequency is equal to that of the B resonance. When γH_{1B} (γ is the gyromagnetic ratio of proton) is made considerably larger than the equivalent frequency of the indirect coupling, the multiplet will be smeared out into a single line with the intensity given by the sum of the intensities of the normal multiplet lines.

This type of double resonance has been analysed by Bloch⁽¹⁾, and Anderson⁽²⁾ has demonstrated the effect by his successful experiment. However, since the difference between these two frequencies is usually less than a few hundred cycles per second, a fairly large beating makes it rather difficult to apply this method to extensive investigation of indirect coupling in complex organic compounds.

We have carried out similar experiments by making use of a side band technique. It is well known that when the static field is modulated slightly by audiofrequency $\omega_m/2\pi$, small side band peaks appear at the magnetic fields $\pm\omega_m/\gamma$ distant from the main resonance field. The intensity of the side band peaks is determined by the degree of the modulation. So, making the degree of the modulation quite small, the main resonance can be strongly saturated while the side band peaks are always kept in unsaturated state. If we choose $\omega_m/2\pi$ equal to the frequency difference between the A and B resonances, one of the side band peaks of the A resonance will then appear exactly at the B resonance, and *vice versa*. When H_1 is very weak, this side band peak is hardly recognized, being completely hidden in the main line. But, when H_1 is increased to saturate the main resonance, keeping the side band peak in unsaturated condition, this side band peak will become to be seen on a broad peak of the saturated main line. If γH_1 overcomes the indirect spin-spin conpling frequency considerably, this indirect interaction will be ineffective to form normal multiplet and the side band peak will become a single line with the intensity equal to the sum of the intensities of the multiplet lines.

We have examined this consideration on CH_3CHO. A Varian 4300 B high resolution NMR spectrometer was used. The frequency difference between the proton resonances from CH_3 and CHO groups in this molecule at 40 mc/sec was 303 cps. By the indirect spin-spin coupling, they have doublet and quartet structures, respectively. Keeping $\omega_m/2\pi$ constant, 303 cps, H_1 was increased upto such a value as to wash out the indirect interaction, and the side band line from CH_3 group was observed which appeared just at the main B resonance. Fig. 1 shows the result of the observation. As is predicted by the foregoing argument, only a single line appears in this figure, instead of the normal doublet. When $\omega_m/2\pi$ was altered slightly from 303 cps, the normal doulet structure appeared again as shown in Fig. 2.

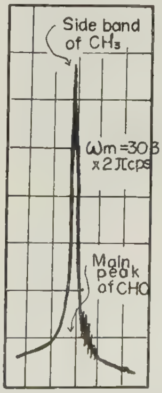

Fig. 1.

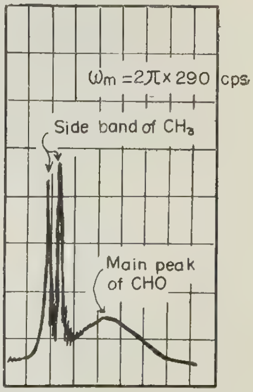

Fig. 2.

This method of double resonance may be found useful for analysing complex spectra in nuclear magnetic resonance of organic molecules.

Avalanche Electroluminescence in CdS Single Crystal

By Makoto KIKUCHI and Sigeru IIZIMA
Electrotechnical Laboratory, Tokyo, Japan

(Received April 11, 1959)

CdS single crystal having an ohmic evaporated In electrode and a non-ohmic Ag-paste electrode generally shows N-type rectifying characteristic.[1] CdS rectifying cells whose construction is shown in fig. 1 are made with flaky single crystals. With these cells, when the forward voltage is increased up to 25∼50 volts, the forward current increases rapidly and light is emitted as shown in fig. 2.

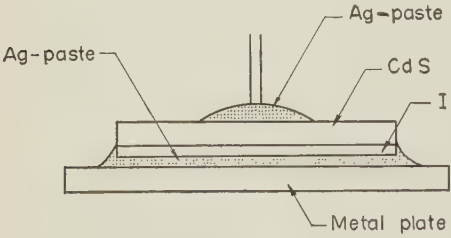

Fig. 1. The construction of the rectifying cell.

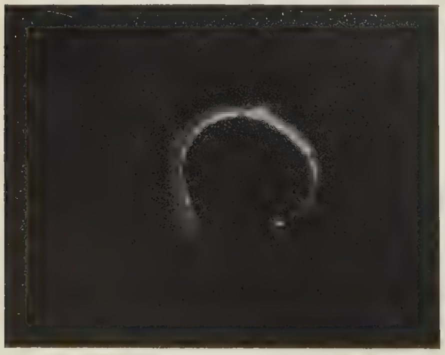

Fig. 2. Photograph of light emission from the Ag-paste electrode.

The relationship between the current through the cell and the light intensity is shown in fig. 3. Since the creep of the light intensity occurs with DC steady current, voltage pulse is used for the measurement. The repetition frequency is 5,000 cps, and the pulse width is 20 microseconds. The current which passes through the cell is read on an oscilloscope and the average current of photomultiplier is measured by a DC microammeter.

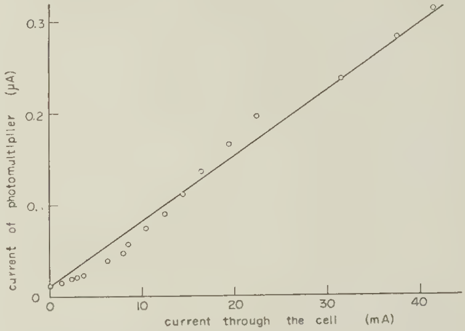

Fig. 3. The light intensity versus the current through the cell.

V-I characteristic of the cell is shown in fig. 4. Again, the voltage pulse is used to eliminate the creep effect. The repetition frequency is 100 cps and the pulse width is 20 microseconds. When the voltage reaches a critical value, current increases rapidly. This behavior is quite similar to that of the gas discharge tube.

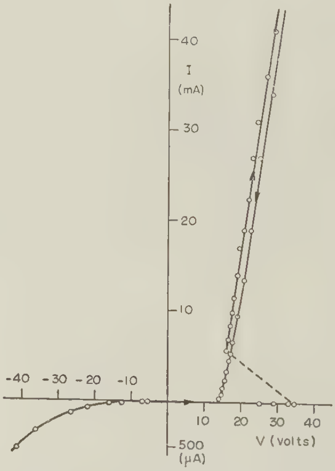

Fig. 4. The V-I characteristic of the cell.

It is believed that when the forward voltage reaches a certain value, the avalanche breakdown occurs in the bulk of the crystal, taking the low differential resistance in on-state (about 400 ohms) into account. The emission of the light is due to the recombination of electrons and holes generated in the above process.

Ferrimagnetic Resonance Line Width in Polycrystalline $Y_3Fe_{5-x}In_xO_{12}$

By Tomonao MIYADAI, Yuzo SHICHIJO
Electrical Communication Laboratory,
Nippon Telephone and Telegraph Public
Corporation, Tokyo
and Ichiro TSUBOKAWA
Research Institute for Iron,
Steel and Other Metals,
Tohoku University, Sendai

(Received April 9, 1959)

Since the discovery by Bertaut et al[1], intense interests have been taken to the ferrimagnetic oxides with garnet structure, having a general formula, $M_3Fe_5O_{12}$. The discovery by Dillon[2] of an extremely narrow ferrimagnetic resonance line width in an yttrium-iron garnet (YIG) single crystal, strengthened these interests. In this connection, it is interesting to investigate the change in line width in the indium-substituted YIG, $Y_3Fe_{5-x}In_xO_{12}$.

The mixtures of Y_2O_3 (99.9%), Fe_2O_3 and In_2O_3 powders in desired proportions were pressed into disk form, sintered at 1400°C in air for about six hours and cooled in the furnace. The samples for resonance absorption were spheres of 0.32 to 0.49 mm in diameter which had been ground by Bond's method[3]. The microwave frequency was 20080 Mc/sec and a rectangular cavity of transmission type with H_{105} mode was used.

The experimental results are shown in Fig. 1. Each point for the half line width plotted in this figure is the minimum value among those obtained for several samples with the same indium concentration, x. As shown in this figure, at $x=0$ the line width takes a value of 130 Oe and increases rapidly with increasing x to c.a. 900 Oe at $x=1.3$. Beyond this point it decreases slightly. The absorption intensity, however, first increases, passes through a maximum at nearly $x=0.3$, then decreases monotonically and reaches zero at about $x=2$. As is shown in the figure, this variation corresponds exactly to the variation of saturation magnetization, Ms, with x. The g-values of these samples were between 2.01 and 2.03.

According to X-ray analysis, the samples consist only of garnet phase for $0 \leq x \leq 0$, of three phases (Garnet+$YFeO_3$+In_2O_3) for $1.0<x<2.0$ and at $x=2.0$, of two phases ($YFeO_3$+In_2O_3).

The reason for the increase in line width with increasing indium content is not clear since our samples were polycrystals. Schlömann[4] studied the ferrimagnetic resonance in polycrystalline ferrites and concluded that the line width is broadened by $|K_1|/Ms+1.5(4\pi Ms)\Delta V/V$ in a polycrystalline specimen, where K_1 is the 1st order anisotropy constant, Ms the saturation magnetization at a given temperature and $\Delta V/V$ the ratio of the pore-volume in the sample to its apparent volume. Since all our samples have a relative density of more than 90%, the fluctuation through the samples in the value of $\Delta V/V$ will be within a few percent. The saturation magnetization at room temperature varies with x as shown in the figure. This initial increase of Ms in c.a. 15% and, for x greater than 0.3, Ms decreases considerably. Therefore, the amount of increase of the second term, $1.5(4\pi Ms)\Delta V/V$ resulting from the In-substitution will not exceed 20%. It may be certain that $|K_1|/Ms$ will not increase since the ferromagnetic Curie temperature decreases with increasing x. Therefore, so long as depending on the Schlömann's result, the line broadening due to polycrystallinity should be of the same magnitude for all our samples. It might be possible that the greater part of the increase in line width for the single phase region ($0 \leq x \leq 1.0$) results from the irregularities[5] in 16(a) and 24(d) sites caused by the indium substitution for Fe.

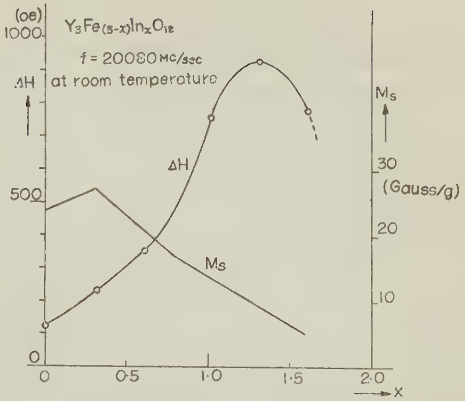

Fig. 1. Variations of the full half line width, ΔH, and of the saturation magnetization at room temperature, Ms, with x in $Y_3Fe_{5-x}In_xO_{12}$.

Electric Resistance and Cation Distribution of Fe-Mn Ferrite System

By Zenya Funatogawa, Nahonori Miyata and Seiji Usami
Department of Physics, Yokohama National University, Yokohama

(Received April 13, 1959)

By means of the electrical resistance measurements of $Mn_xFe_{3-x}O_4$ ($0 \leqq x \leqq 1.14$) the distribution of Mn-ions on the crystal lattice points was estimated. It was concluded that Mn-ions should occupy the B-sites of the spinel lattice at least in the region of low Mn-ion content.

Specimens (3×3×8 mm) were cut from large blocks solidified from the melt in the air. Dependence of the specific electrical resistance (ρ) on absolute temperature (T) (100°K–280°K) was measured by the four probes method with two In-amalgam electrodes on both sides of the specimen for the current flow and two brass electrodes, 4 mm apart, for measuring the potential between them. $\log \rho$ depends linearly on $1/T$ between 120°K and 200°K ($x \geqq 0.1$), and a knick is observed at about 120°K in the region $0.2 \leqq x \leqq 0.6$. Linear dependency mentioned above tells us that specific resistance is expressed by $\rho = \rho_0 \exp(\varepsilon/kT)$. Two constants ε and ρ_0 are plotted against x in Fig. 1 and 2. Experimental values of ρ_0 represented by open circles in Fig. 2 are expressed by a simple relation, $\rho_0 = 6 \times 10^{-3} (x/1-x)$, which is shown by a curve in the figure.

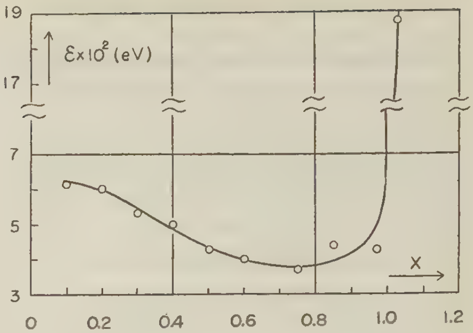

Fig. 1. Activation energy ε *vs.* Mn-ion concentration x.

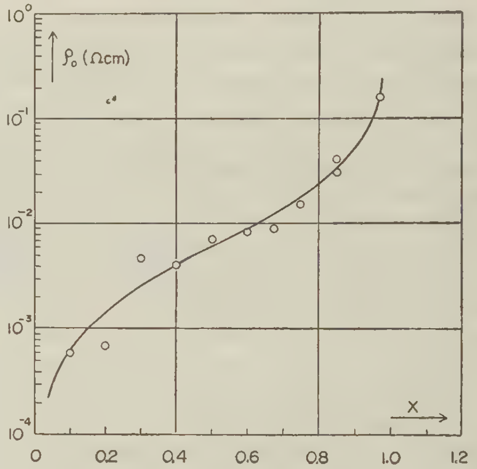

Fig. 2. ρ_0 *vs.* x; open circles represent experimental values and a curve shows $\rho_0 = 6 \times 10^{-3}(x/1-x)\ \Omega$ cm.

Conduction mechanism of these ferrites is understood as the motion of electrons between Fe^{2+} and Fe^{3+} on the B-site of the spinel lattice. Also $\rho_0 = 1/n_0 \mu e$, where n_0 is the concentration of charge carrier at the condition that T is extrapolated to infinity, μ is the mobility, and e is the charge. n_0 is proportional to $(1-x)$, the number of Fe^{2+} ion which is always at the B-sites, and independent of the distribution of Mn-ions. But as for μ, there are two possibilities; (1) it does not depend on x if Mn-ions occupy the A-sites because there are only Fe^{2+} and Fe^{3+} on the B-sites and μ is determined by scattering by thermal motion of crystal lattice, or (2) it is reciprocally proportional to x if Mn-ions are distributed on the B-sites because scattering by Mn-ions is predominant. Then ρ_0 depends on x as const.$\times(1/1-x)$ or const.$\times(x/1-x)$ when Mn-ions occupy A-sites or B-sites respectively. The experiment shows the latter case is actually true. But it must be noted that their difference is not clear in the region of low Fe^{2+} concentration where $1/1-x$ in both expressions is predominant. It is now believed by the neutron diffraction experiment that Fe_3O_4 and $MnFe_2O_4$ have inverse and nearly normal spinel structure respectively¹⁾. Then we should recognize that by substitution for Fe^{2+} in magnetite by Mn^{2+} the latter occupy B-sites in the region of low concentration while normal type spinel is stable in the region of large concentration.

We are now investigating the magnetic crystalline anisotropy of these ferrites and pronounced valley in the curve $-K_1/M$ *vs.* composition x is observed. $-K_1/M$ is a minimum in the region $0.6 < x < 0.7$ and changes its sign. The relation between these facts and distribution of ions mentioned above will be discussed in the paper of this journal very soon.

Magnetic Annealing Effect in α Fe_2O_3

By Takao IWATA, Masako IWATA
and Mikio YAMAMOTO

*The Research Institute for Iron, Steel
and Other Metals,
Tôhoku University, Sendai*

(Received March 11, 1959)

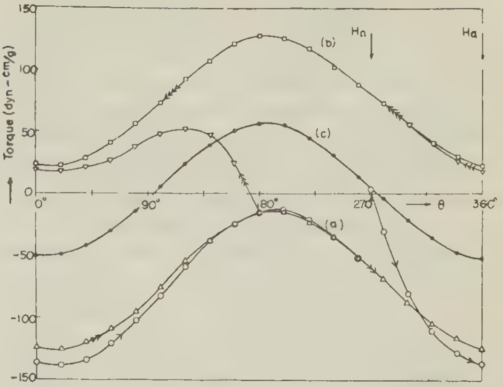

Fig. 1. Torque curves for the rotating field of 1320 Oe of an α Fe_2O_3 disc cooled in magnetic field (H_a) and then placed in a perpendicular field (H_n). The curve (c) is the averge of the curves (a) and (b).

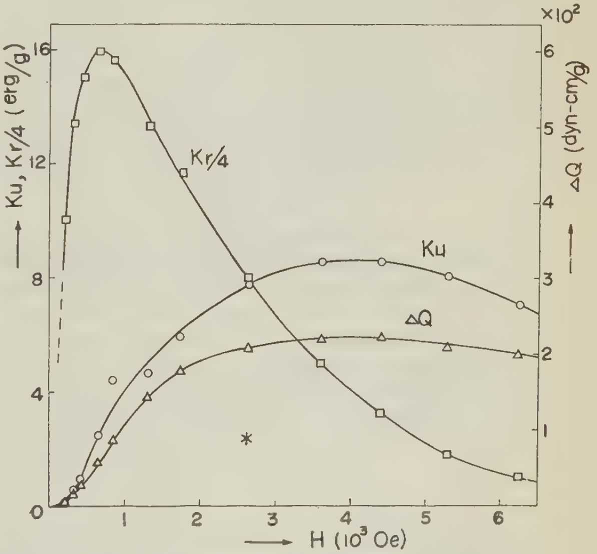

Fig. 2. The measured values of K_u, K_r, and ΔQ as dependent on the measuring field (H) in an α Fe_2O_3 disc. $*$ is the value of measured K_u at the liquid air temperature.

We have studied the magnetic annealing effect in α Fe_2O_3, which is an antiferromagnetic with superposed parasitic ferromagnetism of unknown origin[1].

The disc specimen, 1.62 gr in weight, was made from pure αFe_2O_3 powder (produced from $Fe(NO_3)_3 \cdot 9H_2O$ by heating in air) by sintering at 1000°C in oxygen. It was cooled in air from 750°C (the Néel temperature is about 675°C) in magnetic field (H_a) of moderate intensity (440 Oe), the direction of which is denoted as $\theta=360°$. The magnetic torque measurements of the specimen in this state could not detect any effect of magnetic annealing; the torque curves can be interpreted simply by the presence of the thermo-remanence remaining in the direction of the annealing field. Then, in order to eliminate the effect of the thermo-remanence, the magnetically annealed specimen was magnetized along the $\theta=270°$ direction by an intense field of 6700 Oe (H_n), and the torque of thus treated specimen was measured in the rotating field (H) applied parallel to its disc surface. Typical torque curves as obtained for $H=1320$ Oe are shown in Fig. 1. As is seen clearly, the curve (a) which was measured by the clockwise rotation of H shifts greatly from the curve (b) which was measured by the counter-clockwise rotation of H. This shows that the parasitic ferromagnetism has a large rotational hysteresis in accordance with the observation by Jacobs and Bean[2]. The curve (c) as determined by averaging the curves (a) and (b) cuts the abscissa at a point shifted slightly from $\theta=270°$ towards $\theta=360°$, the deviation angle of this intersecting point being nearly proportional to H.

The Fourier analysis of the averaged torque curves shows that the energy associated with them can be expressed by a formula

$$E=-K_r\cos(\theta+\pi/2)-K_u\cos\theta\ .$$

This formula indicates that the first term is due to the remanent magnetization remaining in the direction of $\theta=270°$ as a result of the application of H_n and the second term is an unidirectional magnetic anisotropy induced by magnetic annealing which stabilizes the magnetization vectors lying in the direction of H_ι ($\theta=360°$). The dependence on H of K_r, K_u, and the magnitude of the rotational hysteresis, ΔQ, which is the difference between the clockwise and counter-clockwise measured torque curves, is shown in Fig. 2. It is to be noted that the value of K_u measured at the liquid air temperature is considerably low, as shown in Fig. 2, which corresponds to the already known experimental fact that the parasitic ferromagnetism of α Fe_2O_3 reduces considerably at low temperatures[1].

The observed unidirectional anisotropy may be explained by assuming, as an origin of the parasitic ferromagnetism, the existence of ferromagnetic layers such as the β phase[3], which are parallel to the basal plane of α Fe_2O_3 crystal and in exchange contact with the antiferromagnetic matrix. When the specimen is cooled from above the Néel temperature in magnetic field of moderate intensity, spins in the antiferromagnetic regions near the ferromagnetic layers aligne themselves parallel to spins in the ferromagnetic layers so as to lower the energy of the exchange contact instead of aligning perpendicularly to the annealing field, and thus an unidirectional effective anisotropy energy is produced within the ferromagnetic layers and brought to the room temperature. The antiferromagnetic spins aligned parallel to the spins in the ferromagnetic layers will not be affected by the normally applied field H_n. Then the unidirectional magnetic anisotropy will be observed only by the above-stated special procedure. In an intense measuring field ($H>4000$ Oe) the stabilizing action of the antiferromagnetic spins will be weakened, so that the unidirectional anisotropy and the rotational hysteresis of the torque will begin to decrease (cf. Fig. 2). Here, it is assumed that the direction of antiferromagnetic spins can rotate in a basal plane so as to become perpendicular to the applied field and the critical field strength for such a rotation is about 2000 Oe after the magnetization measurements of Bizette et al.[4] Finally, it should be remarked that the observed unidirectional anisotropy can not be explained by the uniform body parasitic ferromagnetism such as proposed by Dzyaloshinsky[5].

Quenching Effect of the Photoconductivity Decay in CdS

By Makoto KIKUCHI and Sigeru IIZIMA
Electrotechnical Laboratory, Tokyo, Japan

(Received April 11, 1959)

On one face of the flaky CdS single crystal is evaporated In, and on the opposite face Ag-paste is applied. The cell having such a configuration shows relatively good rectifying characteristic.[1] The decay of photocurrent in forward direction after having been irradiated with very weak light is much faster than that in backward direction. In fig. 1, the time required for the photocurrent to decay down to one fifth of stationary value, $T_{1/5}$, is plotted as a function of applied voltage. The relation between the applied voltage and the stationary photocurrent is also shown.

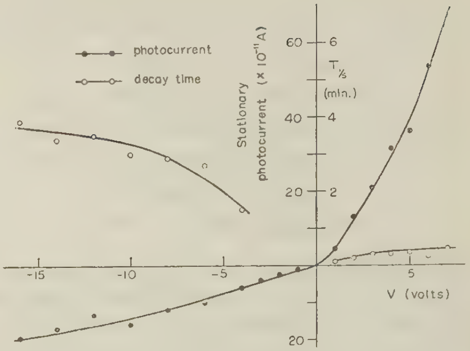

Fig. 1. The stationary value of photocurrent and its decay time versus applied voltage.

When the cell is biased forward, photocurrent and its decay are governed by the photoconductivity and its decay in the bulk of crystal. On the other hand, when biased backward, they are governed by the photoconductivity and its decay in the barrier layer near the surface where Ag-paste is applied. Since the free carriers are exhausted in the barrier, the rate of recombination process is low, and the recovery after the light is removed may be expected to be slow.

The slow decay of the photocurrent in the backward direction is accelerated by temporarily removing the bias voltage or reversing it to forward as shown in fig. 2. The cell on which backward bias (7 volts) is applied is illuminated with a very weak light, and after the photocurrent reaches the stationary value, the light is removed. In the course of the decay of photocurrent, applied bias voltage is reduced to zero, and after 10 seconds raised again to 7 volts. The current is rapidly settled down to original dark value by this process.

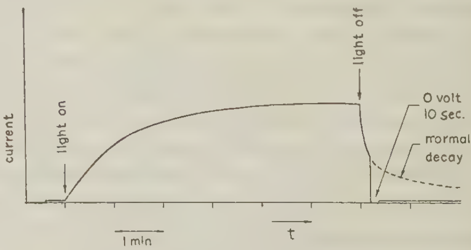

Fig. 2. The quenching effect of photocurrent decay by temporarily reducing the voltage to zero.

A possible explanation is as follows: reducing the voltage to zero, the barrier layer is shrinked, then the region in which the free carriers has been exhausted or nearly exhausted is made to have more free carriers, and the recovery is accelerated.

Luminescence of KI:Tl Induced by Far Ultraviolet Light*

By Masayasu UETA and Takehiko ISHII

Department of Physics, The Faculty of Science, University of Tohoku, Sendai

(Received May 9, 1959)

Luminescence of Tl ion in alkali halide crystals has been investigated so extensively since early decades from both the theoretical and experimental sides, because of the fact that the electronic transition involved in either emission and absorption is considered to take place within the Tl ion, and the model of the luminescence center is quite simple. The emission of the pure and activated crystals was studied in NaI crystal and the fluorescence which is likely attributed to the exciton has been reported[1].

The investigations of Tl emission with irradiations of lights in the fundamental absorption bands of host crystals, will provide valuable informations to the process of the energy transfer in crystals.

This note describes a preliminary results on the quantum yield of Tl-fluorescence in KI crystal when it is excited at room temperature with lights in the far ultraviolet absorption bands. Teegarden[2] has obtained the similar results independently, using a KI crystal containing much smaller concentration of Tl ion (one part in 10^5), hence the comparison is also described.

The KI crystal was grown from the melt containing three mol. per cent thallium, and one tenth of the initial concentration of Tl is considered to be introduced in a single crystal. For the illumination, the monochromatic lights (band pass is 6 mμ) from a hydrogen discharge tube through the previously reported vacuum monochromator[3] was used. The relative intensities of monochromatic lights in the region from 300 mμ to 150 mμ incident upon the crystal surface were obtained by measuring the fluorenscence of a sodium salicylate fluorescent screen which was placed close to the crystal. The fluorescent screen is confirmed to have same uniform quantum efficiency to the lights down to 100 mμ[4].

The fluorescent screen was removed out of the light path by means of rotation mechanism, then the monochromatic lights illuminated the crystal and made it luminesce. The luminescence from the crystal and from the screen were measured alternatively for each monochromatic light with a photomultiplier tube. The direction for receiving the luminescence from the crystal was set to take a proper angle against the path of monochromatic lights to avoid the stray light from the monochromator.

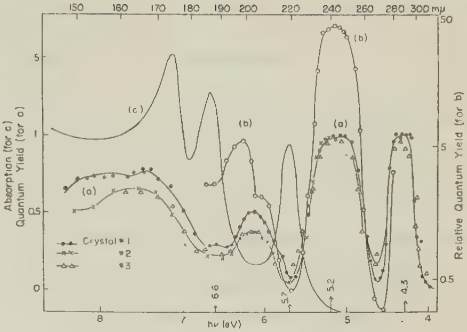

Fig. 1. Quantum yield of Tl emission in KI crystal at room temperature as a function of photon energy. The concentration of Tl is about 0.3% for (a) and 0.001% for (b). Curve (b) is the results by Teegarden. Curve (c) is absorption bands of thin film of KI crystal by Schneider and O'Bryan.

The relative quantum yield thus obtained is shown in Fig. 1 (a). For the comparison, the result by Teegarden is given by (b). Two peaks at $h\nu=4.3$ eV and 5.2 eV are the direct excitation of Tl and correspond to absorption maxima of Tl ion itself. As cleary shown in the absorption curve of pure KI film (c)[5], minima at $h\nu=5.7$ eV and 6.6 eV correspond to the maxima of absorption coefficient of the host crystal, hence they are attributed mainly to the reflection loss.

It is well known that the yield of Tl emission is unity[6] with a light in the region of its absorption bands. Comparing the relative height in Fig. 1 (a), the yield for lights below 175 mμ is determined to have the value of 0.8.

On the other hand, when the host crystal is irradiated in this spectral region, it shows a photoconduction and free electrons and holes are generated. Therefore, the emission in this spectral region is considered to be due to the energy transfer through the recombination of electron and hole.

There is no definite information where the photoconducting region starts, however, it may be considered to extend to the excition peak at $h\nu=5.7$ eV. Therefore, the peak of yield at $h\nu=6.2$ eV will be the superposition of the emission induced by the exciton and the recombination of electron and hole. From these facts, the efficiency of emission of Tl ion induced by only the exciton will be lower than that indicated in Figure, at room temperature.

The quantum yield of the induced emission by exciton or recombination of electron and hole depends on the Tl concentration as seen from figures of (a) and (b). Therefore, with measuring the yield as a function of Tl concentration, the mechanism of energy transfer will be discussed.

Distortion of the Octahedral Charge Distribution in Some Cobalt Complexes

By Tadashi Sugawara
The Research Institute for Iron, Steel,
and Other Metals,
Tohoku University, Sendai

(Received April 14, 1959)

Study of the electric quadrupole interaction of the nucleus of an iron group ion with the local field gradient in crystals gives informations on the nature of the crystalline electric field as the local field gradient has a close relation to the electric local field.1) We studied the quadrupole effect in the nuclear magnetic resonance of Co^{59} in $K_3[Co(CN)_6]$ and $[Co(NH_3)_6]Cl_3$, which are diamagnetic.

Rotation patterns about the a, b and c axes of the pseudo-orthorhombic crystal (twin) of $K_3[Co(CN)_6]$ were measured at 4.2°K. The quadrupole coupling constant e^2qQ/h, the asymmetry parameter η, and the orientation of the principal axes of the field gradient tensor were determined by the usual method. The obtained values were $e^2qQ/h=7.3\pm0.1$ MC and $\eta=0.75\pm0.03$. The orientations of the principal axes for the two equivalent $Co(CN)_6$ groups in an unit cell are shown in Fig. 1. This asymmetric field gradient seems to have its main origin in the asymmetry of charge distribution in the group $Co(CN)_6$, as the directions of the principal axes can not be related to the arrangement of K^+ and $[Co(CN)_6]^{3-}$ ions in the monoclinic unit cell.2) It must be noted that the orientation of the principal axes of the g-tensor of $K_3[Fe(CN)_6]$,3) which is isomorphous with $K_3[Co(CN)_6]$, differs appreciablly from this.

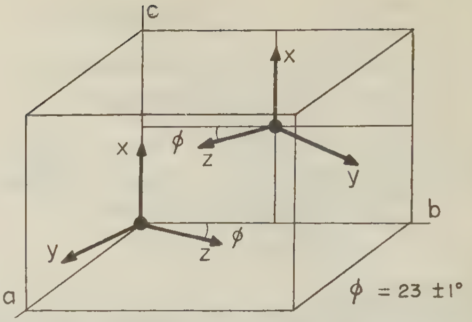

Fig. 1. Orientation of the principal axes of the field gradient tensor in $K_3[Co(CN)_6]$. The z axis lies along the direction of maximum and the x axis along the direction of minimum field gradient. The x axis is parallel to the crystallographic c-axis.

The powdered specimen of $[Co(NH_3)_6]Cl_3$ showed an asymmetrically broadened resonance line at low temperatures. Its shape was quite similar to the second order powder pattern of the central component ($m=+\frac{1}{2}\leftrightarrow-\frac{1}{2}$) for the field gradient of axial symmetry.1) Assuming $\eta=0$, e^2qQ/h was found as 1.5 ± 0.1 MC at 4.2°K. The symmetry axis will probably lie in the [111] direction of the $Co(NH_3)_6$ octahedron.

The above results show that there exists considerable distortion of the octahedral charge distribution around the Co nucleus. Such a distortion will be related to the anisotropy of the crystalline electric field in paramagnetic complexes such as $K_3[Fe(CN)_6]$ and $[Cr(NH_3)_6]Cl_3$. More interesting result will be obtained from the nuclear resonance of Mn^{55} in $K_3Mn(CN)_6$ (paramagnetic) at very low temperatures.

Elastic and Inelastic Scatterings of Protons from Ti, Cr, Ni, Zn, and O at 8 to 14 MeV

Chuin HU*, Ken KIKUCHI**, Shinsaku KOBAYASHI*** Kazuhisa
MATSUDA***, Yukio NAGAHARA****, Yukiyasu ODA*,

(Received March 27, 1959)

The elastic and inelastic (leading to the first excited states of target nuclei) scatterings of protons by medium weight nuclei (Ti, Cr, Ni, and Zn) were studied by observing the dependence of their angular distributions on bombarding energies from 8 MeV to 14 MeV. The angular distributions of protons elastically scattered from oxygen were also measured in the same energy range. There are appreciable regularities in the elastic scatterings by medium weight nuclei as regards the dependence of their angular distributions on the bombarding energy and on the atomic number except in the case of the bombarding energy of 8 MeV. The elastic scatterings from oxygen show an anomalous behaviour at energies about 9 MeV. The angular distributions of protons inelastically scattered from medium weight nuclei can be fitted by the predictions of the direct interaction theory with Born approximation at about 14 MeV, but at the lower bombarding energies they seem not to do so, although they have the prominent forward peaks. The distorted Born approximation or the admixture of amplitudes due to compound process seems to be necessary to explain the angular distributions. In addition, it is found that the yield of the inelastic scattering varies with the bombarding energy appreciably.

For Ni target, the dependence of the yield of the inelastic scattering leading to the first excited state on the bombarding energy was measured in detail by changing the incident proton energy finely at intervals of about 50 KeV. We recognized that there were resonance-like behaviours with spacing of about several hundred KeV.

§ 1. Introduction

Recently rather many experimental investigations have been reported upon the angular distributions of elastic and inelastic (leaving the residual nuclei in discrete states) scatterings of intermediate energy protons by nuclei. The results on elastic scatterings are fitted by optical model analysis. While the results on inelastic scatterings, leaving the residual nuclei in low-lying states, show rather complicated aspects, and do not allow us to make any clear interpretation of the reaction mechanism. The data of most investigations† were, however, confined to some light nuclei and limited to narrow region of incident energy. In this situation, we consider, the accumulation of more experimental data is desirable for further developments.

The experiment reported here is a part of our studies along this line. The whole plan of our study includes the measurements of angular distributions of the elastic and the inelastic scatterings from almost all the even-even nuclei from oxygen to zinc (including

† The works of B. L. Cohen[1] on anomalous inelastic scattering cover a wide range of mass number or that of R. W. Peele[2] on Carbon covers a wide range of incident energy.

nitrogen) in their natural isotopic abundances. The energies of incident protons were varied between 8 MeV and 14 MeV. The present report forms the Part I of our studies and concerns with the experiments with the foil targets of medium weight nuclei; titanium, chromium, nickel and zinc, and also with the gas target of oxygen.

Among the present authors the members of Osaka University had performed systematic investigations³⁾ of inelastic scatterings of protons near 5.5 MeV and had an intension to extend their works using gas targets to the higher energies.

The experimental method and procedure of the present experiment are similar to those of the previous work reported by some of us.⁴⁾

§ 2. Experimental

The proton beam of the INS cyclotron⁵⁾ was brought to the scattering chamber of 100 cm in diameter through a pair of magnetic quadrupole lens, a sector magnet and a collimator. Then the proton beam was scattered by a target mounted at the centre of the scattering chamber and then detected by a NaI (Tl) scintillation crystal and a photomultiplier (RCA 6342), which were located on the turning table in the scattering chamber. Output pulses were amplified and feed to a Johnstone type 20-channel pulse height analyser. Details of the scattering system, beam integration, beam energy measurement and the scintillation counter have all been described in Reference 4. As the gas target, we used a gas chamber, which was made of a brass cylinder of 9 cm in a diameter and of 6 cm in height and had a window extending along the angle of more than 180°, including the beam entrance and the beam exit. This window was covered with a sheet of aluminium foil of 20 μ in thickness.

The thicknesses of the self-supporting foils used as the targets were; Ti (2.09 mg/cm²), Cr (0.37 mg/cm²), Ni (1.02 mg/cm²) and Zn (4.48 mg/cm²), respectively. As the oxygen target we used the gas of 1/2 atom. When excitation curves were measured, the beam energy was varied at intervals of 50 KeV by changing the magnetic field and the frequency of the cyclotron. The energy spread of the incident beam was not determined precisely but it seemed to be less than 50 KeV. Although technique used for continuous changing of the energy was rather preliminary, the agreement between the results of two independent runs were good.

The typical energy spectra of the emitted protons are shown in Fig. 1. Fig. 1 displays also that most parts of the errors in differential cross sections, especially at forward angles, are caused by background subtraction.

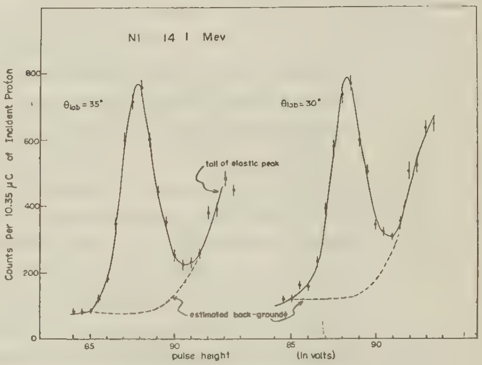

Fig. 1. Examples of pulse height spectrum of inelastic peak at for ward angles.

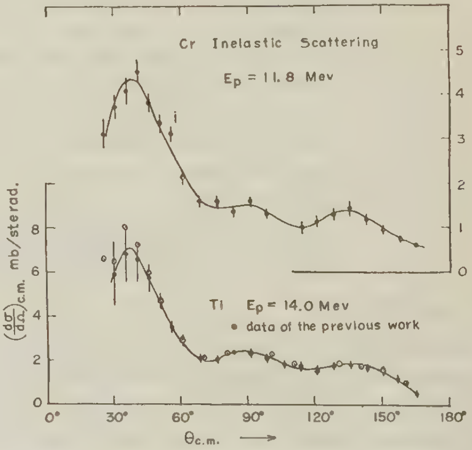

Fig. 2. Differential cross sections with estimated errors (1).

Examples of differential cross sections of inelastic scatterings containing errors due to counting statistics and background subtraction are shown in Figs. 2 to 5. At the bombarding energy of 14 MeV, the figures also include the results of Reference 4. The agreement between both measurements is fairly good.

The errors of the absolute values of cross sections come mainly from the uncertainty in target thickness and were less than 10% for foil targets and less than 5% for gas targets. The relative errors of the cross sections of elastic scattering may be 5% or less. The total cross sections of inelastic scattering, obtained by numerical integration of angular distribution curves, will have the errors less than 20%.

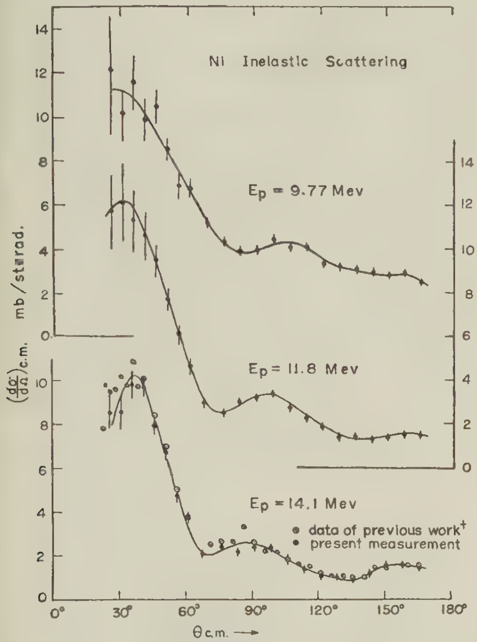

Fig. 3. Differential cross sections with estimated errors (2).

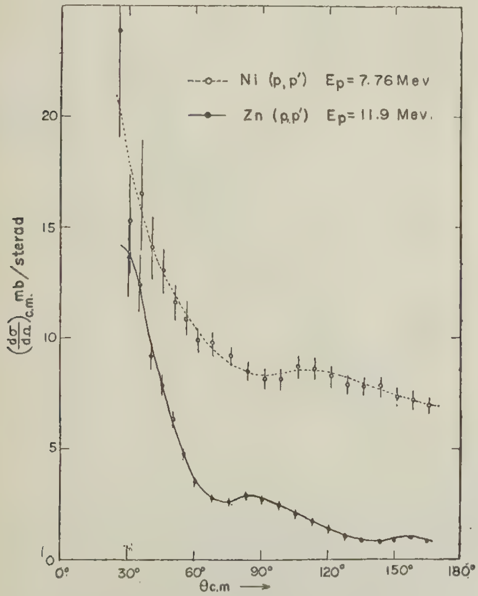

Fig. 4. Differential cross sections with estimated errors (3).

The elastic scattering from oxygen was measured especially for the purpose of subtraction of background due to oxygen contamination in the cases of chromium and magnesium.

§ 3. Results and Discussion

A. *Elastic scattering*

The absolute differential cross sections of elastic scatterings were measured at energies of 14, 12, 10, and 8 MeV for oxygen; 14, and

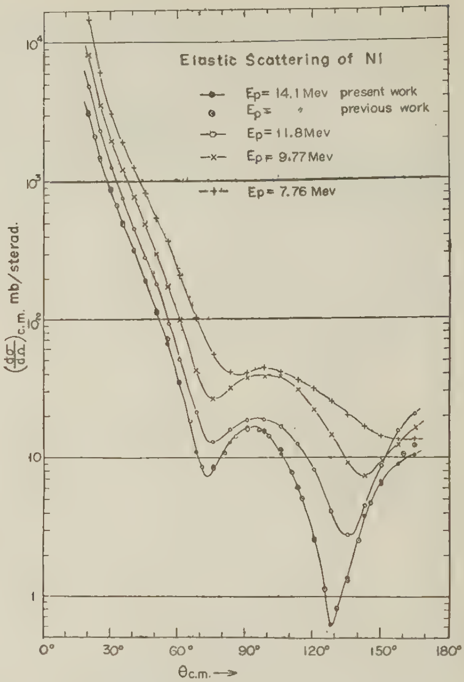

Fig. 9. Angular distributions of elastic scattering on Nickel.

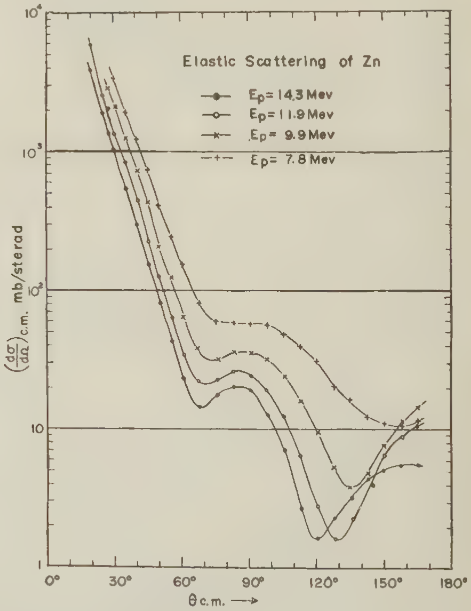

Fig. 10. Angular distributions of elastic scattering on Zinc.

12 MeV for Ti; 14, 12, 10, and 8 MeV for Cr, Ni and Zn. These results are shown in Figs. 6 to 10*. They show that, except the case of

---

* The numerical tables of the differential cross sections of elastic and inelastic scatterings will be reported elsewhere.

oxygen, there exist smooth variations with the bombarding energy and with the atomic number. The latter dependence is shown in Fig. 11. Fig. 12 shows the plots of the positions of the first maxima as a function of $A^{-1/3}$. This figure shows that there exist marked regularities at energies more than 10 MeV, but at 8 MeV the behaviour is somewhat different. Simple calculation shows that there is not the relation that $kR\theta_{\min}$ is constant. For the lighter nucleus; Ti, we recognize a hump at forward angles but it disappears as the atomic number is increased or the bombarding energy is decreased. This hump becomes clear for argon*.

In the case of nuclei from argon* to zinc, the minima in angular distributions are smeared out as the incident energy decreases. But in the case of oxygen, the minima become sharper at about 9 MeV. Such a marked energy dependence in elastic scatterings does not appear in the case of nitrogen** but similar effects occur in the case of neon** from 10 MeV to 14 MeV. This behaviour in oxygen or in neon seems to be anomalous. The angular distribution at 9.07 MeV in the case of oxygen resembles fairly to that obtained by W. E. Burnham et al.[6] at $E_{\text{lab}}=9.5$ MeV. This shows that the above-mentioned anomaly is not confined to narrow region of incident energy. All through this report, we express energies in the centre of mass system.

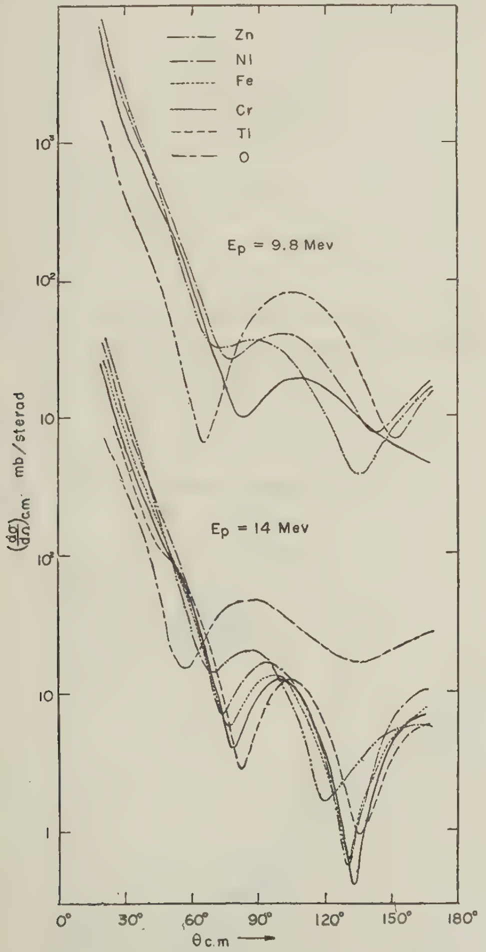

Fig. 11. Comparison of elastic scattering.

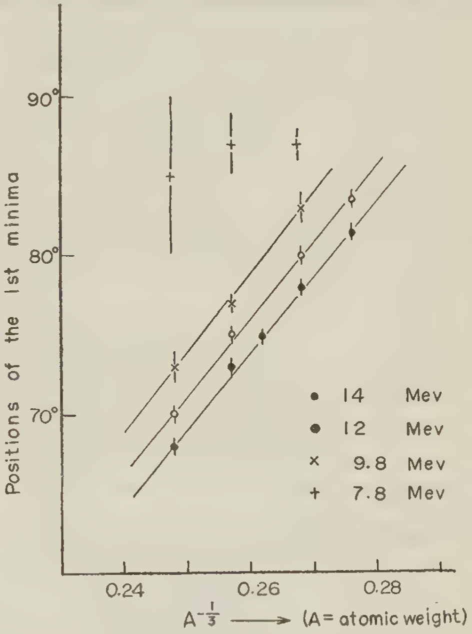

Fig. 12. Regularities in the elastic scattering.

B. *Inelastic scattering*

The angular distributions of inelastic scatterings from Ti, Cr, Ni, and Zn were measured in the same energy region as the elastic scattering, and are shown in Figs. 13 to 16. The curves in these figures are drawn smoothly among experimental points as shown in Figs. 2 to 5. The levels which take part in the measured cross sections are also shown in these figures. The results are not so regular as was in the case of elastic scattering. This circumstance may indicates that the inelastic scattering concerns with details of the structure of nucleus.

We may make some general discussions on the inelastic scatterings of proton, observed in this experiments, leading to the first excited states of even-even nuclei. There are following features in these cases. First, we have a common spin-parity relation between the levels, even though natural elements are used as targets and the first levels of individual isotopes are admixed. Secondly, we may assume the energy spread of the beam cover so many levels of the compound nuclei in these medium weight nuclei and at our bombarding energies.

---

* The results for lighter nuclei will be published in another report.

As reported in reference 4, the angular distributions can be fitted well by the simple theory of the surface-direct reaction based on the Born approximation at about 14 MeV.

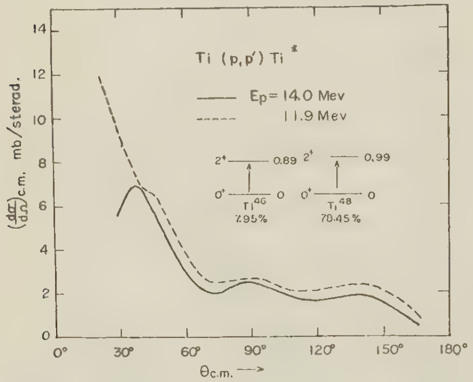

Fig. 13. Angular distributions of inelastic scattering (1st excited state) on Titanium.

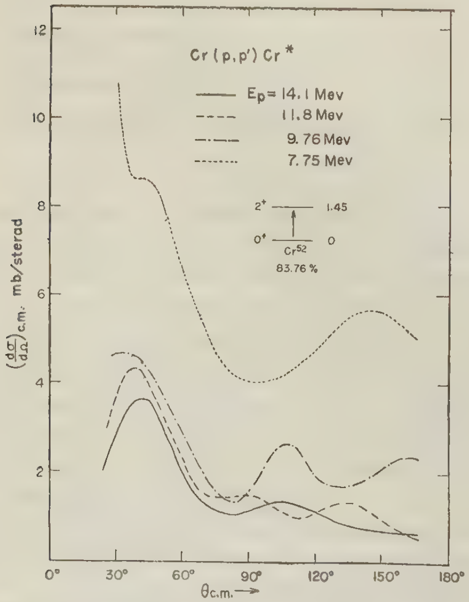

Fig. 14. Angular distributions of inelastic scattering (1st excited state) on Chromium.

However, when the energy is decreased, the first maximum seems to shift to the smalle angle or to disappear, although the prominen formard peaking is preserved all over the energy range.

At present, however, a decisive conclusio on the angular distribution at very small angles might involve some vulnerabilities. W

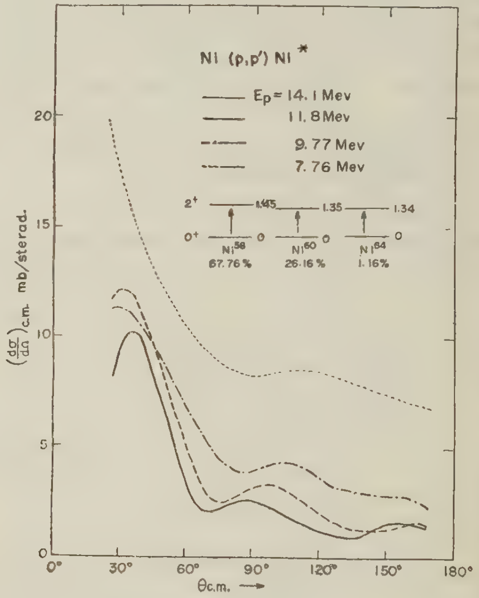

Fig. 15. Angular distributions of inelastic scattering (1st excited state) on Nickel.

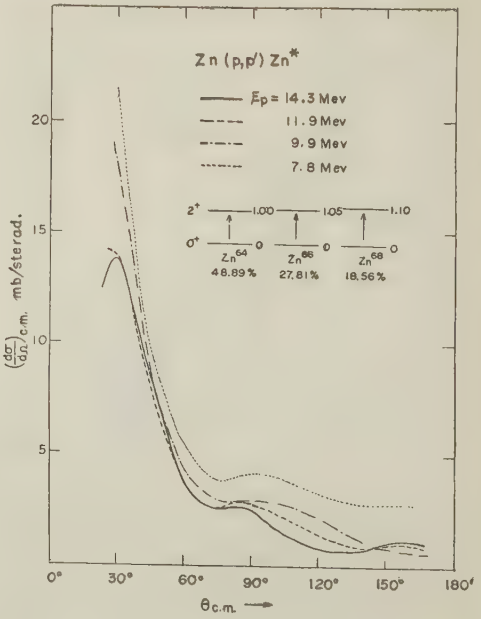

Fig. 16. Angular distributions of inelastic scattering (1st excited statate) on Zinc.

expect further studies with a magnetic reaction particle analyser.

The total cross sections obtained by numerical integration of angular distribution curves are shown in Fig. 17. In performing the integration, the cross sections at forward angles were estimated by extrapolation. The total cross section increases as the incident energy decreases. In the cases of nickel and chromium, this increase becomes steeper from a certain energy.

For nickel, the excitation curves for elastic and for inelastic scattering at laboratory angles of 45° and 90° were measured near 9 MeV and 12 MeV. The bombarding energies were changed at intervals of about 50 KeV. The results shown in Figs. 18 to 19 reveal a very interesting phenomena. The general tendency of forward peaking is preserved all through the energy range. Near 9 MeV, however, $(d\sigma/d\Omega)_{45^\circ}/(d\sigma/d\Omega)_{90^\circ}$ varies violently with bombarding energy; e.g. the angular distribution changes remarkably with small variation of the incident energy. The percentage change at 45° is much larger than that at 90°. In addition, there seems to be no correlation between peaks of inelastic scattering and those of elastic scattering. The resonance at 9.3 MeV has a full width at half maximum of 150 KeV and the spacing of the peaks is several hundred KeV.

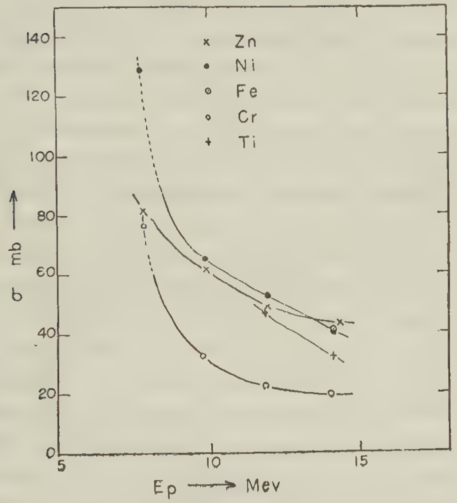

Fig. 17. Total cross sections of inelastic scattering (1st excited state).

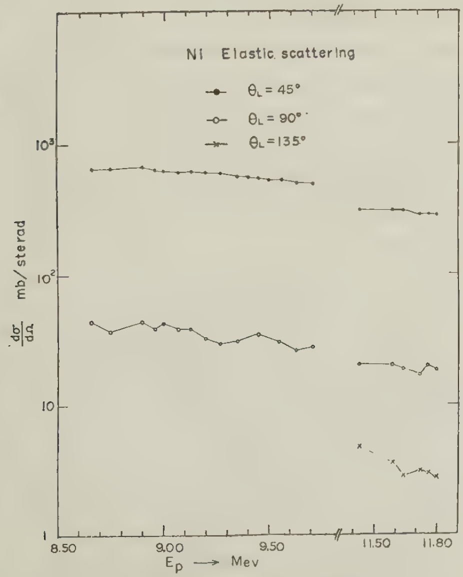

Fig. 18. Excitation curve of elastic scattering on Ni.

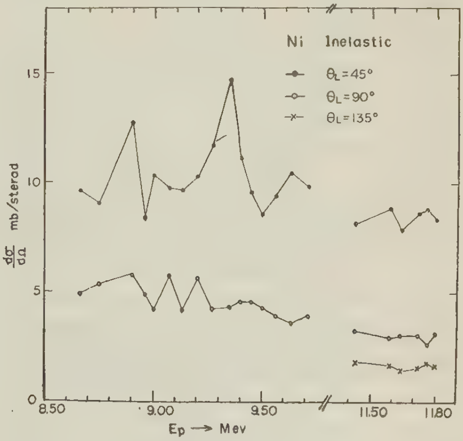

Fig. 19. Excitation curve of inelastic scattering (1st excited state) on Ni.

Some of discussions on the experimental results will be given as follows:

a) The behaviour of angular distributions with decreasing energy may be explained with the distorted Borm approximation. The mean free path of nucleon in nuclear matter is reduced as the incident energy is increased, and so, at higher energy ($E_p>10$ MeV), the direct interaction occurs mainly at the surface of the target nucleus and the nucleon which enter into the nucleus forms a compound nucleus and contributes little to the scattering to the low-lying state as the excitation energy is high and many channels are open. Thus these scatterings could fit well the simple theory of surface interaction with the Born approximation. At the lower energy ($E_p <$ 10 MeV), the above assumption will be violated and the wave will be more distorted. Moreover, as pointed out in c), the admixtures of the compound nucleus formation or some effects like it, may not be neglected as the number of open channel decreases.

b) Sudden increase of total cross sections with decreasing of the incident energy cannot be explained by the simple Born approximation, but it may be conceivable$^{7)}$ in the distorted wave approximation. Alternatively, this may be explained by the compound nucleus formation and the decrease of the number of open channels. It should be noted that such a sudden increase is chiefly due to the increase of nearly isotropic parts of the angular distribution.

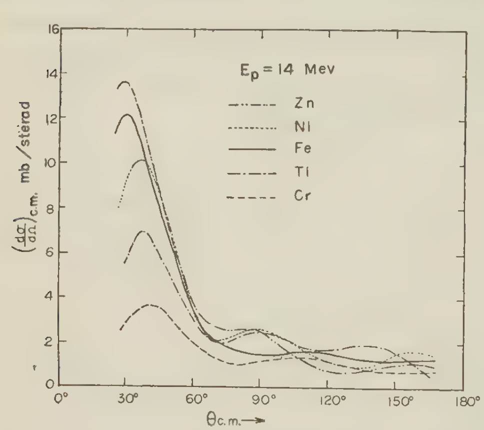

Fig. 20. Comparison of inelastic scattering at $E_p = 14$ Mev.

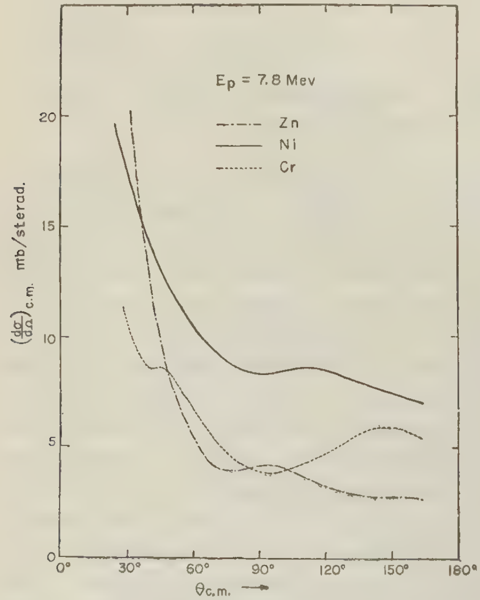

Fig. 21. Comparison of inelastic scattering at 7.8 Mev.

c) Total cross sections and, in particular, the yields of forward peak which are perhaps due to the direct interaction are very different among neighbouring elements. The yield from chromium is very small. The difference between the yield from Cr^{52} (which has the magic neutron number) and that from Ni (which has the magic proton number) suggests some information about the reaction mechanism. (cf. Figs. 20, 21).

d) We did not expect such a variation of differential cross sections as occur in the excitation curves of Ni in these energy range and in such a medium weight nuclei*. These resonance-behaviours are very similar to that have been found in the (d, p) reactions from light nuclei$^{8)}$ (lighter than Ca^{40}). The excitation energies of compound nuclei formed by proton are generally much lower than that formed by deuteron when the bombarding energies are same. In (d, p) reactions, these phenomena are in general regarded as the admixture of the amplitude due to compound process or the resonance interaction between the emitted proton and the residual nucleus. It should be noted that the excitation energy of the Ni$+p$ system is low as compared with that of neighbouring elements. K. Izumo$^{9)}$ has proposed an explanation for such resonances with large spacings. His idea bases on some kind of partial heating of the nucleus. The similar resonance phenomena with large spacings have also been found in our measurements in the case of the inelastic scattering from lighter nuclei, which will be reported in our paper to be published. More exhaustive studies may be necessary to clarity these phenomena.

Acknowledgement

The author wish to thank Professor I. Nonaka for his constant encouragements, and to Professor S. Yoshida and Dr. M. Sano for their suggestions about theoretical interpretation.

They also express their thanks to Mr. H. Ogawa and Mr. T. Miyazawa for their excellent operation of the cyclotron.

---

* As regards the level density of Cu^{59} at the lower excitation energies, see reference 10).

$C^{12}(n,n')3\alpha$ Reaction induced by 14.8 MeV Neutrons

By Yoshikazu TSUNEOKA

Department of Physics, Faculty of Science,
University of Kyoto, Kyoto

(Received September 22, 1958)

The probable mechanism of the $C^{12}(n, n')3\alpha$ reaction when induced by d-T neutrons has been deduced from a study of 403 stars in nuclear emulsions. The angular distribution of the inelastically scattered neutrons show a forward peak, and it is concluded that the reaction occurred mainly through the compound nucleus and that the asymmetry at about 90° is caused by the interference of several levels. The possible decay mode of the C^{12} nucleus was also investigated, and an approximate branching ratio was obtained, assuming that the decay mode via Be^9 was negligible. Then, comparing the angular distributions of the inelastically scattered neutrons which correspond to the different decay modes, Sacks's model for the direct break-up of C^{13*} was found to be in disagreement with the present experimental results.

§ 1. Introduction

Chadwick, Feather and Davies[1] discovered the neutron-induced break-up of C^{12} in a methane filled cloud chamber exposed to Po-Be neutrons. Green and Gibson[2] studied this reaction using d-D neutrons, d-Li neutrons, d-B^{10} neutrons, d-B^{11} neutrons and d-N neutrons, and established that these reactions are $C^{12}+n\rightarrow 3\alpha+n-7.34$ MeV and $N^{14}+n\rightarrow Li^7+2\alpha-8.8$ MeV. These events form " stars " apparently radiating from the points of disintegration, because all the processes under investigation occur within a very short interval. This fact introduces certain difficulties into the task of identifying intermediate stages of the reactions.

The cross section of this reaction was measured by Green and Gibson using d-Li neutrons ranging from 108. to 14.5 MeV, and by Kellog[3] using 90 MeV neutrons, and by Frye *et al.*[4] using d-T neutrons ranging from 12 to 20 MeV. The values of the cross section measured by Frye *et al.* are 78 mb at 12.6 MeV, 265 mb at 16.9 MeV and 223 mb at 20.1 MeV. These values of the cross section were calculated semi-empirically by Sacks[5] and agree well for low energy reactions.

The angular distribution of the inelastically scattered neutrons was measured by Green and Gibson for the first time, and found to be isotropic within the limits of experimental error. O'Neill[6)] was able to show that the angular distribution for all inelastically scattered neutrons was isotropic within about 15% using the time-of-flight technique. And Frye *et al.* observed that all scattered neutrons which made "carbon stars" in nuclear emulsions have isotropic angular distributions when the energies of the incident neutrons were mixed from 12.3 to 13.5 MeV, from 14.1 to 16.9 MeV and from 17.6 to 20.1 MeV.

The decaying mode of this reaction has also been investigated by many authors. Perkin[7)] analyzed 700 stars in nuclear emulsions exposed to *d*-Li neutrons with a maximum energy of 24 MeV, and found indications for Be^8 levels at 2.65, 4.0, 7.25 and 9.8 MeV. He found that the 485 stars correspond to the $C^{12}(n, n')3\alpha$ reaction, but it seems that the carbon stars which involve the ground state of Be^8 were missed in scanning. And the angular distribution of alpha particles was found to be isotropic in the center-of-mass system. Jackson and Wanklyne[8)] studied these events using the cloud chamber and *p*-Be neutrons ranging from 8 to 40 MeV. They found that the evidence based on the energy distribution of the emerging particles shows that the reaction proceeds to an appreciable extent by the formation of a compound nucleus at neutron energies less than 20 MeV, while at higher energies the mechanism is that of excitation of C^{12} by inelastic collision. And they found that in 40% of the events, Be^8 occurs in its ground state, and that in less than 25% of the events involving the 9.6 MeV level of C^{12} decay occurs directly into there alpha particles. Frye *et al.* also found evidence for C^{12} levels at 9.6, 7.7 MeV and for Be^8 levels at 0, 3 MeV. And the processes via Be^9 were estimated to be less than 25% of the events. But the center-of-mass energy spectrum of the scattered neutrons may be fitted by a four-particle phase space distribution.

In the present work, using nuclear emulsions and *d*-T neutrons, the angular distributions of the inelastically scattered neutrons are studied in more detail, and probable mechanisms for neutron interaction and break-up of the carbon nucleus are deduced. Sacks's model for the direct break-up of C^{13*} is also compared with the present experimental results.

§2. Experimental Procedure

The experimental arrangement is shown schematically in Fig. 1. 1″×1(1/2)″ Ilford C2 nuclear emulsions (200 μ) were irradiated by 14.8 MeV neutrons which were produced by the *d*-T reaction, employing magnetically analyzed molecular deuterium of 220 keV from a Cockcroft-Walton machine. The tritium target consisted of 0.5 curies absorbed in a 0.2 mg/cm² zirconium foil and was bombarded with a steady beam of about 100 μA. The distance from the tritium target to the center of the emulsions was 4″ and the direction of the incident neutrons lies in the *y*-*z* plane, and the total flux of neutrons on the emulsions was 9.42×10^8 neutrons/cm².

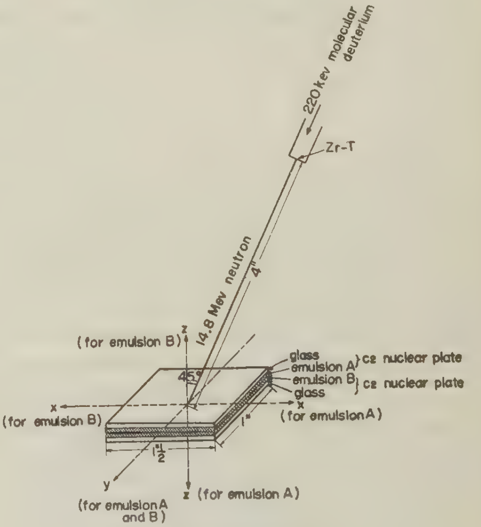

Fig. 1. Experimental Arrangement. The direction of the incident neutrons lies in the $y-z$ plane.

An incident angle of 45° was chosen to minimize the error arising from the variation of shrinkage factor from day to day. The error is averaged over all angles in this case, but the disadvantage of this angle are that more complicated calculations are needed, and that the half width of the calculated curve in Fig. 4 becomes broader owing to a larger error introduced in measuring the depth of tracks. But the advantage of obtaining more accurate angular distributions of inelastically scattered neutrons is essential for the present experimental aims.

Two emulsions A and B were placed face to face as shown in Fig. 1. This setting and the choice of the incident angle has other advantages, *i.e.*, the effects of the neutron attenuation in the glass and emulsion becomes nearly the same for the whole observing volume.

The emulsions were processed by the temperature method[9] using a low *p*H (6.6) amidol developer, and during the hot stage the conditions of 15 minutes and 18°C were chosen as suitable to reduce background fogs and recoil proton tracks.

The processed emulsions were scanned with the " Tiyoda LCM bi " microscope and the " Nippon Kogaku KUG bi " microscope at a magnification of 1350 and 1500 respectively. In the microscopic field, the x, y, z coordinates relative to the vertex of each carbon star were chosen in a right hand system, and the z axis had the direction from the interior region of the emulsion toward the surface. And a nuclear plate was attached to the stage of the microscope so that the direction of the incident neutrons lies in the y-z plane. The x, y, z coordinates of the end point of alpha prongs relative to the vertex of the carbon star were measured in the microscopic field with a eye-piece graticle and a scale of a fine focus screw. As the diameter of the microscopic field is about 100 μ in both types of microscopes, the measurements could be made near the center of the field where the curvature of the field can be neglected. Each depth measurement was subject to about $\pm 0.5\ \mu$ standard deviation. Errors in horizontal projections were about $\pm 0.3\ \mu$.

To determine the shrinkage factor, the Po^{210}-α source was placed on a small portion of emulsion surface, and by measuring the horizontal and vertical components of the length of Po^{210}-α tracks the shrinkage factor was determined graphically[10] to be 2.2. The range-energy relation for the C2 emulsion was obtained from the range-energy relation of Rotblat[11] calibrated for the humidity of laboratory conditions according to the measured range of Po^{210}-α tracks. on the measurement of shrinkage has been reported in another paper.[12]

Data were obtained in two emulsions A and B, and analyzed separately. After it was established that the two sets displayed the same general features, the data were combined. This confirms that there was not a systematic error arising from the measurement of depth and that the method of calculations was not in error. (The depth was measured using the scale of a fine focus screw with attention given to the backrash of gears. But there may exist a personal error and an error arising from the fact that the end point of the track near the surface of the emulsion appears sharp compared to the end point which lies deep within the emulsion.)

Fig. 2 shows the typical microscopic field. The three pronged star is the carbon star, and the single tracks of short range and large grain density are produced by alpha particles emitted probably by the (n, α) reaction of carbon, nitrogen or oxygen. And long tracks with low grain density are produced by the neutron-recoiled protons. Fig. 3 shows the typical carbon stars which are considered (a): cascade break-up that involves the first excited state of Be^8, (b) (c): cascade break-up that involves the ground state of Be^8. The analysis described in § 3 ($E_{ij}^*-E_k$ graph) must be used to determine the decay mode.

§ 3. Star Calculations and Results

As the direction of the incident neutron is known, the energy of the incident neutrons as well as the energy and direction of the inelastically scattered neutrons can be calculated from the measured energy and momentum of the three alpha particles as follows.

Using the conservation law of energy and momentum, we get

$$\left.\begin{aligned} E_n+Q=E_{n'}+\sum E_i \\ X_n=X_{n'}+\sum X_i\,, \quad Y_n=Y_{n'}+\sum Y_i\,, \quad Z_n=Z_{n'}+\sum Z_i \end{aligned}\right\} \tag{1}$$

where E_i $(i=1, 2, 3)$ is the energy of the ith alpha particles in the laboratory system, E_n and $E_{n'}$ are the energy of the incident and the inelastically sattered neutrons, respectively, $Q(=-7.28\,\mathrm{MeV})$ is the Q value for the break-up of C^{12} into three alpha particles, and X_n, Y_n, Z_n; $X_{n'}, Y_{n'}, Z_{n'}$; X_i, Y_i, Z_i $(i=1, 2, 3)$ are the x, y, z component of the momentum of the incident and the inelastically scattered neutrons and the ith alpha particles, respectively. Momentum is taken as $(mE)^{1/2}$, with m in atomic mass units and E in MeV.

Since the incident angle of the neutron is 45° as in Fig. 1,

$$X_n=0\,, \qquad Y_n=\pm Z_n\,, \tag{2}$$

where the double sign is plus for emulsion A and minus for emulsion B, and the energy of the neutrons can be expressed in momentum by,

$$\left.\begin{aligned} E_n=X_n^2+Y_n^2+Z_n^2\,, \\ E_{n'}=X_{n'}^2+Y_{n'}^2+Z_{n'}^2. \end{aligned}\right\} \tag{3}$$

From these formulae (1), (2) and (3), we get

$$E_n=\frac{1}{2}\left[\frac{(\Sigma E_i)-Q+(\Sigma X_i)^2+(\Sigma Y_i)^2+(\Sigma Z_i)^2}{(\Sigma Y_i)\pm(\Sigma Z_i)}\right]^2, \tag{4}$$

where the double sign is the same as in formula (2). Fig. 4 shows the results thus calculated

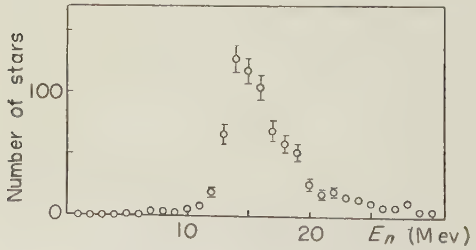

Fig. 4. Calculated energy of the incident neutrons.

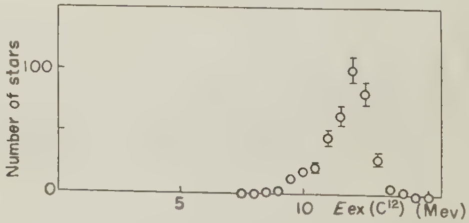

Fig. 5. Excitation energy of C^{12}.

for 889 stars. Some contribution from the $N^{14}(n, 2\alpha)Li^7$ reaction appeared on the higher energy side. Then, 403 stars that gave calculated values in the region of $12.8 \leq E_n < 16.8$ MeV were selected as $C^{12}(n, n')3\alpha$ stars produced by 14.8 MeV monochromatic neutrons.

The excitation energies of C^{12} for these 403 stars were calculated by the following formula, and the results are shown in Fig. 5.

$$E_{ex}(C^{12}) = (\Sigma E_i) - Q - \frac{1}{12}[(\Sigma X_i)^2 + (\Sigma Y_i)^2 + (\Sigma Z_i)^2] \tag{5}$$

where $E_{ex}(C^{12})$ is the excitation energy of C^{12} and the other notations are the same as in the preceding formulae. Figs. 6 and 7 show the energy distribution of the inelastically scattered neutrons and the three alpha particles which made a carbon star in the laboratory system.

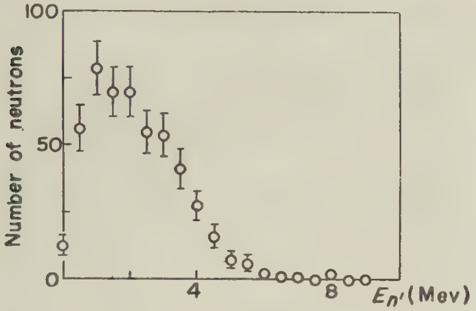

Fig. 6. Energy distribution of the inelastically scattered neutrons in the laboratory system.

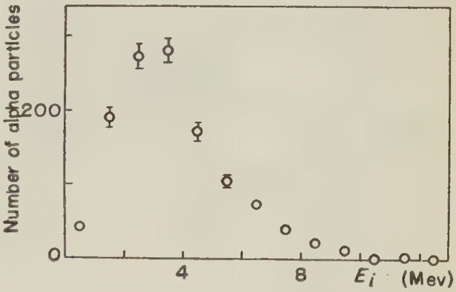

Fig. 7. Energy distribution of the alpha particles in the laboratory system.

The energy $E_{n'}$ and the angle θ_0 of the scattered neutrons in the laboratory system can be obtained by the following formulae, where the double sign is plus for emulsion A and minus for emulsion B:

$$E_{n'} = (\Sigma X_i)^2 + \left[\left(\frac{E_n}{2}\right)^{1/2} - \Sigma Y_i\right]^2 + \left[\pm\left(\frac{E_n}{2}\right)^{1/2} - \Sigma Z_i\right]^2 \tag{6}$$

$$\cos\theta_0 = (2E_{n'})^{-1/2}\left[\left\{\left(\frac{E_n}{2}\right)^{1/2} - \Sigma Y_i\right\} \pm \left\{\pm\left(\frac{E_n}{2}\right)^{1/2} - \Sigma Z_i\right\}\right] \tag{7}$$

To get the angular distribution of the inelastically scattered neutrons in the C^{13} center-of-mass system, Figs. 8 and 9 were drawn using the following formulae (8) and (9) respectively*:

$$\gamma \equiv \frac{v''}{v'} = [1 + 11.42E_{n'} - 6.76(E_{n'})^{1/2}\cos\theta_0]^{-1/2}, \tag{8}$$

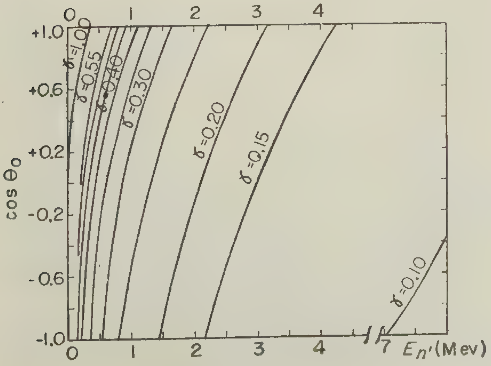

Fig. 8. A plot $E_{n'}$ vs. $\cos\theta_0$.

---

* From kinematical considerations,

$$\gamma = \left[\frac{m_n m_{n'} E_n}{m_{C^{12}}(m_{C^{12}} + m_{n'})Q' + m_{C^{12}}(m_{C^{12}} + m_{n'} - m_n)E_n}\right]^{1/2}$$
$$= \left(\frac{E_n}{12 \cdot 13Q' + 12^2 E_n}\right)^{1/2} \tag{10}$$

and $Q' \equiv Q - E_{ex}(C^{12})$

$$= E_{n'}\left(1 + \frac{m_n}{m_{C^{12}}}\right) - E_n\left(1 - \frac{m_n}{m_{C^{12}}}\right)$$
$$- \frac{2}{m_{C^{12}}}(m_n m_{n'} E_n E_{n'})^{1/2}\cos\theta_0$$
$$= \frac{13}{12}E_{n'} - \frac{11}{12}E_n - \frac{1}{6}(E_n E_{n'})^{1/2}\cos\theta_0, \tag{11}$$

where Q' is the experimental Q value13) and $m_n, m_{n'}$ and $m_{C^{12}}$ are the mass of the incident neutron, the inelastically scattered neutron and the C^{12} nucleus, respectively. Then, substituting the formula (11) into the formula (10) we can obtain the formula (8) using $E_n = 14.8$ Mev.

$$\tan\theta_0 = \frac{\sin\theta}{\gamma + \cos\theta}\,, \tag{9}$$

where θ is the angle, v' and v'' are the velocities of the incident neutron and the C^{12} nucleus respectively, in the C^{13} center-of-mass system.

We can determine γ from $E_{n'}$ and $\cos\theta_0$ using Fig. 8, and θ from γ and $\cos\theta_0$ using Fig. 9. These calculations were made for each star individually and we got the angular distribution of the inelastically scattered neutrons in the C^{13} center-of-mass system, which is shown in Fig. 10.

Then, we divided the scattered neutrons into three regions according to their energy.

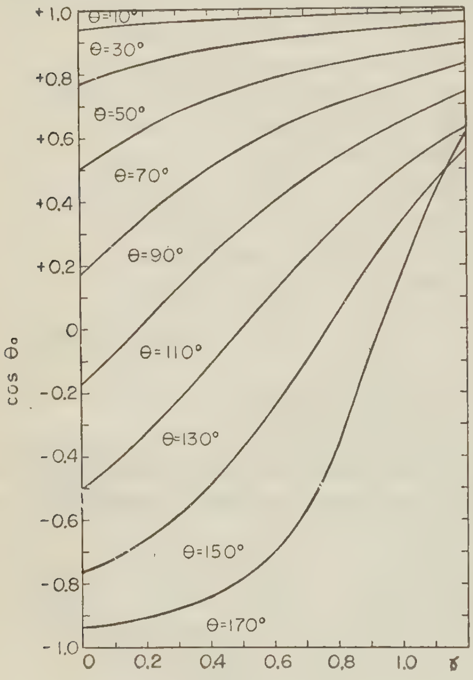

Fig. 9. A plot γ vs. $\cos\theta_0$.

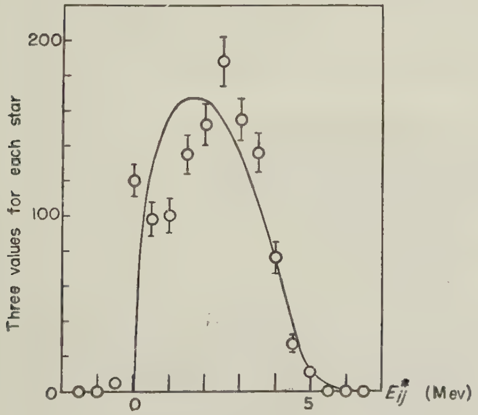

Fig. 14. Distribution of E^*_{ij} values. (three values for each star, *i.e.*, E^*_{12}, E^*_{23} and E^*_{31}). Two peaks at 0 Mev and 3 Mev correspond to the levels of Be^8, and the solid curve shows the theoretical distribution of E^*_{ij} values when the decay mode is the tripartition of C^{12*} directly into three alpha particles.

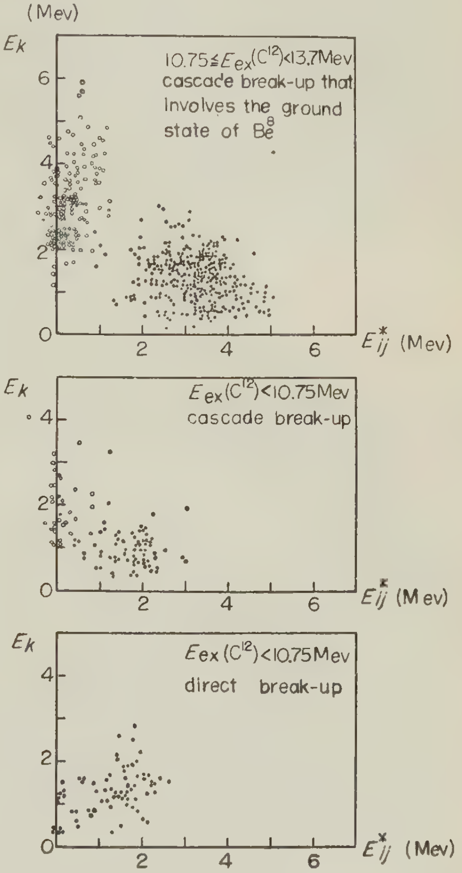

Fig. 15. Some examples of $E^*_{ij} - E_k$ graphs, where the open circles show the "real" values and the closed circles show the "spurious" values.

	star (a)	star (b)	star (c)
$E_{ex}(C^{12})$	12.4 Mev	11.3 Mev	9.6 Mev
$E_{ex}(Be^8)$	3.1	0.0	0.0
E^*_{12}	3.9	2.5	1.7
E^*_{23}	0.4	0.0	0.0
E^*_{31}	3.1	3.2	1.5
E_1	2.0	2.1	1.1
E_2	2.0	1.0	0.8
E_3	1.5	1.9	0.9

$$\sigma(\theta)=22+21P_1(\cos\theta)+16P_2(\cos\theta)+20P_3(\cos\theta)+16P_4(\cos\theta)\,, \quad \text{for } 12.25 \leqq E_{ex}(C^{12}) < 13.7\ \text{MeV}\,, \tag{13}$$

where $P_l(\cos\theta)$ is the Legendre polynomial of the l th degree. As can be seen from Fig. 13, there are four levels in the region of $8.5 \leqq E_{ex}(C^{12}) < 11.75$ MeV, and two levels in the region of $12.25 \leqq E_{ex}(C^{13}) < 13.7$ Mev. The angular distribution for the region of $11.75 \leqq E_{ex}(C^{12}) < 12.25$ MeV shows the intermediate character of Figs. 11 and 12 ; and there is no level in this region of the excitation energy as can be seen from Fig. 13.

If the cascade break-up of C^{12*} that involves the intermediate Be^8 nucleus is more predominant than the direct break-up of C^{12*} into three alpha particles, evidence for Be^8 levels would appear when the excitation energy of Be^8 was calculated. As no one can decide, from the shape of the carbon stars, which two of the three alpha particles came from the break-up of Be^8, three calculations must be made for each star giving at most one third " real " values superimposed upon a two thirds background of spurious values. The excitation energy of Be^8 nucleus E^*_{ij} is given by

$$E^*_{ij}=E_i+E_j-0.1-\frac{1}{8}[(X_i+X_j)^2+(Y_i+Y_j)^2+(Z_i+Z_j)^2]\,, \quad (i, j=1, 2, 3) \tag{14}$$

where 0.1 is the Q value for the break-up of Be^8 into two alpha particles. Fig. 14 shows the distribution of E^*_{ij} values, there being three values for each star as described above. If the C^{12} nucleus does not break-up in a cascade form but directly into three alpha particles, these E^*_{ij} values are all suprious. But, as can be seen from Fig. 14, there is good evidence for the mechanism involving the ground state and the first excited state of Be^8. As for the possible decay mode, Frye *et al.* showed that the mode involving Be^9 was negligible compared with the mode involving Be^8 or direct break-up, and we assumed that all the stars undergo the Be^8 or direct break-up.

Then, we plotted the $E^*_{ij}-E_k$ graph $(i, j, k=1, 2, 3)$, and selected the stars which had nearly zero E^*_{ij} which may correspond to cascade break up involving the ground state of Be^8 and having large E_k value. Similiarly the stars that involve the first excited state of Be^8 were selected. Fig. 15 shows some of these $E^*_{ij}-E_k$ graphs, open circles show the " real " values and closed circles show the " spurious " values. For example, analysis of the carbon stars shown in Fig. 3 gives the following values, where $E_{ex}(Be^8)$ is the " real " excitation energy of Be^8.

From this analysis, the branching ratio of the various disintegration modes was found as follows :

$$\begin{pmatrix}\text{direct}\\ \text{break-up}\end{pmatrix} : \begin{pmatrix}\text{cascade break-up}\\ \text{via the ground}\\ \text{state of } Be^8\end{pmatrix} : \begin{pmatrix}\text{cascade break-up}\\ \text{via the first ex-}\\ \text{cited state of } Be^8\end{pmatrix} = 148 \text{ events} : 193 \text{ events} : 62 \text{ events} \approx 2:3:1 \tag{15}$$

§ 4. Discussion

Carbon 12 is a very tightly bound nucleus, and (p, p') experiments on this nucleus can be accounted for by the direct interaction mechanism, according to Austern, Butler and Mc Manus[15], when the residual nucleus is in the lower excited state. Therefore we expected at first that the contribution from the direct interaction would appear in the angular distributions of the inelastically scattered neutrons, but as can be seen in Figs. 6, 10, 11 and 12 there is no high energy group of inelastically scattered neutrons and the angular distribution of the " lower " energy group of the inelastically scattered neutrons shows the stronger forward peak. If the forward peaks in Figs. 11 and 12 arise from the mixing of the direct interaction process, the " higher " energy group of the inelastically scattered neutrons ought to show a stronger forward peak; and in addition to this result, Frye *et al.* showed that all scattered neutrons which made carbon star had isotropic distribution when the energies of the incident neutrons were mixed from 14.1 to 16.9 MeV. Therefore we should conclude that the reaction occurred mainly through the compound nucleus, and the angular distributions in the present experiment were probably due to the interference effect of several levels.

As for the decay modes, disintegration of the compound nucleus C^{13*} may be considered mainly as follows.

(a): the cascade break-up that involves Be^8($C^{13*}\rightarrow C^{12*}+n'\rightarrow Be^{8*}+\alpha_1+n'\rightarrow 2\alpha+\alpha_1+n'$),

(b): the direct break-up of C^{12*} into there alpha particles ($C^{13*}\rightarrow C^{12*}+n'\rightarrow 3\alpha+n'$),

(c): Sacks's model ($C^{13*}\rightarrow 3\alpha+n'$).

According to Fig. 5 there is evidence for the 9.6 MeV level of C^{12}, but the peak at about 12 MeV cannot be considered as a peak which corresponds to a single level, since the peak shifts with increasing neutron energy[4] and the level spacing of C^{12} near 12 MeV is less than the resolution of the present experiments. Therefore the peak at about 12 MeV can be accounted for by either (a), (b) or (c). On the other hand, if the direct break-up of C^{12*} into three alpha particle occurs as the main process and the statistical assumption of equal probability in phase space is made for these three alpha particles, the distribution of E_{ij}^* values can be calculated by,

$$P(E_{ij}^*)dE_{ij}^*=\frac{8}{\pi[E_{ex}(C^{12})-Q]}(E_{ij}^*)^{1/2}\times[E_{ex}(C^{12})-Q-E_{ij}^*]^{1/2}dE_{ij}^* \qquad (16)$$

where $P(E_{ij}^*)dE_{ij}^*$ is the probability for finding E_{ij}^* values in the domain of $(E_{ij}^*, E_{ij}^*+dE_{ij}^*)$, and for $E_{ex}(C^{12})$ we used the experimental result. The solid curve in Fig. 14 was calculated in this way, but the experimental results cannot be fitted by this curve. Therefore good evidence for the ground and the first excited state of Be^8 can be obtained, which is in good agreement with the result by Frye *et al.*

Further, as the analysis using the $E_{ij}^*-E_k$ graph shows that the cascade break-up that involves Be^8 is about twice the rest of the other decay modes as indicated by the formula (15), we can conclude that the possible decay mode is the cascade break-up of C^{12*} that involves Be^8, superimposed by the small amount of direct break-up of C^{12*} or/and C^{13*}. To determine which process of direct break-up occurs, the inelastically scattered neutrons were divided into two groups. Fig. 16 shows the angular distribution of the inelastically scattered neutrons for direct break-up, and the angular distribution of the inelastically scattered neutrons for the cascade break-up that involves Be^8. Even the ambiguity of classifying the decay mode by Fig. 15 is taken into account, the angular distribution for the direct break-up of C^{13*} is expected to be more isotropic than the angular distribution for the cascade break-up or the direct break-up C^{12*}, because the semi-empirical theory of Sacks[5] predicts the isotropic angular distribution for neutrons and alpha particles. But the present experimental results show that both the angular distributions in Fig. 16 are similar in shape, and the angular distribution for direct break-up is peaked forward rather strongly. Therefore we can conclude that the angular distribution for direct break-up

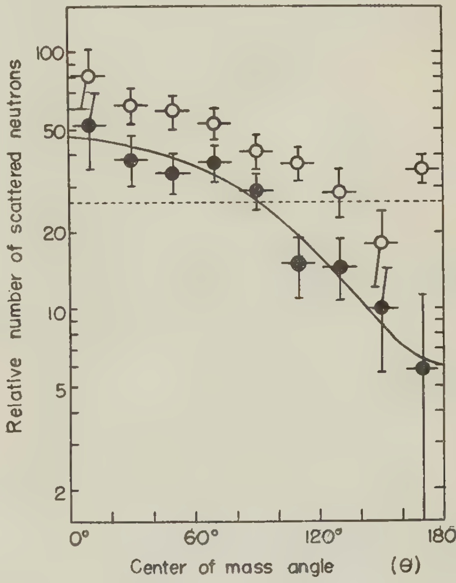

Fig. 16. Angular distribution of the inelastically scattered neutrons, where the open circles correspond to the carbon stars that break-up in cascade form, while the closed circles correspond to the carbon stars that break-up directly into three alpha particles. The solid curve is the experimental curve corresponds to the closed circles, while the dotted curve is the theoretical curve when the decay mode is Sacks's type.

corresponds not to the direct break-up of C^{13*}, but to the direct break-up of C^{12*} superimposed by some amount of the cascade break-up of C^{12*} that involves Be^8. In this case, the intermediate state of Be^8 is probably the first excited state, because the classification of direct and cascade break-up using $E^*_{ij}-E_k$ values is easier for the cascade break-up that involves the ground state of Be^8. The solid curve in Fig. 16 corresponds to the cabon stars that break-up directly into three alpha particles, which has the following equations when fitted by the method of least squares:

$$\sigma(\theta)=26+20P_1(\cos\theta) \tag{17}$$

and the dotted curve shows the prediction by Sacks's model.

Although the cross section calculated by Sacks agrees very well for low energy reactions, we could not find evidence for this process. The disagreement with Sacks's model in the angular distribution measurement was also fount by Sakisaka[16] in his recent experiments on the reaction $Be^9(n, 2n)2\alpha$ using 14 MeV neutrons.

The present experimental results for the decay mode of carbon nucleus is also reasonable, if we compare this result with the other experiments[17] for the break-up of C^{12*}, for which the excitation energy is about the same and the mechanism of excitation is different than that in the present experiment. In these experiments, the disintegration of excited C^{12*} nucleus proceeds in most cases by successive emissions of alpha particles rather than by tripartition of C^{12*} directly into three alpha particles. The branching ratio of direct break-up given in the formula (15) seems rather too large compared with such other experiments; for example, we did not obtain the evidence of tripartition of C^{12*} by p-Li γ rays even though the excitation was higher than the present experiment, and the peak or shoulder that corresponds to the first emitted alpha particles cannot be seen in Fig. 7, while it can be clearly seen in the experiment by Cook *et al.* on the study of $B^{12}(\beta^-)C^{12*}\cdot(\alpha_1)Be^{8*}(2\alpha)$, $E_{ex}(C^{12})\leq 13.4$ MeV. But this small discrepancy for the branching ratio of direct break-up is not so important because the mechanisms for exciting C^{12*} are different in these cases.

Fig. 17 shows the angular distribution of the inelastically scattered neutrons for the carbon stars that break-up in cascade form. The solid curves have the following equations when fitted by the method of least squares:

$$\sigma(\theta)=16+3P_1(\cos\theta)-P_2(\mathrm{cor}\,\theta)-8P_3(\cos\theta)\,,\quad \text{for } 8.5\leq E_{ex}(C^{12})<11.75\text{ MeV}, \tag{18}$$

$$\sigma(\theta)=16+14P_1(\cos\theta)+10P_2(\cos\theta)+10P_3(\cos\theta)\,,\quad \text{for } 12.25\leq E_{ex}(C^{12})<13.7\text{ MeV}. \tag{19}$$

The difference of two angular distributions in Fig. 17 is more conspicuous than that of the angular distributions in Figs. 11 and 12.

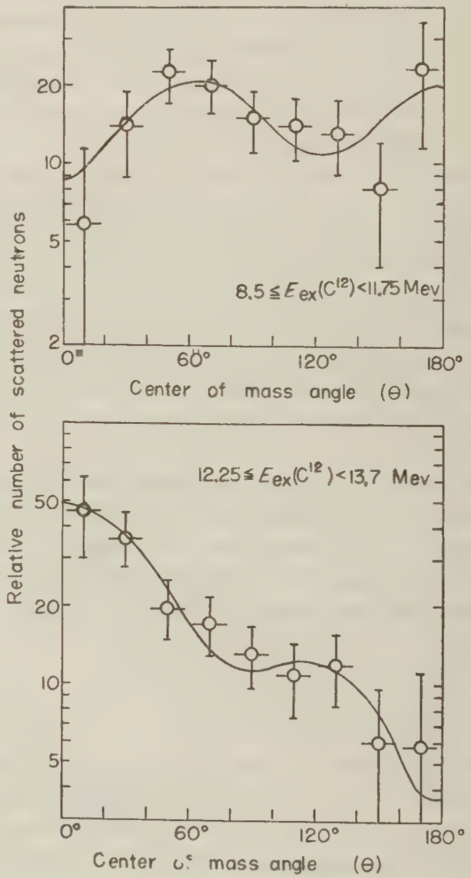

Fig. 17. Angular distribution of the inelastically scattered neutrons for the carbon stars that break-up in cascade form.

§ 5. Conclusion

The results of the present experiment can be summarized schematically as follows, where the double arrows represent the predominant processes.

A Jet Shower with Energy of 5×10^{13} eV found in Emulsion Chamber

By Kiyoshi NISHIKAWA

Institute of Physics, Wakayama University, Wakayama

(Received January 11, 1959)

A high energy jet shower suitable for detailed analysis was found in one of the emulsion chambers flown in 1956 as the "Emulsion Chamber Project". The charged secondary particles of this jet were analysed in the usual way and especially the energy of π^0-mesons was determined by making use of the cascade showers developed from the γ-rays decayed from these π^0-mesons. The energy of incident particles was obtained by the use of usual median angle method, and was estimated to be 5×10^{13} eV ($\gamma_c = 165$).

Next, by making use of the fact that transverse momenta of points are constant and by analysing cascade showers developed from γ-rays produced by the decay of π^0-mesons, the energy of secondary particles was estimated. It was thus found that the differential momentum spectrum obtained is of the form dP/P^3. Also inelasticity coefficients K', K'' and K in the definition of the Bristol group were estimated to be 0.15, 0.10 and 0.5 respectively.

Further, the results of the present analysis were compared with various theories.

§ 1. Introduction

In recent years a great number of works on cosmic ray jet showers in nuclear emulsions have been performed. In order to study the detailed mechanism of multiple meson production at extremely high energy, the "Emulsion Chamber Project"[1] was carried out in 1956 with a collaboration of several laboratories in Japan. One of the most important results obtained is that the value of the transverse momentum of π-mesons is several hundred MeV/c over the wide ranges of both primary and secondary energies. The emulsion chamber has an advantage over ordinary emulsion stacks in that it is possible to estimate the energy of π^0-mesons accurately by the use of separate cascade showers developed from the γ-rays from π^0-mesons.

In the present paper we shall report the results of a detailed analysis of one jet shower "*ST 2*" which was found in one of the emulsion chambers and seemed to be favourable for the detailed study. In this case, not only many cascade cores from secondary π^0-mesons but also charged particles were clearly observed.

For the study of extremely high energy phenomena the emulsion chamber seems to be more preferable to ordinary emulsion stacks, because in the case of usual stack the electron pairs converted from γ-rays mix with the charged secondary particles in the inner core of the extremely high energy jet, thus making the detailed analysis of these secondary particles difficult. Therefore, it is desirable to accumulate much data about the extremely high energy jet by the use of emulsion chambers which have better arrangement than those in the present experiment.

§ 2. Experimental Procedure

a) The balloon flight and the arrangement of the experiment

Our emulsion chambers were flown at an altitude of 23 Km by polyethylene balloons (5600 m^3) launched from Kobe in summer 1956. The emulsion chamber, in which the jet we are going to report was found, is of the type B[1]. Its arrangement is shown in Fig. 1. It consists of seventeen G 5 200 microns plates (6″×8″), ten plates of carbon with thickness of 8 mm, eight plates of lead with thickness of 5 mm and two air gaps of 2 cm. In this chamber the upper part, which is consisted of material with low atomic number, acts as a jet producing layer, while the lower part of material with high atomic number acts as a detecting layer of cascade showers developed from γ-rays which are the decay products of π^0-mesons resulting from jets.

b) **Observation and measurement**

Scanning was carried out to search for cascade showers in the emulsion plate at the bottom of the emulsion chamber. A shower having 11 cascade corres, as shown in Fig. 2, was found in the course of this scanning. By tracing the tracks of the shower back to the upper plates a jet was found, in which one heavily ionized track and 53 shower particles could be seen. Fig. 3 shows the target diagram of the charged shower particles. The origin of the jet was in the top carbon plate, so that the primary particle could not be seen. The axis of the jet was determined in two ways, namely from the analysis of the cascade showers[1)] and from the center of mass of the charged particles. These two determinations were in very good accord, and it was found that the said axis makes an angle of 76° with the emulsion surfaces.

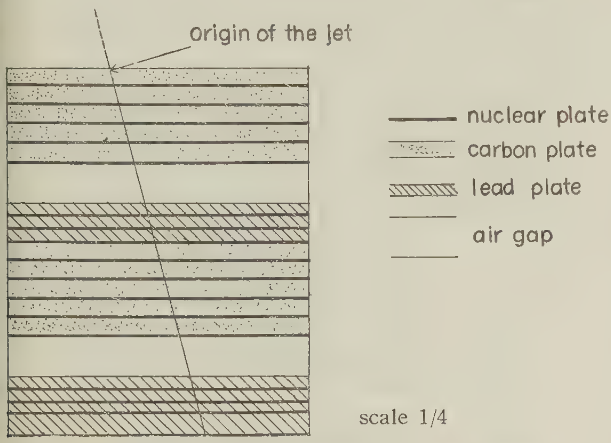

Fig. 1. Elevation of the type **B** of the emulsion chamber, showing the arrangement of plates and air gaps.

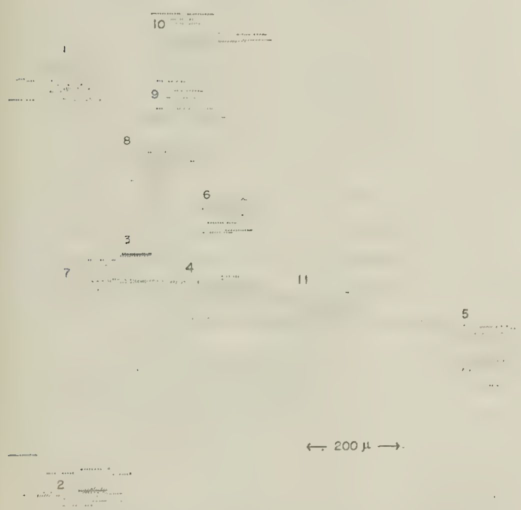

Fig. 2. Illustration of the cascade showers having 11 cores observed at the bottom of the emulsion chamber.

From an analysis of the cascade showers[1)] developed in the inner cone, the energy of π^0-mesons, $E\pi^0$, was estimated by the use of Nishimura-Kamata's distribution function[1)]. The angles, $\theta\pi^0$, which π^0-mesons make with the shower axis were also estimated from the analysis of the cascade showers. The results are tabulated in Table I. Over wider region outside the inner cone, electron pairs and cascade showers were scanned. These γ-rays are also considered to be due to the π^0-mesons belonging to the outer cone of this jet, because the γ-rays from the bremsstrahlung by the charged particles are estimated to be negligible[2)]. The angles θ_γ, between the γ-rays and the shower axis were measured by making use of the target diagram, obtaining the results as tabulated in Table II.

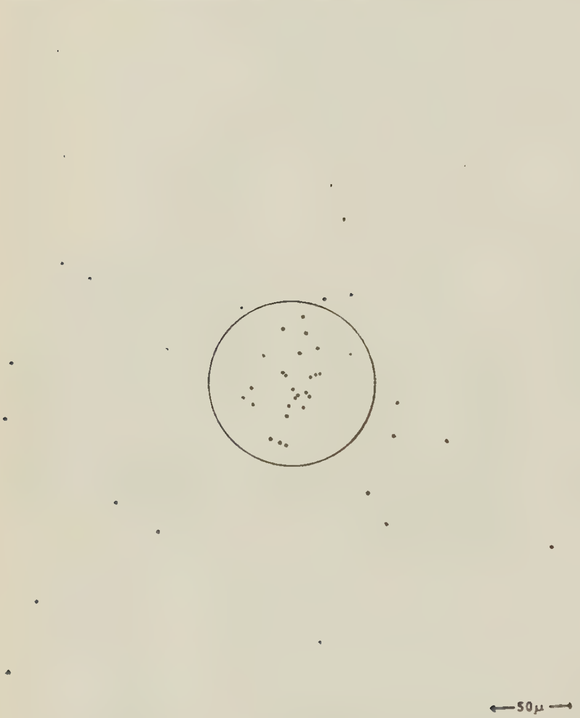

Fig. 3. The target diagram of charged shower particles at 8.5 mm beneath the origin of the jet.

Charged shower particles were observed in several plates near the origin. The angles, θ, which these shower particles make with the shower axis are given in Table III. The target diagram (Fig. 3) used for measuring these angles is that in the emulsion plate just beneath the production point of the jet shower, because the number of electron pairs from the γ-rays of π^0-mesons is estimated to be negligible.

§ 3. Estimation of the Incident Energy

An estimation of the energy of the primary particle is made by kinematical method due to Castagnoli *et* al.,[3] assuming that the interaction is a nucleon-nucleon collision. From the data of charged shower particles, the Lorentz factor γ_c of the center of momentum system is obtained from the equation:

$$\frac{1}{n_s}\sum_{i=1}^{n_s}\log\tan\theta_i=\log\frac{1}{\gamma_c}, \qquad (1)$$

where n_s is the number of the charged shower particles, and θ_i the angle of the ith shower particle with the shower axis in the laboratory system (L. system). Then, the energy E_0 of the primary nucleon in the L. system is

$$E_0=(2\gamma_c^2-1)Mc^2, \qquad (2)$$

where Mc^2 is the rest mass of a nucleon. Plotting the values of $\tan\theta_i$ on the logarithmic scale as in Fig. 4, the following results are obtained:

$$\gamma_c=165.4^{+26.6}_{-19.9},$$

$$E_0=(5.10\,^{+1.83}_{-1.14})\times10^{13}\ \mathrm{eV},$$

Table III. Angles between charged shower particles and the jet axis.

1.94	4.05	8.15			

the errors estimated above being merely statistical.

According to the theory of the multiple meson production by Landau[4] or Fermi[5], the relation between the multiplicity and the the energy of primary particle of mass number A is given by[6]

$$n_s=2Al\sqrt{\gamma_c}\ , \qquad (3)$$

where l is the ratio of the length of column in target nuclear matter to that in incident nuclear matter. In the present jet l is estimated as 2.1 if A is 1 and as 1.0 if A is 2. Therefore, three nucleons are considered to be involved in the collision. Then, the energy of incident particle will be

$$E_0=2l\gamma_c^2Mc^2=10^{14}\ \text{eV}\ .^{7)}$$

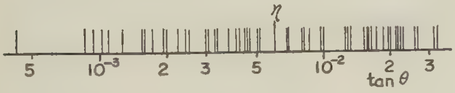

Fig. 4. Tan θ plot of charged shower particles.

§ 4. Multiplicity and Ratio of Numbers of Neutral and Charged Particles

The number of the shower particles obtained from the above-mentioned observations is shown in Table IV. In this table "charged" contains not only $\pi^{\pm}$-mesons but also the more heavy particles, *i.e.*, "x-particles" as mentioned by the Bristol group.[8] The ratio of the number of π^0-mesons to that of $\pi^{\pm}$-mesons plus x-particles is shown in the last row of the table. It will be seen that the ratio of the numbers of neutral and charged particles emitted in both the inner and outer cones is 0.45, in agreement with the results hitherto obtained. However, it is to be noticed that the said ratio in the inner cone is somewhat less than that in the outer cone.

Table IV. Number of shower particles and ration of numbers of neutral and charged particles.

	inner cone	outer cone	total
charged	26	27	53
π^0	7	17 (31 cascades)	24
total	33	44	77
$\dfrac{\pi^0}{\pi^{\pm}+x^{\pm}}$	0.27	0.63	0.45

§ 5. Angular Distribution of the Shower Particles

If we transform the angle θ in the L. system, which the shower particle makes with the jet axis, to the angle $\bar{\theta}$ in the C. M. system by the use of the relation:

$$\gamma_c \tan\theta=\tan(\bar{\theta}/2)\ , \qquad (4)$$

the angular distribution in the C. M. system of the charged shower particles and π^0-mesons emitted in the inner cone becomes as shown in Fig. 5 (a) and (b).

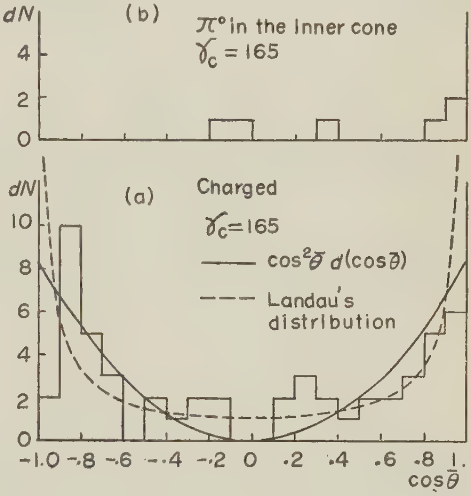

Fig. 5. The angular distribution of shower particles in the C. M. system.
(a) Charged secondary particles
(b) π^0 in the inner cone

Following B. Edwards *et al.*[8], this angular distribution may be represented approximately by an expression $\cos^m\bar{\theta}d(\cos\bar{\theta})$, with m positive even integer, and a convenient parameter specifying the degree of anisotropy is $(\text{cosec}\ \bar{\theta})_{\text{av.}}$, which for the above expression becomes

$$(\text{cosec}\ \bar{\theta})_{\text{av.}} \simeq 1.25\sqrt{m} \qquad (\text{for large } m).$$

In our jet m is nearly equal to 2, so that the anisotropy is of rather low degree in comparison with that obtained by other authors for such a high energy collision. The angular distribution is also compared with that given by Landau's theory in Fig. 5 (a), by normalizing the total number of mesons with the experimental values.

The integral angular distribution in the L. system for charged shower particles is shown in Fig. 6 by plotting $\log[F(\theta)/\{1-F(\theta)\}]$

against los $(\gamma_c \tan\theta)$, where $F(\theta)$ is a fraction of the number of tracks with angles less than θ making with the jet axis.[9] It will be seen that a straight line with slope 1.3 fits the observed values fairly well. In this connection it may be noted that in a similar representation, the isotropic distribution in the C. M. system is expressed by a straight line with slope 2,[10] while in the extremely anisotropic distribution of Heisenberg a straight line has slope 1.[11]

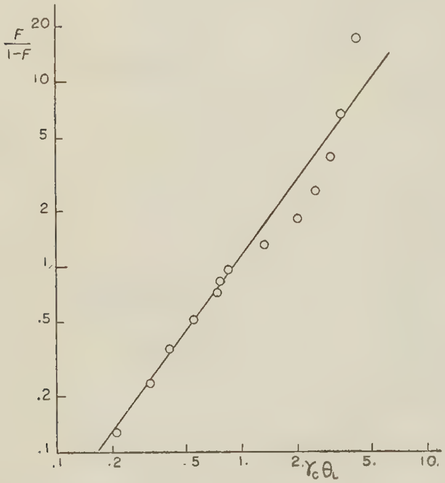

Fig. 6. $\log [F(\theta)/\{1-F(\theta)\}]$ *versus*. $\log \gamma_c \tan\theta$ plot of charged particles.

Also, it is found that the integral distribution in cosec $\bar{\theta}$ for charged shower particles is represented by a relation of the form $N(>\operatorname{cosec}\bar{\theta}) \propto (\operatorname{cosec}\bar{\theta})^{-2}$. This implies that the differential momentum spectrum of the shower particles subject to the assumption $P_T =$ const. is, on the average, of the form dP/P^3. This result does not agree with the form dP/P^2 as assumed by Heisenberg[12] and the experimental results obtained by the Bristol group[8] as well as an estimation made by S. Hasegawa *et al.*[13] Further, it is found that as shown in Fig. 7, the differential momentum spectrum falls off fairly rapidly with increasing pion energy as in the form dP/P^4 from the point at which the momentum of pion is about 0.8 GeV/c.

§ 6. Energy Estimation of the Shower Particles

The energy of π^0-mesons emitted in the inner cone can be determined in the same way as in our previous experiment[1] and the results obtained are shown in Table I. The energy for charged particles was estimated assuming that their transverse momenta P_T are all of the same value 0.38 ± 0.02 GeV/c as obtained for π^0-mesons in our previous experiment cited above. For π^0-mesons emitted in the outer cone the total energy was estimated as the total sum of energies of γ-rays produced by the decayed π^0-mesons, using the result that their transverse momenta $P_{T\gamma}$ are one half of those of π^0-mesons, namely $P_{T\gamma} = 0.19 \pm 0.01$ GeV/c.[8] The ratio of the energy of neutral particles to that of charged ones in the L. system was calculated using the values above estimated. The results are shown in Table V, where $E_{\pi^\pm}$ denotes the total enrgy of the π^+- and π^--mesons and E_{charged} is that of all the charged particles, which was

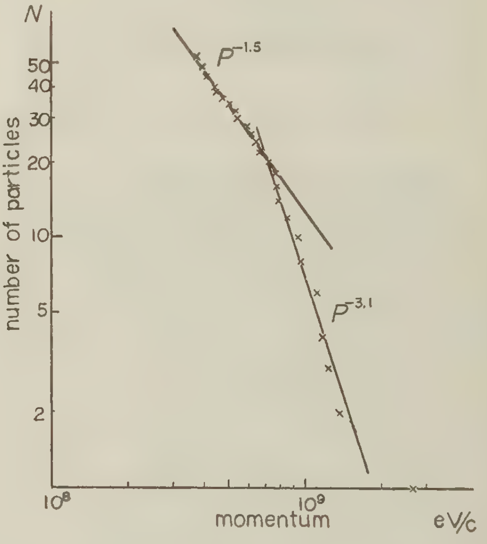

Fig. 7. (a) Integral momentum distribution of charged shower particles in the C. M. system.

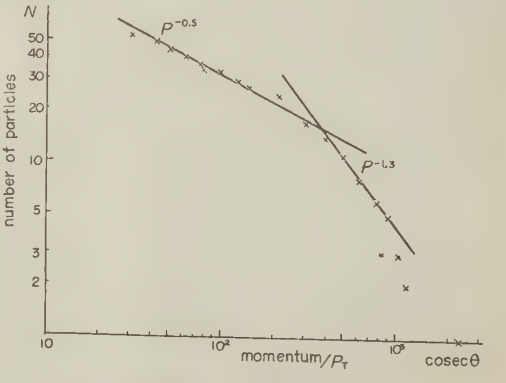

Fig. 7. (b) Integral momentum distribution of charged shower particles in the L. system.

Table V. Energy in GeV of secondary particles.

In the C. M. system

	inner cone	outer cone	total
charged	20.3 ±4.1 (12.8±2.8)	15.1±3.0 (9.71±2.16)	35.4±5.1 (22.5±3.6)
π^0	4.25±1.74	4.25*±1.74	8.5*±2.5
total	24.55±4.4 (17.05±3.33)	19.35*±3.47 (13.96*±2.77)	43.9*±5.6 (31.0*±4.4)

In the L. system

	inner cone	outer cone	total
charged	5460±1098 (3030±673)	727±145 (645±143)	6187±885 (3675±588)
π^0	1198±76	339±63	1537±90
total	6658±1101 (4228±677)	1066±158 (984±153)	7724±890 (5212±596)

Here, errors indicated are merely statistical.

The ratio of the energy of neutral particles to that of charged ones in the *L.* system.

	inner cone	outer cone	total
E_{π^0}/E charged	0.22	0.47	0.25
$E_{\pi^0}/E_{\pi^\pm}$	0.40	0.53	0.42

calculated by regarding them as pions. In this table, the value in parentheses are those calculated for the shower particles by excluding x-particles, being 20 per cent of all the particles, emitted forwards and backwards near the axis in the C. M. system. Also, the values with asterisk are those estimated under a conventional assumption that for the same kind of particles the energy emitted in the outer cone in the C. M. system is equal to that emitted in the inner cone.

As will be seen from the table, the values of the ratio $E_{\pi^0}/E_{\pi^\pm}$ in the inner and outer cones are nearly equal to each other, namely ~0.4 and ~0.5 respectively. It is to be noted, however, that the values of the ratio of the total energy of π^0-mesons to that of all the charged particles, including x-particles, $E_{\pi^0}/E_{\text{charged}}$ are different, being ~0.2 for the inner cone and ~0.5 for the outer cone. These results seem to suggest that both the percentage here adopted for the x-particles, *i.e.* 20 per cent, and their angular distribution are not far from reality.

§ 7. Inelasticity

The inelasticity coefficient, K', defined as the ratio between the total energy of secondary particles and the kinetic energy of nucleons before collision in the C. M. system assuming all the shower particles as pions, was estimated in three different ways:

(1) Thus, in the first place, by making use of the fact that the transverse momentum P_T of pions is constant and assuming charge independence in meson creation, the value of K' was estimated by the formula:

$$K' = \frac{1.5\, P_T \times \Sigma \operatorname{cosec} \bar{\theta}}{2\gamma_c},$$

obtaining the result that $K' = 0.16 \pm 0.03$.

(2) Secondly, estimating the energy of charged pions by the same method as above as well as the energy of neutral pions from the analysis of cascade showers developed from γ-rays which decayed from them, the value of K' was determined, and it was found that $K' = 0.13 \pm 0.02$.

(3) Thirdly, the value of K' was also estimated by estimating, by the same method as in the second case, the energies of charged pions as well as of neutral pions emitted only in the inner cone, obtaining the result that $K' = 0.15 \pm 0.03$.

On the other hand, the value of the inelasticity coefficient K'', i.e., a fraction of the available energy radiated as points, was calculated, assuming that 20 per cent of the secondary particles are x-particles and are emitted with the smallest forward and backward angles in the C. M. system. It was thus found that $K'' = 0.10 \pm 0.02$, 0.09 ± 0.02 and 0.10 ± 0.02 corresponding to each K' in the above three cases respectively.

The values of K' and K'' in reference to the L. system were also calculated, obtaining the result that

$$K_L'=0.14\pm0.03,\ K_L''=0.10\pm0.02\ .$$

It is seen that the values of K' and K_L' determined in the above four different ways are in good agreement with each other, and similar situation can be found in the values of K''.

Since the transverse momentum P_T of x-particles is estimated to be 1.8 ± 0.5 GeV/c and according to the results of the Bristol group[8], the number of x^0-particles is 1.25 ± 0.5 times as large as that of charged x-particles, the energy of various particles in reference to the C. M. system are calculated as follows:

Energy of $\pi^\pm$: $22.5\pm\ 3.6$ GeV .
Energy of $x^\pm$: 60.7 ± 24.7 GeV .
Energy of x^0 : 75.8 ± 43.2 GeV .
Energy of π^0 : $8.5\pm\ 2.5$ GeV .

Total : 167.5 ± 50.0 GeV .

Thus, the value of the inelasticity coefficient K, *i. e.*, a fraction of the energy radiated as secondary shower particles, becomes 0.51 ± 0.17.

Also, in reference to the L. system we find that

energy of $\pi^\pm$: $(\ 3.68\pm0.59)\times10^3$ GeV ,
energy of $x^\pm$: $(11.94\pm4.86)\times10^3$ GeV ,
energy of x^0 : $(14.92\pm8.50)\times10^3$ GeV ,
energy of π^0 : $(\ 1.54\pm0.09)\times10^3$ GeV ,

total : $(32.08\pm9.81)\times10^3$ GeV .

Therefore, the value of the inelasticity coefficient K_L in reference to the L. system corresponding to the above K becomes 0.59 ± 0.20. All the errors estimated in this section are merely statistical.

Judging from the above results it may be considered that fairly appropriate and reliable values for K'' and K are respectively

$K''\sim0.1$ for pions only,

$K\sim0.5$ for all the secondary particles.

All the above values of the inelasticity coefficients have been calculated assuming that the event is caused by a nucleon-nucleon collision. However, in case when the value of l is 2 and the target is a nucleus with two proton mass, each of the above values should be divided by 2. In this case the comparatively reliable values of K'' and K are respectively

$$K''\sim0.05,\quad K\sim0.3\ .$$

§ 8. Conclusion and Discussion

The results of our present experiment may be summarized as follow:

(a) A jet found in one of the emulsion chambers has 53 shower particles and 24 π^0-mesons created in the interaction, and the ratio R of neutral to charged particles is 0.45.

(*b*) The value of γ_c is 165, and the incident energy in the L. system is $(5.10^{+1.83}_{-1.14})\times10^{13}$ eV when the event is assumed to be due to a nucleon-nucleon collision.

(c) The angular distribution is anisotropic in the C. M. system and agrees to some degree with Landau's distribution. The indication of anisotropy is as follows:

(i) If we approximate the angular distribution in the C. M. system by an expression $dn=\cos^m\bar{\theta}d(\cos\bar{\theta})$, the value of m becomes 2.

(ii) In the L. system, the slope of a straight line obtained by plotting $\log[F/(1-F)]$ against $\log(\gamma_c\theta)$ is 1.3.

(d) The differential momentum distribution of secondary particles in the C. M. system is, on the average, of the form dP/P^3, and it falls off sharply with increasing pion energy in the form dP/P^4.

(e) The inelasticity coefficients estimated are respectively as follows:

$K'=0.15$	regarding all shower particles as pions,
$K''=0.1$	for pions only,
$K=0.5$	for pions plus x-particles.

(f) The value of l in Eq. (3) is 2.

It was shown by previous experiments by the Bristol group[8] and other workers[14,15] that in general the higher is the energy of the primary particle of the nuclear collision, the larger the degree of anisotropy of the angular distribution. It is interesting to note, however, that although our jet is of high energy (5×10^{13} eV), the degree of anisotropy is comparatively small as indicated by the results that the value of m is 2 and the slope of the F-plot is 1.3. Further, it is to be noted that as indicated by the result that the value of l is 2, the present jet has high multiplicity for its energy, and is not considered to be an event caused by a single nucleon-nucleon collision.

The value of the inelasticity coefficient K is nearly 0.5, but not unity as suggested by the theory of Fermi[5] or Landau[4], in spite of taking account of an appreciable error in the results by the Bristol group on x-particle. By adjusting the value of P_T of x-particles it is able to make the value of K unity, but the adjusted value of P_T of 25 x-particles (charged: 11 and neutral: 14) is, on the average, as high as 4 GeV/c. Judging from the results by the Bristol group, however, it is not reasonable to consider that all the x-particles have such a high P_T as 4 GeV/c. Therefore, about one half of the incident energy may be carried away by a nucleon or nucleons involved in the collision, or may not contribute to the collision.

These experimental results do not agree with the theory of Fermi or Landau as to the inelasticity coefficient K, but they are considered to be in fairly good agreement with Landau's theory in respect of the angular distribution in the C. M. system of shower particles. It will be important to compare the experimental results with various theories by using the parameters essential to the theories. This can be done when more experimental results will be accumulated and one can then clarify what is really essential to a particular theory.

Acknowledgement

The author wishes to express his hearty gratitude to Professor K. Kimura and Professor O. Minakawa for their sustained interest and encouragement throughout the course of the present work. His sincere appreciation and thanks are also due to Professor S. Tokunaga and Miss. T. Ishii for their cooperative efforts, and to the staff of the Institute for Nuclear Study, University of Tokyo, and the Emulsion Research Group in Japan for making the balloon flight possible.

This work was financially supported by a grant-in-aid for scientific research of the Ministry of Education for the 1956 fiscal year.

An Experimental Investigation on the Mode of Slip in Face-Centered Cubic Metals

By Tadami TAOKA*, Kō YASUKŌCHI, Ryūkichi HONDA*
and Isao ŌYAMA**

Department of Physics, Faculty of Science, University of Tokyo

(Received January 8, 1959)

The changes of saturation of magnetization of the ordered Ni_3Mn and Pt_3Co alloys caused by plastic deformation were used as the criterion to decide whether the slip in metals is "homogeneous" or "inhomogeneous", i.e., whether it takes place in atomic steps on many successive atomic planes or in large steps on widely separated single atomic planes. It was found that in the ordered Ni_3Mn alloy, the saturation magnetization decreases with the amount of elongation at room temperature, while in the ordered Pt_3Co alloys, the intensity of magnetization at temperature near the Curie point increases with the amount of compression. These changes, which are roughly proportional to the amount of deformation, are probably understood only from the point of view that new disordered regions with Curie point different from that of the ordered state are produced during the deformation, being associated with homogeneous slip on successive atomic planes.

§ 1. Introduction

During recent years, following the original work of Heidenreich and Shockley[1] which was undertaken to get a clear understanding of slip mechanism within crystals, many observations on the surface structures of deformed metals have been accumulated by Brown,[2] Kuhlman-Wilsdorf and Wilsdorf,[3] Thomas and Nutting,[4] Seeger et al.[5] and others.[6] They are mainly concerned with the dependence of the fine structures of slip bands on the stages of deformation, the alloying elements of the specimen, and temperature. In the above investigations, it has been usually presupposed that the slip, in the course of slip band formation, takes place in large steps on single atomic planes separated by laminae of undeformed regions. In the following, the term "inhomogeneous" slip will be used for the slip on widely separated single atomic planes, as schematically shown in Fig. 1 (a). This assumption has been supported by Mott's theoretical description[7] given of the edge and screw dislocation net-works on {111} planes in a face-centered cubic lattice. These net-works lead to an account of Frank-Read sources multiplying dislocations in single atomic planes. Recently H. Wilsdorf and J. T. Fourie[8] succeeded in showing directly by an electron microscope using high resolution replica techniques that there does not exist angular difference between the slip plane and the surface exposed within the slip zones. This result might be doubtless so far as concerned with the slipbands on the surface of deformed α-brass.

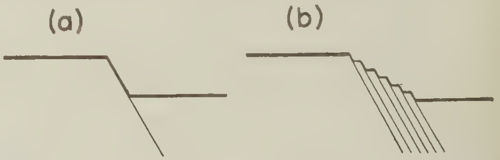

Fig. 1. Two schematical modes of slip: (a) "Inhomogeneous" slip on one plane. (b) "Homogeneous" slip on a number of neighbouring planes.

On the other hand, Yakutovitch et al.,[9] who repeated the work of Heidenreich and Shockley on aluminium, failed to confirm their results. They arrived at a conclusion that each elementary slip band is a region of finite width in which localized deformation of the amount of order of one atomic distance per successive slip plane is concentrated. This type of slip is called "homogeneous" slip which is schematically shown in Fig. 1

(b). H. Suzuki and F. E. Fujita[10] observed the fine surface structures of α-brass before and after cold-work by electron microscope and were also led to the same view. T. Suzuki and H. Suzuki[11] have pointed out that Frank-Read sources on {111} planes multiplying dislocations on only one atomic plane proposed by Mott seem to be very rare as compared with those on {113} planes multiplying dislocations in successive atomic planes. They also pointed out that the surface structures of deformed crystals might be produced rather by the operation of the surface sources which are different from those in the interior of metals.

Brown and Honeycombe[12] and others have experimentally shown that the slip structure observed on specimen surface depends on the difference of surface structures obtained after various preparations of the surface. These results are summarized in "Surface Effect in Plastic Deformation of Metals" by Brown.[12] There remains more or less a distorted layer after mechanical polishing, an oxide layer after an electropolishing and a fine surface structure after chemical polishing. The slip structures on the crystal surfaces sensitively depend on these surface structures. It is extremely difficult to decide whether any one of different observations described above reveals the true state of affaiars in the interior of crystal or not. It will be necessary to develope the techniques other than the surface observations to understand the correct process of slip in the interior of crystals. The experiment of Blewitt and Koehler[14] on slip in ordered alloy Cu_3Au seems hopeful to get some answer on the slip mode in the interior of crystals. The significant point of this work is that the disordering process in deformation is a direct result of atomic slip. The residual resistance was used as the criterion of the order and it was found possible to calculate the degree of order in a semiquantitative way. The result shows that there are three stages of deformation and it can be understood by using the same mechanism of slip as that proposed by Heidenreich and Shockley, namely an inhomogeneous slip. In spite of their good idea, we are doubtful of their conclusions because the assumptions presupposed in their calculations are too simple to deduce their results. Moreover, the electric resistance is structure sensitive and depends not only on the degree of order but also on the various types of lattice defects which would be introduced during the cold work.

Now, we will focus our attension to make clear which mode of slip actually takes place inhomogeneous or homogeneous slip. It is likely that the spontaneous magnetization of ferromagnetic order-disoder alloys is a favourable physical quantity to decide the mode of slip, because it is structure insensitive. For this purpose we have picked up two alloys, Ni_3Mn and Pt_3Co of which the saturation magnetization largely depends on the degree of order. In case of Ni_3Mn,[15] it is ferromagnetic in ordered state, but is paramagnetic in disordered state at room temperature, while Pt_3Co is paramagnetic in ordered state and ferromagnetic in disordered state at room temperature, as is recently found by Simpson and Tredgold.[16]

Let us consider the changes of spontaneous magnetization produced during the deformation of these ordered alloys in both cases of slip modes. In homogeneous slip, the saturation magnetization of Ni_3Mn will gradually decrease, while that of Pt_3Co will increase, with a formation of slip bands which are assumed as the disordered regions. On the other hand, in inhomogeneous slip, any appreciable change might not be expected in both alloys. Then this circumstance will be utilized for the criterion whether the slip mode is "homogeneous" or "inhomogeneous".

§ 2. Specimens and Experimental Methods

2.1 Ni_3Mn

The materials investigated were prepared by melting together electrolytic nickel and electrolytic manganese in vacuum and the alloys were drawn to a wire of 1.0 mm in diameter after a homogenizing heat treatment at 1200°C for 6 hours. It was cut in rods of 200~250 mm length and further annealed at 1200°C for 2 hours to remove the mechanical strain, and then they were sealed in evacuated quartz tubes. Different states of order of this alloy were obtained by quenching, in a course of slow cooling, from 600°C (disorder), 460°C, 400°C (intermediate order) and by slow cooling to room temperature (perfect order), following the suggestion by S. Kaya.[15] As a measure of ordering, the electrical resistance and saturation magnetization measured at room temperature are tabulated in Table I. After these heat treatments, the alloy was chemically analysed and was found to be about 1% richer in nickel compared with the stoichiometric composition Ni_3Mn. The size of grains was larger than the diameter of rods. The specimens were carefully electropolished to produce a clean surface before extension of them. They were extended up to several percent at a rate of one percent per second. After various stages of elongation, the magnetization curves and saturation magnetization were measured by the usual ballistic method at room temperature.

Quenching Temperture, °C	600	460	400	20
Electrical Resistivity, Ω-cm	72.7	42.7	26.6	19.8
Saturation Magnetization, gauss/cc	30	699	852	916

2.2 Pt_3Co

The alloy was prepared by melting together the known amounts of pure (99.99%) platinum and (99.99%) cobalt in vacuum to give the Pt_3Co composition. The alloy was cold-rolled after a homogenizing annealing at 1200°C and was cut into the form of rectangular parallelepiped, about 2 mm × 2 mm × 4 mm. The polycrystalline specimens were sealed in evacuated quartz tubes, and annealed at 1200°C for 2 hours and some of them were quenched into cold water. These specimens were at the disordered state. An intermediate state of order was obtained by quenching the specimens from 600°C, in the course of slow cooling from 800°C to room temperature for 18 days. The electrical resistivity and saturation magnetization of these specimens measured at room temperature are tabulated in Table II.

For the purpose of slip formation within the specimens, they were compressed up to several percent at a rate of one precent per second. To measure their saturation magnetization in the temperature range from liquid oxygen temperature to 400°C, a modified Domenicali type magnetometer was used. The details of this apparatus will be described elsewhere.[17] The saturation values of magnetization of specimens with various stages of deformation were measured in a magnetic field of 7500 Oe. The values were actually found to be independent of the field strength between 4100 Oe and 8900 Oe. The temperature of specimens could be changed up to room temperature in an evacuated quartz tube which was initially immersed into liquid oxygen. For the measurements at higher temperatures, the liquid oxygen vessel was replaced by an electrical furnace. The heating rate was about 2°C per minute through the whole temperature range.

§ 3. Experimental Results and Discussions

3.1 Ni_3Mn

Some examples of magnetization curves are shown in Fig. 2, which represent the variation of magnetization as a function of reciprocal of field, I/H, for the specimens quenched from 460°C. They can be represented by straight lines in the range of considerably large field, namely a simple from $I=I_s(1-a/H)$ where I and I_s are the magnetization at field intensity H and infinity respectively and a is a constant, showing the inclination of the straight line. As W. F. Brown[18] has already explained, the inclination a increases with the amount of cold work. The saturation values of magnetization I_s can be determined by extrapolating the lines to an extremely large field. As can be seen in the figure, the saturation values so determined decrease with the amount of elongation. Fig. 3 (a) shows the decrease of the saturation magnetization, ΔI_s, measured at room temperature, as function of elongation for the specimens quenched from various temperature. In Fig. 3 (b), ΔI_s is replaced by $\Delta I_s/I_s$. As can be seen in these figures, the decrease of saturation magnetization is approximately proportional to the amount of elongation in the range of extension smaller than about 6%.

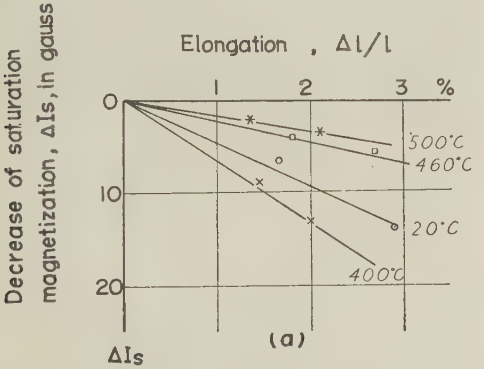

Fig. 3. Variation of decrease of saturations magnetization, ΔI_s and $\Delta I_s/I_s$, as a function of elongation. The quenching temperatures are indicated on the curves.

These results must be attributed to either a uniform decrease of ordering within the whole specimen or discrete disordered regions created by the cole work. Considering that the disordering process is a direct result of atomic slip, the latter case is reasonable, because the slip in metals is concentrated on widely spaced regions. If a lamina of crystal glide relative to its neighbour by an odd number of atomic distances, the effect is to disorder the atomic arrangement between these two neighbouring planes. Now, let us return to the slip mode. In the inhomogeneous slip, the disordering occurs only between two neighbouring atomic planes. Then one can not expect the appreciable decrease of the saturation magnetization due to cold work. Moreover, such a disordering occurs only when the slip distance is an odd number of atomic spacings. From energy consideration, such a slip seems to be rare compared with the slip of an even number of atomic spacings which does not accompany the disordering process. While, in the homogeneous slip, the disordered regions the thickness of which is more than a few hundreds A would be produced and accordingly the magnetization will decrease with the increase of the disordered region.

In the above discussion, only single dislocations are considered. However, in the ordered alloy, pairs of dislocations seem to appear and the number of them will increase with degree of order, because the slip plane is in anti-phase in either side of single dislocation being accompanied by high energy, which is reduced by the pair of dislocations. In case of pairs of dislocations, disordering does not occur as the direct results of the propagation of such dislocations. In inhomogeneous slip, the conclution mentioned above need not be changed. Moreover, even in the case of homogeneous slip, disordering process will not occur and appreciable decrease of magnetization is not expected after the cold work.

The present experimental results, i.e. the decrease of magnetization in Ni_3Mn proportional with the extension, lead to the conclusion that the slip takes place on many successive atomic planes by the movement of an appreciable number of single dislocations, even though the existence of pairs of dislocations might not be deniable. Under the extension smaller than about 3%, only one system of the slip planes within each crystal grain will be active, as was already shown by our electronmicroscopic observations.[19] In the homogeneous slip caused by single dislocations, the disordered regions and accordingly the change of magnetization as well will be proportional to the amount of elongation, in agreement with our experimental results. Moreover, the other experimental result that the decrease of magnetization caused by the cold work is larger in intermediate order than in ordered state might be explained by the facts that energy contained in anti-phase boundary is lower in intermediate order and consequently single dislocation is likely to be more probable to exist than in perfectly ordered state. The above argument leads one to believe that the slip in Ni_3Mn crystal takes place in atomic steps extending on many successive atomic planes, namely by the "homogeneous" slip.

However, there exists another factor which may affect the apparent saturation value of magnetization measured by ballistic method, that is, the deviation of shape of specimens from the ideal cylindrical from which is introduced during the cold work. It is difficult to estimate theoretically the amount of this effect. One experimental estimation of this effect is given by considering the same experiment on Ni_3Fe alloy of which saturation value scarecely changes due to the disordering (nearly 4%). The result on Ni_3Fe is indicated in Fig. 3 (b) by a mark, ⊙. The amount of this change can not be neglected, but is still small compared with that of Ni_3Mn.

Because of the difficulties to measure the absolute value of saturation magnetization more acurately, it seems favourable to assume that the distorted specimen consists of two kinds of regions with different Curie points. Unfortunately, as the magnetic intensity of the disordered Ni_3Mn alloy falls very gradually with increasing temperature, it is not easy to apply such an analysis to this case. While, in the case of Pt_3Co, the value of saturation magnetization falls so sharply with increasing temperature that one can apply this analysis. Moreover, as this alloy has higher Curie point in disordered state than in ordered state a small portion of disordered region embedded in the matrix of ordered phase gives a comparatively large contribution to total intensity of magnetization at a temperature near the Curie point of ordered state. This is a very favourable fact to our present purpose.

3.2 Pt_3Co

The magnetization-temperature curves of Pt_3Co with various stages of order are shown by full lines in Fig. 4, which were measurred at 7500 Oe from liqued oxygen temperature to 400°C using the magnetic belance described in Section 2.2. These curves are typical saturation magnetization-temperature curves for ferromagnetic substances of single phase, the Curie points of which are about 12°C, 51°C and 209°C respectivery, and these curves seem to tend the same saturation value at 0°K. The saturation value of disordered state is about 18.9 gauss/g at room temperature, while that of ordered state is about 2.5 gauss/g.

The ordered specimen was compressed by a specially devised small compressor. Fig. 5 shows the saturation magnetization-temperature curves of the ordered alloy of various stages of compression measured at temperatures near their Curie points. The differences between these curves are represented in Fig. 6. As shown in this figure, a considerable amount of difference can be seen between the curves of undeformed and deformed specimen, especially in temperature above the Curie point of the undeformed alloy. Roughly speaking, this result may be understood as a formation of new regions, of which the Curie point is higher than that of original phase, in argeement with the result on Ni_3Mn alloy.

To make clear this situation, it will be appropriate to replace Fig. 6 by Fig. 7. Fig. 7 represents the ratios of $\sigma_5/\Delta\sigma_2$ and $\Delta\sigma_8/\Delta\sigma_5$ in temperature above the Curie point of undeformed

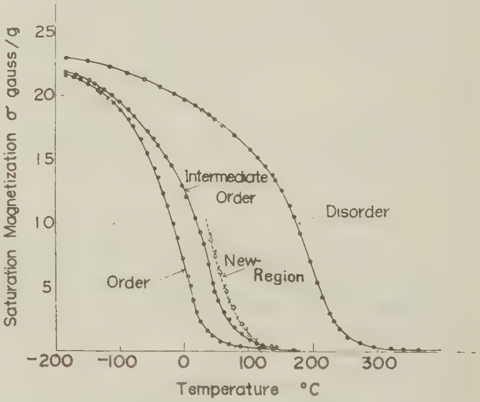

Fig. 4. Magnetization-temperature curves of Pt_3Co alloy with various stages of order. The dotted line represents the estimated curve for the new disordered region produced after slight compression; for 4% elongation and for 7% elongation.

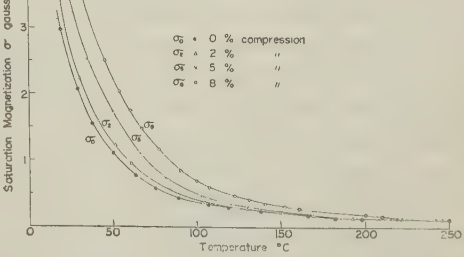

Fig. 5. Magnetization-temperature curves of the ordered Pt_3Co alloy of various states of compression near the Curie point. The amounts of compression are indicated in the figure.

formed ordered alloy, where $\Delta\sigma_2$, $\Delta\sigma_5$ and $\Delta\sigma_8$ are the differences between magnetization values of 2%, 5% and 8% compressed specimens and that of undeformed alloy respectively. As can been seen, the values of $\Delta\sigma_5/\Delta\sigma_2$ and $\Delta\sigma_8/\sigma_5$ are approximately constant over wide range of temperature. This result is reasonable quantitatively from the point of view that any amount of compression is associated with the creation of new disordered region with higher Curie point than that of the original ordered phase. The constant value 3.2 and 2.0 obtained from the figure are slightly larger than the simply expected values 5/2 and 8/5. This may be attributed to the following two factors; one is the experimental error in the measurment of amount of compression, the other is the appearance of multiplicated slip system associated with the increase of deformation.

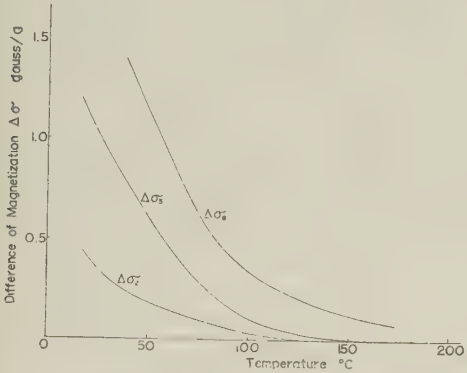

Fig. 6. Difference of magnetization between deformed specimens and undeformed one in the temperature near the Curie point for ordered state of Pt_3Co alloy. The amount of elongation are indicated on the curves.

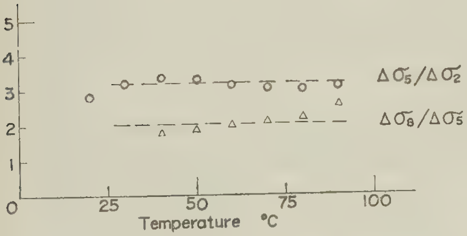

Fig. 7. $\Delta\sigma_5/\Delta\sigma_2$ and $\Delta\sigma_8/\Delta\sigma_5$ as a function of temperature.

The saturation magnetization-temperature curves of the new disordered region produced after 2% and 5% compression can be estimated and represented by a dotted line in Fig. 4. The difference between Curie points of the mechanically disordered region and that of thermally disordered phase would be reasonable because the new region is in a directional order, namely ordering in a perpendicular direction to the slip plane is broken away but that on the slip plane is maintained constant. This curve is nearly the same as one of intermediate state of order as shown in this figure. Thus the increase of magnetization of the deformed alloy may be explained due to the new disordered regions produced during the deformation where the slips take place by an amount of order of one atomic distance on many successive planes, namely by the "homogeneous" slip.

§ 4. Summary and Acknowledgment

The experimental results can be summarized as follows:

1) In the ordered Ni_3Mn alloy, of which the Curie point is higher than that of disordered state, the saturation magnetization decreases with an amount of elongation at room temperature.

2) In the ordered Pt_3Co alloy, of which the Curie point is lower than that of disordered state, the intensity of magnetization in temperature near the Curie point increases with an amount of compression.

3) These changes of magnetization are roughly proportional to an amount of deformation.

These results can be only understood from the point of view that a new disordered phase of which the Curie point is different from that of original phase is produced during the deformation, in which the slips take place by an amount of order of one atomic distance on successive plane, namely by the "homogeneous" slip.

It is great pleasure for the authors to thanks Prof. S. Kaya for his valuable suggestions, discussions and encouragement throughout this work. The authors also wish to express hearty thanks to prof. R. R. Hashiguchi, Prof. S. Chikazumi, Dr. T. Suzuki, Dr. Y. Tomono, and Dr. S. Iida for their kind discussions.

Photoconduction and Darkening of AgCl Crystals at Low Temperatures

By Noriaki Itoh

Department of Electrical Engineering, College of Engineering, Osaka University

and Tokuo Suita

Department of Nuclear Engineering, College of Engineering, Osaka University

(Received February 9, 1959)

Photocurrent of AgCl was measured using light and voltage pulses of about 50 μsec duration between −150°C and −50°C. Experimental results show that the life time of electrons has a maximum between −80°C and −110°C depending on the treatments of the samples. Darkening of the crystals was also measured at lower temperatures, showing that the darkenability increases with temperature higher than −80°C. The results were discussed with models containing sensitivity centers and recombination centers and it seems to be clear that the temperature dependence of the life time is concerned with the darkening properties of the crystals.

§ 1. Introduction

According to Gurney and Mott theory[1] on photographic processes in silver halide crystals, there are two fundamental stages in it, namely the electronic stage and the ionic stage. In the first stage, pairs of conduction electrons and holes are created by absorbing photons and these charge carriers are trapped at some trapping sites after wandering in the crystals. In the second stage, the negatively charged centers attract interstitial silver ions which combine with the trapped electrons to form silver atoms. This principle was verified by Haynes and Shockley[2], who showed that photolytic silvers were displaced by voltage pulses and showed that electrons are participating in the photolytic processes,

Gurney and Mott theory, however, explained nothing about the detailed mechanisms involved, for example, about the nature of the trapping centers nor about the behaviors of holes. In these connections Seitz[3] and Mitchell[4] gave another theories, although the principle by Mott and Gurney remained unchanged. Seitz explained that the photolytic silvers are formed at the incipient vacancies which have half charge and attract electrons and silver ions alternately. By Mitchell's theory holes are trapped with the production of interstitial silver ions and this silver ions combine with liberated electrons at so-called sensitivity centers.

In order to clarify the mechanism of photographic processes, it is necessary to study the nature of trapping centers. Although most of the features of trapped electrons and holes in alkali halide crystals have been studied by optical methods[5], these methods are not so powerful in silver halide crystals. Kaiser[6] found a peak at 375 mμ in AgCl having excess silver at low temperatures. This center changed into colloidal silver when crystals were warmed to room temperatures, and Seitz considered it to be a kind of F-center.[7]

Another method of obtaining some knowledges of trapping centers for electrons and holes is to measure photocurrent. Gilleo[8] measured photocurrent by monochromatic light after filling up trapping centers by photoemission from electrodes. His results showed that there are five bands for electrons and two bands for holes. Van Heyningen and Brown[9] have studied current glow curve of AgCl after illumination at 9°K, and showed that there are three kinds of electron traps having glow peaks at 15°K, 35°K and 170°K. It has also been cleared that photolytic silvers are formed preferentially near dislocation lines by the observation of Hedges and Mitchell[10], showing that the sensitivity centers are located near dislocation lines. In spite of these studies, the detailed nature of trapping centers have not been specified yet.

The purpose of the present investigation is to study the behavior of photoelectrons by measuring photocurrent and darkening at various temperatures. Crystals used in the present experiments were grown by Kyropoulos method in air and they may contain a certain amount of oxygen and have some effects on photoelectric and photolytic properties as pointed out by Brown[11] and Mithcell[12]. Therefore, our results may be concerned with the presence of oxygen. Studies on these points and effects of impurities are now in progress.

§ 2. Experimental Procedures

As silver chloride crystals are good ionic conductors, it should be avoided to apply them D. C. voltages, especially at higher temperatures. It also should be avoided to illuminate the crystals for overly long period to prevent their photographic reactions. Therefore, both voltage and light pulses were used for the measurement of photocurrent. The length of both pulses was about 50 μsec, and their repeatness was 30 cycles/sec.

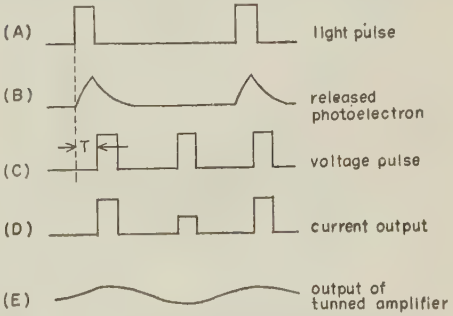

Fig. 1. Waveforms of the measuring system.

In order to obtain higher sensitivity and to measure the time response of photocurrent, we used the methods shown schematically in Fig. 1. Some devises have been made in order to separate photocurrent component from dark current and charging current component. The similar methods were utilized in the measurements of optical absorption change of gasses.[13] The crystal was illuminated by light pulses (A) (Fig. 1), having frequency of 30 cycles/sec, by which photoelectrons will be released as shown in (B). The rectangular voltage pulses (C) of 50 μsec, were applied to the specimens at a frequency of 60 cycles/sec, and the current output would be as shown by (D). The difference between the magnitude of any current pulses and the following ones coinsides with the conductivity change induced by light pulses. This difference was amplified by a narrow band amplifier, which has the center frequency of 30 cycles/sec. By changing the delay time, T, of the voltage pulses to the light pulses, the time dependence of photocurrent was also measured. Measurements were also done using 800 cycles/sec light pulses instead of 30 cycles/sec light pulses.

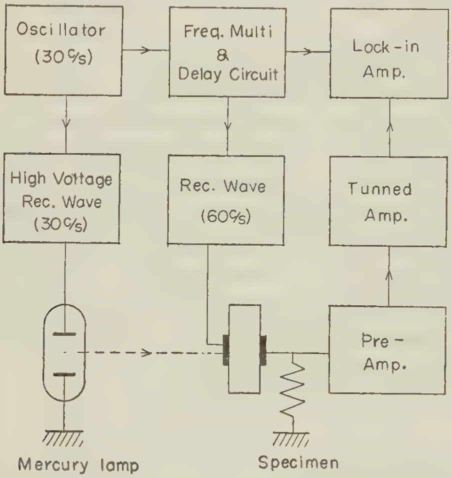

Fig. 2. Block diagram of the measuring apparatus.

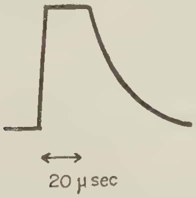

Fig. 3. Waveform of light pulses.

The block diagram of the apparatus is shown in Fig. 2. The light pulses were generated by applying rectangular high voltage pulses to a mercury arc lamp with V-V1A filter. The waveform of the light pulses is shown in Fig. 3, and its decay time constant was 50 μsec. The delay circuit between the 60 cycles/sec rectangular wave generator and the master oscillator could change the time interval between light pulses and voltage pulses. The tunned amplifier contained a rejection filter of 60 cycles/sec, so that the gain at 60 cycles/sec was at least some thousandths of that at 30 cycles/sec.

For the darkening experiments, the high pressure mercury lamp of 100 watt with V-VIA filter were used as a light source and the absorption coefficients were measured by Beckman type spectrophotometer (Shimazu, QB-50) at room temperature.

The crystals of AgCl were grown by Kyropoulos method in air. Recrystallization was repeated three or four times in order to get pure specimens. The specimens were cut from large crystal blocks. For the measurement of photocurrent the specimens were $1\times20\times20$ mm^3 plates and for the measurement of optical absorption the specimens were $1\times10\times10$ mm^3 plates. After being cut the specimens were ground by sand paper, polished on dry oil stone and washed by distilled water, which served a good optical surface. The electrode were thin silver plates made by development on the surface of the specimens with photographic developer, and through these electrodes the specimens were illuminated. The measurements were done in a vacuum cell with quartz windows.

§ 3. Experimental Results

We measured the temperature dependence of photocurrent using voltage and light pulses, the results of which are shown in Fig. 4. In this case every light pulses were superimposed on the voltage pulses, and there was no delay between the light pulses and voltage pulses. These results did not depend on the duration of both voltage and light pulses, showing that they are free from space charge effects.

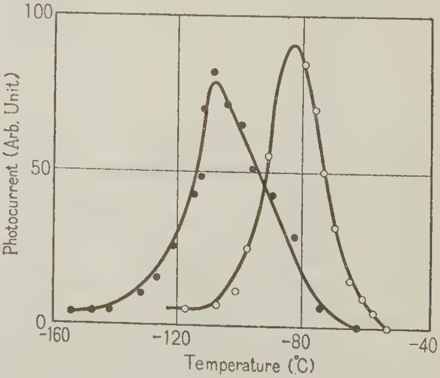

Fig. 4. Temperature dependence of photocurrent of AgCl measured by light and voltage pulses of 50 μsec duration. Applied voltage, 650V/cm; —○—○— with specimens not pre-illuminated; —●—●— with specimens pre-illuminated for 30 min at room temperature.

They also did not depend upon the repeatness of both pulses except at the lowest temperatures where decay time constant of photocurrent is near the time interval of voltage pulses (Fig. 7). As shown in Fig. 4, the photocurrent temperature curve takes a maximum and the temperature of the maximum photocurrent shifts to lower temperature side by pre-illumination at room temperature. In the case of virgin specimen the photocurrent takes a maximum at about −80°C, and this results are almost reproducible during several runs as long as the measurements were limited below −50°C. But in order to avoid the complication due to changes of the results during the measurements for virgin specimens, we used the specimens pre-illuminated for 30 minutes at room temperature in the following measurements of photocurrents.

As the photocurrent depends on the quantum yield of free electrons and holes formation η, mobility of electrons μ, and mean life time of electrons τ as $i=Ie\eta\mu\tau$ (holes are not expected to move), where I is the number of incident photons per second, it is necessary for us to know which factors are the most important to explain the photocurrent temperature curve shown above. Therefore, the voltage current curve were measured at several temperatures, the results of which are shown in Fig. 5. From these curves the Schubweg of electrons[14] $w=\mu\tau$ can be calculated. At −106°C we obtained the Schubweg of 5×10^{-4} cm^2/volt and from which we get the life time of 5×10^{-6} sec using the mobility of 100 cm^2/volt sec.[15] The Schubweg at −80°C and −128°C is about one tenth of the value at −106°C, showing that the Schubweg takes a maximum near −108°C. We can conclude qualitatively from these results that the temperature dependence of the photocurrent is determined mainly by the temperature dependence of Schubweg and not of quantum yield.

It can be shown that the dependence of mobility on temperature obtained by various authors[15] is quite small comparing with that of photocurrent obtained by us. Therefore the rapid change in photocurrent with temperature seems to be almost entirely due to

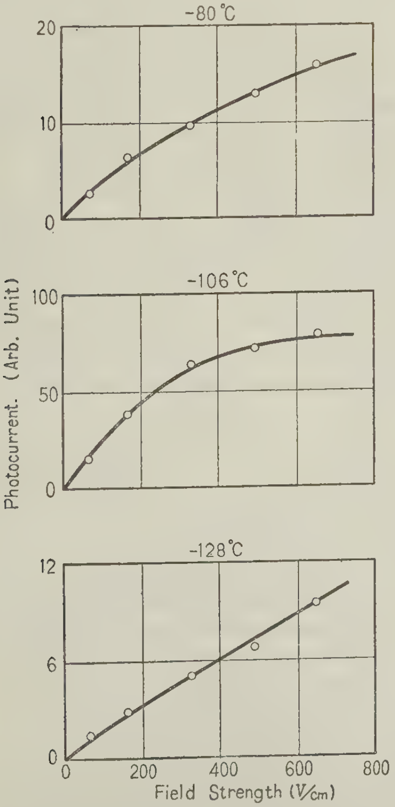

Fig. 5. Photocurrent vs. field strength measured with light and voltage pulses

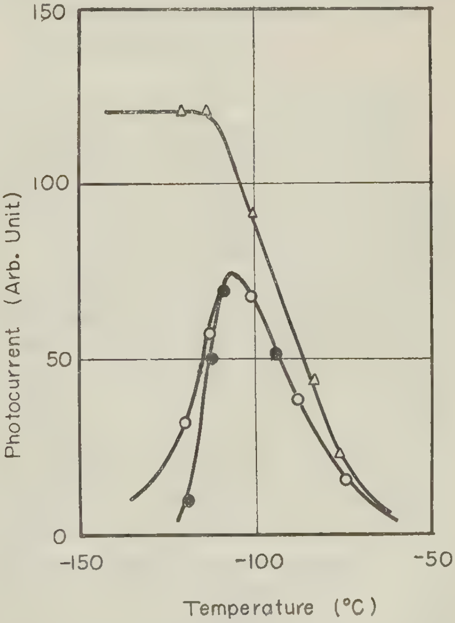

Fig. 6. Effect of continuous illumination on pulse photocurrent: —○—○—, without continuous illumination; —●—●—, with continuous illumination of 600 mμ; —△—△—, with continuous illumination of 400 mμ. Applied pulse voltage, 650 v/cm.

the change of life time of electrons with temperature.

In order to get some knowledges about the nature of the trapping centers which may cause such a temperature dependence of photocurrent, measurements were done on the change of pulse photocurrent due to constant illumination. These additional illumination may vacant the trapping centers if its wavelength corresponds to the energy depth of trapping centers, and may fill up the trapping centers if its wavelength corresponds to the energy of the forbidden gap. The effect of additional continuous illumination are shown in Fig. 6. The additional light was illuminated from the side wall. Photocurrent due to continuous illumination can be discriminated from that due to light pulses because the amplifier is sensitive only to 30 cycles/sec signals. When the wavelength of continuous light was 400 mμ, the photocurrent increased at lower temperatures and showed no maximum. When it was near 600 mμ, the photocurrent decreased a little at lower temperatures.

The decay characteristic of photocurrent was also measured at several temperatures, the results of which are shown in Fig. 7, where the abscissa is the time interval T between voltage pulse and light pulse (see Fig. 1). At higher temperatures than −108°C the decay time constant was lower than 50 μsec. However, at −120°C the decay time constant was about 1 msec. Measurements were also done on the build-up of photocurrent by 1 msec light pulses and obtained the results showing slow build-up at lower temperatures than −108°C.

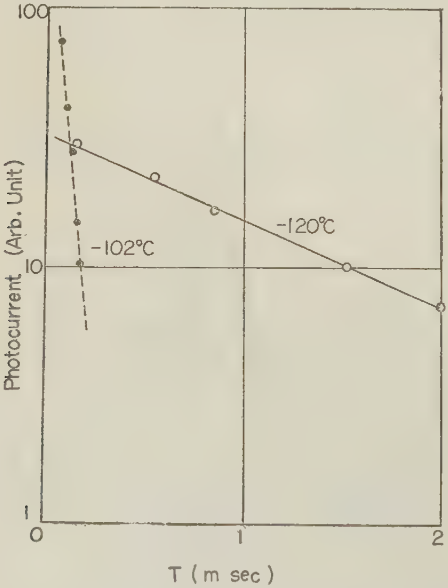

Fig. 7. Decay curve of photocurrent after light pulses. T, time difference between light pulses and voltage pulses; applied voltage, 650 V/cm (The result at −102°C is shown by a dotted line because it is the same as the decay of light pulse)

In the case of photographic film, it was shown that photographic sensitivity increased rapidly with increasing temperature.[16] It is interesting to know if there are any relations between the photocurrent-temperature curve and the temperature dependence of the rate of formation of photolytic silver in silver chloride crystals. In order to examine the rate of formation of photolytic silver with various temperatures, the change of absorption coefficient at room temperatures were

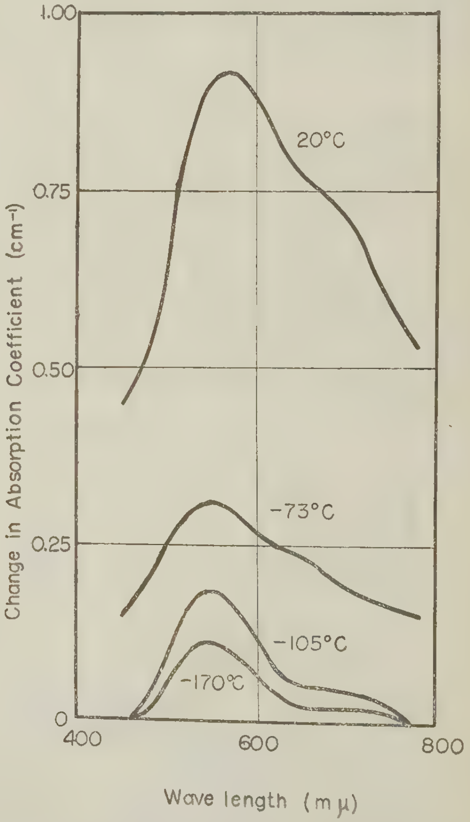

Fig. 8. Change of absorption coefficient measured at 20°C, after low temperature illumination. Illumination was done from lower temperature subsequently, that is, −170°C, −105°C, −73°C, and 20°C.

measured after illuminations at lower temperatures. Wainfan[17] showed that optical absorption changes did not occur by illumination at −100°C, but they occured after warming to room temperature by our results. It may be possible because silver ions will be attracted to trapped electrons during warming up. In Fig. 8 the change of absorption coefficient after subsequent illumination from lower temperatures for virgin specimens is shown. The results for 20°C are just the same as Wainfan's results, but for lower temperature illumination the peak is rather narrow. Fig. 8 shows that at higher temperatures than −73°C the change of absorption coefficient due to illumination becomes considerable although at −105°C it was just the same as that at −170°C. It may be concluded from this results that the formation of photolytic silver becomes considerable at higher temperatures than −80°C.

In order to know the concentration of sensitivity centers, it is useful to investigate the relation between the darkening and the illumination period at low temperatures. At low temperatures only a few silver atoms are formed in each sensitivity centers because Ag^+ ions move very slowly in these temperatures. As shown in Fig. 9 the absorption change is independent on the illumination period more than 1 hour illumination, which seems to indicate that all sensitivity centers are filled up by about 1 hour illumination at −170°C. From the absorption curve for three hours illumination we can estimate* the concentration of sensitivity centers by Smakula's formula[18], getting the value of the order of 10^{16}, if we take the oscillator strength about 0.1.

§ 4. Discussion

As explained in the previous sections, it seems to be clear that the abrupt change of photocurrent observed in the present experiments seems likely to be due to the temperature dependence of life time of electrons. We are going to discuss the nature of the trapping centers in silver chloride crystals from the experimental results obtained.

The types of trapping centers which we should take into consideration are as follows;
(1) shallow trapping centers, the depth of which is comparable with kT,
(2) recombination centers in which recombination of electrons and holes occurs, and
(3) sensitivity centers in which photographic silver are formed.

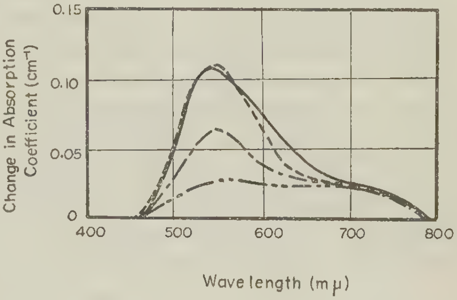

Fig. 9. Change of absorption coefficient measured at 20°C, after illumination at −170°C. ———, 3 hours illumination; - - - - -, 1 hour illumination; —·—· 10 min. illumination; and —··—··, 2 min. illumination.

In discussing our results it should be noted that we are measuring by repeated light pulses whose interval was about 30 msec. By each pulse, photoelectrons are released which will be trapped at several kinds of trapping centers within less than 10 μsec. These trapped electrons will redistribute themselves in the following time interval, and photocurrent for the next light pulse is dependent upon the number of vacant trapping centers at the start of the light pulse. As the measurement was done after the steady state was established, the magnitude of our photocurrent depends upon the rate of neutralization of trapped electrons.

It seems clear that the increase of photocurrent with temperature can be explained by the presence of shallow trapping centers as discussed in the case of alkali halide[19]. At lower temperatures electrons trapped by these centers can hardly be released from them within the termination of light pulse, whereas at higher temperatures they are released instantaneously by thermal agitation which serves to increase the photocurrent. This consideration is consistent with the results of decay time measurement; decay time is long when the thermal release occurs slowly. The depth of shallow trapping centers from the conduction band bottom is estimated to be about 0.3 eV, if we assume that the frequency factor is about 10^{13}.

---

* It is not clear that the Smakula's formula are applicable to the case of this center. However it seems reasonable that the equation can be used for order estimation, if we consider the facts obtained by F. C. Brown and N. Wainfan[17] that the absorption band due to the coloration at room temperature can be bleached by illuminating the crystal by the light near the peak of the band. Moreover, the center causing the absorption peak of Fig. 9 seems to be composed of a few silver atoms because the illumination was done at low temperatures.

The decrease of photocurrent with temperature has not been reported in other insulating crystals. In semiconductors such as CdS these phenomena were observed[20]. It can be explained if we assume that the number of effective trapping centers for electrons increases with temperature. In the case of CdS these phenomena are explained by the increase of recombination velocity of free electrons and holes with increasing temperature. In extremely low temperatures holes are trapped by shallow hole traps which can trap only holes. Therefore, recombination do not occur, and recombination center are all filled with electrons during the measurement. With increasing temperature the trapped holes begin to be released thermally and recombine with electrons at recombination centers. Thus the rate of trapping electrons at recombination centers increases with temperature.

The explanation above may be applicable in the case of silver halide crystals. We can, however, make another explanation taking sensitivity centers into consideration. It is suggeseted by the theory of photographic sensitivity that the photographic silvers are formed by the neutralization of trapped electrons by interstitial silver ions at sensitivity centers. With increasing temperature the mobility of silver ions increases and the formation of photographic silver occurs with higher rate. As sensitivity center can trap electrons again after neutralization, the photocurrent will decrease with temperature because the number of effective trapping centers increases with increasing temperature.

Energy diagram for the both explanation are shown in Fig. 10. In any case we should assume the existence of deep lying centers besides the shallow trapping centers, which are filled with electrons generated by successive light pulses at low temperatures. In our measurement by repeated voltage and light pulses, it takes several seconds to reach a stational value of photocurrent after illumination is begun. This fact supports the existence of such deep lying trapping centers. Another evidence of such trapping centers is given by the results of Fig. 6. The fact that the photocurrent decreases by the illumination with 600 mμ light at lower temperatures shows that these trapping centers are filled at lower temperatures. These phenomena occur by the illumination near 600 mμ, so that the depth of these centers can be estimated near 1.5 eV below the conduction band.

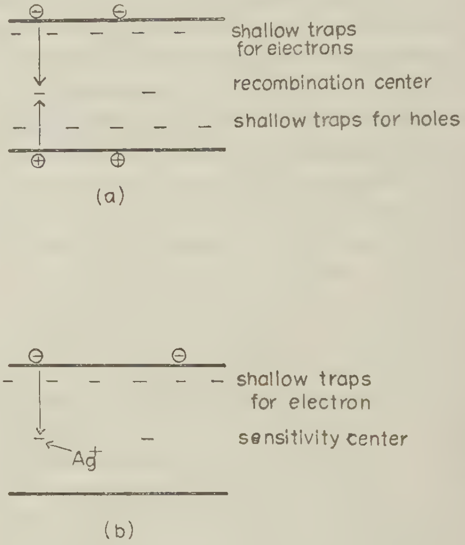

Fig. 10. Energy diagram of models, containing (a) recombination centers and (b) sensitivity centers.

The effect of illumination with 400 mμ light can be explained considering shallow trapping centers. Electrons are always released from valence band by constant illumination, which are trapped by shallow trapping centers at low temperatures. Therefore, current response due to light pulse is much higher in the presence of continuous illumination at these temperatures. With increasing temperatures, the neutralization with silver ions or positive holes become more frequent which *surpasses* the rate of electron liberation by continuous illumination.

Considering the facts that the photographic sensitivity increases with temperature, second explanation seems to be more reasonable. That is because if recombination rate increases with temperature the photographic sensitivity should decrease with temperature.

The following fact seems to support the above explanation. If we plot the decreasing part of our photocurrent-temperature curve by log (photocurrent) and $1/T$, we get a straight line, the slope of which shows the activation energy of 0.5 eV. It can be easily seen that the effective number of trapping centers is proportional to the velocity of neutralization of trapped electrons, which will be proportional to the diffusion velocity of silver ions. The activation energy obtained from the conductivity-temperature curve in these temperature regions[21)] is approximately the same as that obtained from the photocurrent-temperature curve.

The results of our experiments seems to be explained by considering two kinds of trapping centers. The one is shallow trapping centers whose depth is about 0.3 eV. The another is rather deep one whose depth is about 1.5 eV and the density is estimated to be of the order of 10^{15}/cc. The nature of these centers is not known clearly. From the results of Fig. 4 they are sure to depend on the existence of large silver aggregates formed by pre-illumination at room temperature. We are now proceeding the experimental study to know the effect of impurity and imperfections on the photocurrent and darkening.

We would like to express our gratitude to Dr. E. Mizuki and other staffs of the Research Laboratory of Fuji Photo Film Co. for their valuable discussions and their supplying raw material. We are also thankful to Dr. Y. Inuishi and other staffs of our Laboratory for their helpful discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol 14, No. 7, JULY, 1959

On the Non-Isothermal Diffusion Theory of Rectifiers*

By Tadasi NUMATA

Nagasaki University, Ohasi-Machi, Nagasaki, Japan

(Received February 26, 1959)

The general non-isothermal diffusion theory of rectifiers has been derived by using the non-isothermal diffusion equation deduced from the formal theory of conduction. The rectification equation obtained depends clearly upon temperature distribution in a barrier. If a temperature difference exists between the both ends of the barrier, then the appearance of thermoelectromotive force is predicted from the present theory. Taking into account the non-isothermal property of the barrier, the present theory shows the tendency that the values of the dielectric constants of barrier materials for Cu_2O and Se rectifiers determined from the capacitance-voltage characteristics seem to approach those of the bulk materials of Cu_2O and Se, respectively.

§ 1. Introduction

The diffusion theories of rectifiers which were first presented by Wagner[1] have been later developed by Mott[2], Schottky[3], and many other authors.[4] Especially Billig[5] and Landsberg[6] have recently developed the theory further in a general way. But all these theories have been so constructed as to be essentially isothermal since these theories had been developed by using the well-known isothermal diffusion equation established by Wagner.

While an electric current flows through a rectifier disk, the heat generation occurs necessarily in a barrier region. Therefore the barrier and its neighbour playing an important part in respect of rectification phenomena should become non-isothermal, and this tendency would become more conspicuous with increased applied voltage in both forward and reverse directions. So it is desirable from the theoretical point of view to construct a non-isothermal diffusion theory of rectifiers taking into account the non-isothermal property of the barrier. Of course, in order to construct such a theory, it is necessary to introduce the non-isothermal diffusion equation which is a starting-point for non-isothermal theories.

In this paper, we shall first introduce a general non-isothermal diffusion equation of rectifier theory by generalizing a non-isothermal diffusion equation deduced from the formal theory of conduction, and next construct generally a non-isothermal diffusion theory on the same line as the isothermal theory presented by Landsberg.[7]

§ 2. A General Non-Isothermal Diffusion Equation

We shall presuppose a simple n-type semiconductor. Results derived on this assumption can be applied to a p-type semi-conductor by making some modifications for the charge and the mass of charge carriers and for the energy, etc..

Supposing first that the Maxwell-Boltzmann distribution function applies to conduction electrons in a conduction band of a semiconductor, electrical conduction by those electrons in the absence of magnetic fields is given by

$$j = eK_1\left\{eE - kT\frac{\partial}{\partial x}\left(\ln\frac{n}{T^{3/2}}\right)\right\} - \frac{e}{T}K_2\frac{\partial T}{\partial x} \tag{1}$$

from the formal theory of conduction,[8] where j is the current density which flows in the direction of the positive x-axis, e the (algebraic) charge on the electron, n the volume density of the conduction electrons, k the Boltzmann's constant, T the absolute temperature, E the electric field applied parallel to the x-axis, and K_s is given by the following equation :

$$K_s = \frac{2^{\frac{1}{2}p+2}\mu n}{3\pi^{1/2}m^{\frac{1}{2}p+1}}(kT)^{S+\frac{1}{2}p-1} \cdot \Gamma\left(S + \frac{1}{2}p + \frac{3}{2}\right), \tag{2}$$

in which m is the effective mass of electron,

---

* A part of this paper was published in Science Bulleín of the Faculty of Liberal Arts and Education, Nagasaki University, **7** (1958) 13 (in Japanese).

Γ the gamma function, and the electron energy has been measured from the bottom of the conduction band. In obtaining Eq. (1) it has been assumed that a time of relaxation is given by $\tau=\mu c^p$, where μ is a constant, c the velocity of an electron, and p a suitable parameter.[9]

Provided we put as follows:

$$v\equiv-\frac{eK_1}{n}, \tag{3. a}$$

$$D\equiv\frac{K_1kT}{n}, \tag{3. b}$$

$$\delta\equiv\left(\frac{K_2}{T}-\frac{3}{2}kK_1\right), \tag{3. c}$$

then Eq. (1) yields

$$j=-envE-eD\frac{\partial n}{\partial x}-e\delta\frac{\partial T}{\partial x}. \tag{4}$$

For $\partial T/\partial x=0$, we get the isothermal diffusion equation

$$j=-envE-eD\frac{\partial n}{\partial x}, \tag{5}$$

which has been used hitherto for rectifier theories. Here v and D are the mobility and the diffusion coefficient, respectively.

Dividing the both sides of Eq. (4) by eD, we obtain

$$-\frac{j}{eD}=\lambda n\frac{\partial V}{\partial x}+\frac{\partial n}{\partial x}+\Lambda\frac{n}{T}\frac{\partial T}{\partial x}, \tag{6}$$

where V is the potential energy of an electron.

By using Eqs. (2), (3. a), (3. b), and (3. c), we get

$$\lambda=-\frac{v}{eD}=\frac{1}{kT}, \tag{7. a}$$

$$\Lambda=\frac{T}{n}\frac{\delta}{D}=\left(1+\frac{1}{2}p\right). \tag{7. b}$$

Eq. (7. a) represents the validity of Einstein's relation under the above assumptions. Eq. (7. b) shows that Λ is a constant including p as a parameter.

In the case that the Fermi-Dirac distribution function applies to the conduction electrons, we get the same expression for the current density j as Eq. (4), where v, D, and δ are, respectively, given by[10]

$$v\equiv-\frac{eK_1}{n}, \tag{8. a}$$

$$D\equiv\frac{2kT}{n}K_1\frac{F_{1/2}(\zeta^*)}{F_{-1/2}(\zeta^*)}, \tag{8. b}$$

$$\delta\equiv\left(\frac{K_2}{T}-3kK_1\frac{F_{1/2}(\zeta^*)}{F_{-1/2}(\zeta^*)}\right), \tag{8. c}$$

where K_s and $F_\xi(\zeta^*)$ are, respectively, the following integrals

$$K_s=-\frac{16\sqrt{2}\pi m^{1/2}}{3h^3}\int_0^\infty\tau E^{s+\frac{1}{2}}\frac{\partial f_0}{\partial E}dE, \tag{9}$$

$$F_\xi(\zeta^*)=\int_0^\infty\frac{x^\xi dx}{1+e^{x-\zeta^*}}, \quad (\xi>-1), \tag{10}$$

here h is the Planck's constant, f_0 the Fermi-Dirac distribution function in a thermal equilibrium state, ζ^* the thermodynamic potential divided by kT. In the equation corresponding to Eq. (6) we obtain

$$\lambda=-\frac{v}{eD}=\frac{1}{2kT}\frac{F_{-1/2}(\zeta^*)}{F_{1/2}(\zeta^*)}, \tag{11. a}$$

$$\Lambda=\frac{\delta T}{nD}=\frac{1}{2}\frac{5+p}{3+p}\frac{F_{-1/2}(\zeta^*)}{F_{1/2}(\zeta^*)}\frac{F_{3/2+p/2}(\zeta^*)}{F_{1/2+p/2}(\zeta^*)}-\frac{3}{2}, \tag{11. b}$$

according to

$$n=\frac{8\sqrt{2}\pi(mkT)^{3/2}}{h^3}F_{1/2}(\zeta^*).$$

The values of ζ^* should in general be negative, so that we can expand the denominator of the integrand in $F_\xi(\zeta^*)$ in terms of $\exp[-x+\zeta^*]$. Then we get

$$F_\xi(\zeta^*)=\Gamma(\xi+1)\sum_{s=1}^{\infty}(-1)^{s-1}\frac{e^{s\zeta^*}}{S^{\xi+1}}. \tag{12}$$

Using this equation, Eqs. (11. a) and (11. b) yield approximately

$$\lambda=\frac{1}{kT}\left(1-\frac{e^{\zeta^*}}{2^{3/2}}\right), \tag{13. a}$$

and

$$\Lambda=\left[\left(\frac{5}{2}+\frac{p}{2}\right)\left\{1-\frac{(2^{p/2}-1)e^{\zeta^*}}{2^{3/2+p/2}}\right\}-\frac{3}{2}\right], \tag{13. b}$$

respectively. For $e^{\zeta^*}\ll1$, Eqs. (13. a) and (13. b) tend, respectively, to

$$\lambda=\frac{1}{kT} \tag{14. a}$$

and

$$\Lambda=\left(1+\frac{1}{2}p\right). \tag{14. b}$$

Eqs. (13. a) and (13. b) show that λ and Λ are weak functions of ζ^*. But for $e^{\zeta^*}\ll1$, Λ tends to a constant, and also the Einstein's relation is approximately established.

From the above considerations, we have seen that if we denote v, D, δ, λ, and Λ by the above equations, respectively, we can express the non-isothermal diffusion equation in the same form as (4) or (6) in both of Maxwell-Boltzmann and Fermi-Dirac statistics, though slight differences exist between the two cases.

§ 3. Barriers

The potential energy of current carriers in a rectifying barrier has a maximum $V_m (= V(b))$ at some plane $x=b$ and drops to zero at a plane $x=a$ close to a metal electrode, due to the image force (see Fig. 1). x is measured into the semiconductor from the metal-semiconductor interface and the zero of potential energy is taken at the bottom of the conduction band of the semiconductor in the absence of applied voltages. a is very small compared to b which depends on an applied voltage.

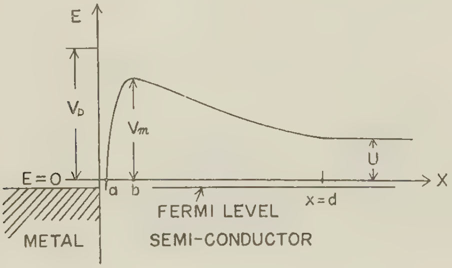

Fig. 1. Potential barrier of an n-type semiconductor in the presence of an applied voltage U/e.

The thickness, d, of the barrier is defined b

$$n(d)=n(x)=\text{const.} \quad \text{for } x \geqq d ,$$

where $n(d)$ is the volume density of the cur rent carriers in the bulk semiconductor, bein assumed to be independent of applied voltages The volume density of the current carriers $n(a)$, at the plane $x=a$ may be assumed to b nearly equal to the one at the surface of th metal and to be independent of applied vol tages. Defining an applied voltage $U/e >$ for a forward voltage, we have $V(x, U) = U$ for $x \geqq d$.

The potential energy of the current carrier in the heterogeneous barrier, $V(x, U)$, can b obtained by adding the term due to the imag force to the solution of the differential equa tion

$$\frac{d}{dx}\left\{\varepsilon(x)\frac{dV}{dx}\right\}=4\pi e^2 N(x) , \tag{15}$$

where $\varepsilon(x)$ is the dielectric constant of the barrier material, which is a function of since the temperature in the barrier is function of x, $N(x)$ the volume density of the ionized impurity centres in the barrier. W have $n(x)=N(x)$ for $x \geqq d$ since the net charg in the interior of the bulk semiconducto must vanish.

Integrating Eq. (15) twice with respect t x over the region $[x, d]$ and reducing the double integral by a partial integration, we obtain

$$V(x)=U-\varepsilon(d)\tilde{\varepsilon}(x)V'(d)+4\pi e^2\int_x^d \{\tilde{\varepsilon}(x)-\tilde{\varepsilon}(y)\}N(y)\,dy-\frac{e^2\varphi(x)}{4\varepsilon(b)x} , \tag{16}$$

where

$$\tilde{\varepsilon}(x)=\int_x^d \frac{dt}{\varepsilon(t)} . \tag{17}$$

In the last added term, which is due to the image force, $\varphi(x)$ is the function introduced as a correction coefficient by taking into account the temperature dependence of the dielectric constant. Let V_D be the diffusion potential in the absence of the image force, then V_D has the form

$$V_D=U-\varepsilon(d)\tilde{\varepsilon}(0)V'(d)+4\pi e^2\int_0^d \{\tilde{\varepsilon}(0)-\tilde{\varepsilon}(y)\}N(y)\,dy . \tag{18}$$

Inserting the condition $dV/dx=0$ at $x=b$ into the equation obtained by differenting Eq. (16 with respect to x, we obtain

$$\frac{1}{b^2}=\frac{16\pi}{\nu(b)\varphi(b)}\int_b^d N(y)dy-\frac{4\varepsilon(d)V'(d)}{e^2\nu(b)\varphi(b)} , \tag{19}$$

where

$$\nu(b)=1-\frac{\varphi'(b)}{\varphi(b)}b\approx 1 . \tag{20}$$

Since b is in general small (of order 10^{-7} cm.), ν is of order unity.

By using Eqs. (16), (17), (18), and (19), we obtain

$$V_D - V(b) = \frac{e^2\eta(b)\varphi(b)}{2\varepsilon(b)b}, \tag{21}$$

where

$$\begin{aligned}\eta(b) &= \frac{1}{2}\left[1 + \frac{\nu(b)\varepsilon(b)}{b}\int_0^b \frac{dt}{\varepsilon(t)} + \frac{16\pi\varepsilon(b)b}{\varphi(b)}\int_0^b \{\tilde{\varepsilon}(0) - \tilde{\varepsilon}(y)\}N(y)\,dy\right] \\ &\approx \frac{1}{2}\left(1 + \frac{\nu(b)\varepsilon(b)}{b}\int_0^b \frac{dt}{\varepsilon(t)}\right),\end{aligned} \tag{22}$$

and by Eq. (16)

$$-V''(b) = \frac{e^2\varphi(b)\phi(b)}{2\varepsilon(b)b^3}, \tag{23}$$

where

$$\begin{aligned}\phi(b) &= 1 - \left(\frac{1}{2}\frac{\varepsilon'(b)}{\varepsilon(b)} + \frac{\varphi'(b)}{\varphi(b)}\right)b + \frac{1}{2}\left(\frac{\varepsilon'(b)\varphi'(b)}{\varepsilon(b)\varphi(b)} + \frac{\varphi''(b)}{\varphi(b)}\right)b^2 - 8\pi\frac{N(b)}{\varphi(b)}b^3 \\ &\approx 1.\end{aligned} \tag{24}$$

§ 4. Derivation of Rectification Equation

In order to obtain a rectification equation, we must integrate the non-isothermal diffusion equation (6) over the barrier. As a heat generation by an electric current occurs in the barrier, the temperature distribution should depend on an applied voltage U/e. Let the temperature and the electrical potential energy in the barrier be, respectively,

$$T = T(T_d, U, x) \quad \text{and} \quad V = V(T_d, U, x), \tag{25}$$

where T_d is the temperature at $x=d$, and it will be assumed to be equal to the temperature in the interior of the bulk semiconductor.

The diffusiom equation (6) is a linear differential equation with respect to n, since D, λ, and A can be expressed as some functions of a variable x only by means of Eq. (25), respectively. Integrating Eq. (6) in the region $[x, d]$ using an integrating factor

$$\exp\left[-\int_x^d\left(\lambda\frac{dV}{dz} + \frac{A}{T}\frac{dT}{dz}\right)dz\right],$$

we have

$$-\int_x^d \frac{j}{eD}\exp\left[-\int_y^d\left(\lambda\frac{dV}{dz} + \frac{A}{T}\frac{dT}{dz}\right)dz\right]dy + n(x)\exp\left[-\int_x^d\left(\lambda\frac{dV}{dz} + \frac{A}{T}\frac{dT}{dz}\right)dz\right] = n(d) \tag{26}$$

Now putting $n(a)$ as

$$n(a) = An(d), \tag{27}$$

then Eq. (26) yields

$$j = \frac{en(d)}{j_0}\left[A\exp\left\{-\int_a^d\left(\lambda\frac{dV}{dx} + \frac{A}{T}\frac{dT}{dx}\right)dx\right\} - 1\right], \tag{28}$$

where

$$j_0 = \int_a^d \frac{1}{D}\exp\left[-\int_y^d\left(\lambda\frac{dV}{dz} + \frac{A}{T}\frac{dT}{dz}\right)dz\right]dy. \tag{29}$$

In the case of isothermal barriers, inserting the condition $j=0$ when $U=0$ into Eq. (28), we have

$$A = \exp\left(\int_a^d \lambda\frac{dV}{dx}\,dx\right). \tag{30}$$

Furthermore, if the Einstein's relation holds, A becomes unity being independent of temperature.

In the case of non-isothermal barriers, supposing that both metal and bulk semiconductor are to be in thermal equilibrium, and at low temperatures $n(d)$ is simply given by[11)]

$$n(d)=(2)(2\pi mkT/h^2)^{3/4}N_0^{1/2}e^{-(\Delta E/2kT)}\ , \tag{31}$$

and at high temperatures $n(d)$ tends to the value N_0 which is the density of impurity centres in the bulk semiconductor, the value of A can be easily given by

$$A(T_a,T_d)=\begin{cases} 1 & \text{for high temperatures,} \quad (32.a) \\ \left(\dfrac{T_a}{T_d}\right)^{3/4}\exp\left[-\dfrac{\Delta E}{2k}\left(\dfrac{1}{T_a}-\dfrac{1}{T_d}\right)\right] & \text{for low temperatures,} \quad (32.b) \end{cases}$$

where T_a and T_d are the temperatures at $x=a$ and $x=b$, respectively, and $\Delta E(>0)$ the energy difference between the bottom of the conduction band of the semiconductor and the impurity level.

The exponent in Eq. (29) can be integrated by a partial integration:

$$\int_y^d\left(\lambda\frac{dV}{dz}+\frac{A}{T}\frac{dT}{dz}\right)dz=\int_y^d\lambda\frac{dV}{dz}dz+\ln\frac{T_d^{A(d)}}{T_y^{A(y)}}-\int_{T_y}^{T_d}(\ln T)\frac{dA}{dT}dT\ . \tag{33}$$

The third term on the right-hand side of Eq. (33) will be generally small in camparison with the others, hence in the following calculation we shall neglect this term. Substituting Eq. (33) into Eq. (29) we get

$$j_0=\Psi\int_a^b\left[\frac{1}{D}\left(\frac{T_x^{A(x)}}{T_d^{A(d)}}\right)\exp\left\{-\int_x^d\lambda\frac{dV}{dy}dy\right\}\right]dx\ , \tag{34}$$

where

$$\Psi\equiv1+\frac{\displaystyle\int_b^d\left[\frac{1}{D}\left(\frac{T_x^{A(x)}}{T_d^{A(d)}}\right)\exp\left\{-\int_x^d\lambda\frac{dV}{dy}dy\right\}\right]dx}{\displaystyle\int_a^b\left[\frac{1}{D}\left(\frac{T_x^{A(x)}}{T_d^{A(d)}}\right)\exp\left\{-\int_x^d\lambda\frac{dV}{dy}dy\right\}\right]dx} \tag{35}$$

The value of the dimensionless factor Ψ depends upon applied valtages and temperatures of the barrier, and is limited usually for variation of temperature as follows:

$$\Psi\geqq\lim_{kT\to0}\Psi\ (\approx2) \tag{36}$$

Figs. 2 and 3 show the variation of Ψ calculated for special barriers by assuming an isothermal barrier, a constant mobility, Eqs. (7. *a*) and (7. *b*).

The potential energy in the region $[a, b]$ has a steep slope for both the reverse and the

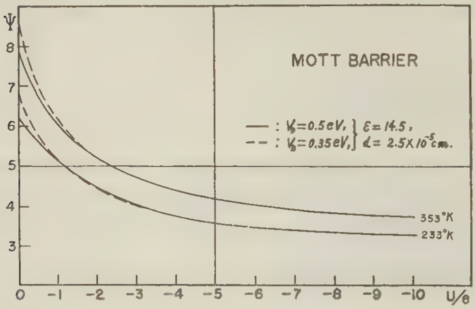

Fig. 2. Ψ as function of applied voltage U/e for an isothermal Mott barrier. Calculations have been done using Simpson's 1/3 rule.

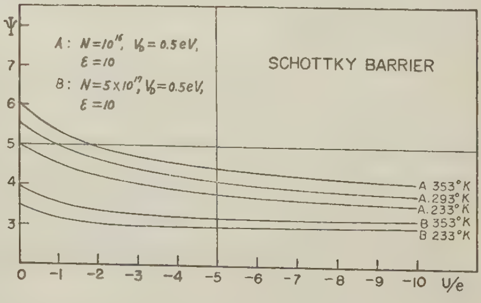

Fig. 3. Ψ as function of applied voltage U/e for an isothermal Schottky barrier.

small forward applied voltages (see Fig. 1), hence we shall use Laplace's approximation to calculate the integral in Eq. (34) in this region, but not use Laplace's approximation in the region $[b, d]$ where the slope of the potential energy is not so steep excepting high reverse applied voltages. If Laplace's approximation would be used for both of these two regions of the barrier as has been done by Landsberg, then we get $\Psi=2$, but this value of Ψ is smaller than its true value, since Laplace's approximation is applicable in the limit kT (which λ involves) → zero.

The theorem of Laplace's approximation[12] to be used is

$$\int_a^b \phi(x)\exp[h(x)]dx \approx \left(-\frac{\pi}{2h_m''}\right)^{1/2}\phi_m \exp[h_m]\,, \tag{37}$$

where the subscript m denotes the values at the maximum of $h(x)$. Since the variation of the electric field is likely to be larger than that of the temperature in the barrier, the maximum h_m will occur at the plane at which the potential energy V reaches its maximum (at $x=b$). Hence by a partial integration

$$h_m = \int_d^b \lambda \frac{dV}{dx}dx = \lambda(b)V(b) - \lambda(d)V(d) - \int_d^b V\frac{d\lambda}{dx}dx\,. \tag{38}$$

Making use of Eqs. (21), (23), (34), (37), and (38), we obtain

$$j = J\Psi^{-1}y^{3/2}\left(\frac{T_d^{\Lambda(d)}}{T_b^{\Lambda(b)}}\right)e^y\left\{A\frac{T_a^{\Lambda(a)}}{T_d^{\Lambda(d)}}\exp\left(-\int_a^d \lambda\frac{dV}{dx}dx\right)-1\right\}\exp\left[\left(\int_d^b V\frac{d\lambda}{dx}dx\right)+\lambda(d)U\right], \tag{39}$$

where

$$J = 2\left(\frac{2}{\pi}\right)^{1/2}\frac{\phi^{1/2}(b)\varepsilon(b)}{\eta^{3/2}(b)\varphi(b)}n(d)\frac{D(b)}{e\lambda(b)}\exp[-\lambda(b)V_D]\,, \tag{40}$$

and

$$y = \frac{e^2\eta(b)\varphi(b)\lambda(b)}{2\varepsilon(b)b}\,. \tag{41}$$

Eq. (39) may be rewritten as follows:

$$j = J\Psi^{-1}y^{3/2}\left(\frac{T_d^{\Lambda(d)}}{T_b^{\Lambda(b)}}\right)e^y\left\{A\frac{T_a^{\Lambda(a)}}{T_d^{\Lambda(d)}}\exp\left(\int_a^b V\frac{d\lambda}{dx}dx\right)-\exp\left(\lambda(d)U-\int_a^d V\frac{d\lambda}{dx}dx\right)\right\}. \tag{42}$$

Eqs. (39) and (42) are the general formulas which give the characteristics for reverse and small forward applied voltages.

When the values of $d\lambda/dx$ is so small to satisfy the conditions $\int_a^b V\frac{d\lambda}{dx}dx\approx 0$ and $\int_d^b V\frac{d\lambda}{dx}dx\approx 0$, Eq. (42) becomes

$$j = J\Psi^{-1}y^{3/2}\frac{T_d^{\Lambda(d)}}{T_b^{\Lambda(b)}}e^y\left\{A\frac{T_a^{\Lambda(a)}}{T_d^{\Lambda(d)}}-e^{\lambda(d)U}\right\}, \tag{43}$$

Further, assuming Eqs. (14. *a*) and (14. *b*), that is $\lambda=1/kT$ and Λ=constant, Eq. (43) takes the form

$$j = J_E\Psi^{-1}y^{3/2}\left(\frac{T_d}{T_b}\right)^\Lambda e^y\left\{A\left(\frac{T_a}{T_d}\right)^\Lambda - e^{U/kT_d}\right\}, \tag{44}$$

where

$$J_E = -2\left(\frac{2}{\pi}\right)^{1/2}\frac{\phi^{1/2}(b)\varepsilon(b)}{\eta^{3/2}(b)\varphi(b)}n(d)\frac{v(b)}{e^2}k^2T_b^2\exp\left[-\frac{V_D}{kT_b}\right], \tag{45}$$

and

$$y = \frac{e^2\eta(b)\varphi(b)}{2\varepsilon(b)b}\frac{1}{kT_b}\,. \tag{46}$$

§ 5. Special Cases of the Rectification Equation

a) Isothermal barriers

In this case, $T_a=T_b=T_d$ and $A(T_a,\ T_d)=1$, so that Eq. (42) yields

$$j=J\Psi^{-1}y^{3/2}T^{\Lambda(d)-\Lambda(b)}e^{y}\left[T^{\Lambda(a)-\Lambda(d)}\exp\left(\int_a^b V\frac{d\lambda}{dx}dx\right)-\exp\left(\lambda(d)U-\int_b^d V\frac{d\lambda}{dx}dx\right)\right] \tag{47}$$

If, furthermore, $\lambda=1/kT$ and $\Lambda=$ constant, Eq. (47) leads to

$$j=J_E\Psi^{-1}y^{3/2}e^{y}\left[1-\exp\left(\frac{U}{kT}\right)\right]. \tag{48}$$

In this case, $\varphi(b)$ and $\phi(b)$ in j and J_E are equal to unity, respectively. When $\Psi=2$, Eq. (48) is just the same as obtained by Landsberg,[13] but the value of Ψ does not usually become equal to 2 excepting the limit of $T\to 0$ as seen from Figs. 2 and 3 or Eq. (36).

b) Characteristics for zero applied voltage

Putting $U=0$ into Eqs. (42) and (44), we obtain, respectively,

$$j=J\Psi^{-1}_{U=0}\,y^{3/2}_{U=0}\frac{T_d^{\Lambda(d)}}{T_b^{\Lambda(b)}}e^{y_{U=0}}\left[A\frac{T_a^{\Lambda(a)}}{T_d^{\Lambda(d)}}\exp\left(\int_a^b V\frac{d\lambda}{dx}dx\right)_{U=0}-\exp\left(-\int_b^d V\frac{d\lambda}{dx}dx\right)_{U=0}\right] \tag{49}$$

and

$$j=J_E\,\Psi^{-1}_{U=0}\,y^{3/2}_{U=0}\left(\frac{T_d}{T_b}\right)^{\Lambda}e^{y_{U=0}}\left[A\left(\frac{T_a}{T_d}\right)^{\Lambda}-1\right]. \tag{50}$$

If $T_a\neq T_d$, the insides of the brackets in Eqs. (49) and (50) are not generally equal to zero. Hence, if the rectifier is in series with a negligible resistance in a circuit, then a thermoelectric current given by Eq. (49) or (50) flows in the circuit. According to Eq. (50), if $\Lambda>0$, then

$$\left.\begin{matrix} j<0 \\ j>0 \end{matrix}\right\}\ \text{as}\ \left\{\begin{matrix} T_a>T_d \\ T_a<T_d \end{matrix}\right.. \tag{51}$$

For an open circuit, according to Eq. (42) or (44), a thermoelectromotive force

$$\frac{U}{e}=\frac{1}{e\lambda(d)}\left\{\ln\frac{n(a)}{n(d)}+\ln\frac{T_a^{\Lambda(a)}}{T_b^{\Lambda(b)}}+\int_a^d V\frac{d\lambda}{dx}dx\right\} \tag{52}$$

or

$$\frac{U}{e}=\frac{kT_d}{e}\left\{\ln\frac{n(a)}{n(d)}+\Lambda\ln\frac{T_a}{T_d}\right\} \tag{53}$$

takes place between the both ends of the barrier, respectively.

c) Characteristics for reverse applied voltage

In this case, $\exp[U/kT]\ll 1$, then Eqs. (42) and (44) yield, respectively,

$$j=J\Psi^{-1}Ay^{3/2}\frac{T_a^{\Lambda(a)}}{T_b^{\Lambda(b)}}e^{y}\exp\left(\int_a^b V\frac{d\lambda}{dx}dx\right) \tag{54}$$

and

$$j=J_E\,\Psi^{-1}Ay^{3/2}\left(\frac{T_a}{T_d}\right)^{\Lambda}e^{y}. \tag{55}$$

If the temperature gradient due to self-heating in the barrier is such as $T_b>T_a>T_d$, the larger reverse current than that expected from the isothermal theory will flow through the barrier, nevertheless the factor $\exp\left(\int_a^b V\frac{d\lambda}{dx}dx\right)$ acts usually to decrease j. When $A(T_a,\ T_d)\approx 1$, the magnitude of the reverse current is mainly dominated by the magnitude of J which ncreases exponentially as increasing of the temperature T_b. But it should be noted that the factor $\Psi(T_d, U)$ acts to increase in some degree the magnitude of the reverse current with decreasing temperature of the rectifier as seen from Figs. 2 and 3, and that the nobility of charge carriers is temperature-dependent. Therefore the reverse current may, n some special cases, increase with decreasing temperature of the barrier.

§ 6. Barrier Capacitance

If the lower limit in the integral in Eq. (19) is put equal to zero,[13] the charge, q, per unit area of the heterogeneous barrier layer is approximately given by

$$q=e\int_0^a N(x)\,dx=\frac{e\nu(b)\varphi(b)}{16\pi}\frac{1}{b^2}+\frac{\varepsilon(d)V'(d)}{4\pi e}\,, \tag{56}$$

the contribution of the current carriers to this charge being neglected compared with the charge due to the ionized impurity centres.

Using Eqs. (56) and (41), the capacitance, C, per unit area is given by

$$C=e\frac{dq}{d(V_D-U)}=\frac{1}{4\pi e^2}\left\{\Sigma(b)\frac{d(y^2)}{d(V_D-U)}+y^2\frac{d(\Sigma(b))}{d(V_D-U)}\right\} \tag{57}$$

where

$$\Sigma(b)=\frac{\nu(b)\varepsilon^2(b)}{\eta^2(b)\varphi(b)\lambda^2(b)}\,, \tag{58}$$

The term $V'(d)$ in Eq. (56) has been assumed to be negligible or at least to be approximately independent of V_D-U, so that the following considerations do not apply to a Mott barrier.

On integrating Eq. (57), we obtain

$$\frac{\Sigma_U(b)}{\Sigma_0(b)}y^2(U)-y^2(0)=4\pi\left(\frac{e\lambda(T_a)}{\varepsilon(T_a)}\right)^2\int_U^0 C(U)dU\,, \tag{59}$$

where $\Sigma_U(b)$ and $\Sigma_0(b)$ are the values of $\Sigma(b)$ at the applied voltages U/e and at the zero applied voltage, respectively, and also $\Sigma_0(b)$ is equal to $\varepsilon^2(T_a)/\lambda^2(T_a)$ since the temperature at the zero applied voltage is constant through the barrier and equal to the ambient temperature T_a.

Eq. (59) is slightly different from that obtained for isothermal barriers by Landsberg[13] in the point that the coefficient of $y(U)$ is not unity, but $\Sigma_U(b)/\Sigma_0(b)$.

§ 7. Analysis of Experimental Characteristics

Assuming Eqs. (7.a) and (32.a) (the latter corresponds to the the case where all impurities are ionized; this seems to hold for Se.[14]), and neglecting $\ln(T_a^{\Lambda(a)}/T_b^{\Lambda(b)})$, Eq. (54) can be rewritten as follows (see Appendix):

$$\frac{3}{2}\ln y(U)+y(U)=\ln j(U)-\ln J_E(T_a)+\ln\Psi-\frac{1}{kT_a^2}(V_D-\theta V(b))\Delta T\,, \tag{60}$$

where

$$J_E(T_a)=2\left(\frac{2}{\pi}\right)^{1/2}\frac{\phi^{1/2}(a)\varepsilon(a)}{\eta^{3/2}(a)\varphi(a)}n(d)\frac{v(a)}{e^2}k^2T_a^2\exp\left[-\frac{V_D}{kT_a}\right], \tag{61}$$

and

$$\Delta T=T_b-T_a\,,\qquad 0<\theta<1\,. \tag{62}$$

The last term on the right-hand side of Eq. (60) represents the effect due to temperature rise of the barrier.

On the other hand, from Eq. (59) we can obtain approximately

$$\ln[y^2(U)-y^2(0)]=\ln\left[4\pi\left(\frac{e}{kT_a}\right)^2\int_U^0 C(U)dU\right]-2\ln\varepsilon(T_a)\,, \tag{63}$$

since $\ln\left[\frac{\Sigma_{U}(b)}{\Sigma_0(b)} y^2(U)-y^2(0)\right]$ may be approximately equal to $\ln[y^2(U)-y^2(0)]$ except for the case of large reverse applied voltages.

As seen from Eqs. (60) and (63), we can draw the theoretical curves of $3/2 \ln y(U)+y(U$ as function of $\ln[y^2(U)-y^2(0)]$ for given suitable values of $y(0)$, since $3/2 \ln y(U)+y(U)$ and $\ln[y^2(U)-y^2(0)]$ are connected through the parameter $y(U)$. On the other hand, using the measured j and C values for each reverse voltages, we can plot the experimental curves o $\ln j$ as function of

$$\ln\left[4\pi\left(\frac{e}{kT_a}\right)^2\int_U^0 C\,dU\right].$$

The latter experimental curve should coincide with one of the theoretical curves by parallel displacements of $2\ln\varepsilon(T_a)$ horizontally and $\ln J_E(T_a)-\ln\Psi+\frac{1}{kT_a^2}(V_D-\theta V(b))\Delta T$ vertically. This type of analysis in the isothermal cases was first used by Lees[15] and next by Moriguchi and Okazaki.[16]

Now from the above non-isothermal theoretical point of view, it may be desired to analyse the experimental results obtained by Moriguchi and Okazaki to check up how the temperature rise of the barrier affects experimental results. But we can not find the values of Ψ, θ, $V(b)$, and ΔT necessary for the analysis, because the temperature distribution in the barrier is not yet given and we can not analyse the experimental results along the same lines as Moriguchi and Okazaki have taken. Under the present situation we should be obliged to do a very rough analysis under the following assumptions:

(1) The value of $V(b)$ is that for a Schottky barrier;

(2) $V_D=0.5$ eV, $\theta=0.5$ for both Cu_2O and Se rectifiers;

(3) The temperature-and voltage-dependences of Ψ are approximately of the form of the curve A illustrated in Fig. 3;

(4) ΔT is zero at the lowest applied voltage and has a maximum value, ΔT_m, at the highest applied voltage (the assumed values of ΔT_m are shown in Tables I and II).

From the above assumptions we get only two experimental values for the lowest and highest applied voltages. Therefore, we can not get an experimental *curve* to fit one of the above-mentioned theoretical curves. To get a rough knowledge on the effect of the temperature rise in the barrier, we may make the above two experimental points, for which the correction due to the temperature rise is applied, fit the same curve as the theoretical one, which is first determined by neglecting the temperature rise, (this is, under the isothermal condition), by suitable parallel displacements. From the values of these parallel displacements we can find the values of $y(0)$, $\varepsilon(T_a)$, and $J_E(T_a)$. Some of the results obtained by the present analysis are shown in Tables I and II, which include the results by Moriguchi and Okazaki. By the above parallel displacements, the experimental points, for which the correction due to the temperature rise is not applied, should displace from the above theoretical curve. From the vertical component of this displacement for each experimental point, we may estimate the temperature rise of the barrier at each applied voltage except the lowest and highest ones.

Under the isothermal condition, the overlap of each experimental curve with one of the theoretical curves after suitable parallel displacements is found to be better than that obtained by Moriguchi and Okazaki. The reason may be possibly due to the fact that the factor Ψ modifies, especially, the low reverse characteristics. The results for the isothermal condition are also given in the third line of Tables I and II.

§ 8. Discussion

In the preceding sections, we have developed generally the non-isothermal diffusion theory of metal rectifiers by integrating the general non-isothermal diffusion equation newly introduced here. In the development of the theory, the assumption of temperature-and voltage-independences of mobility and diffusion coefficient have not been made with dropping of the Einstein mobility relation. Hence the present theory has been constructed under fewer theoretical restrictions. The rectification equation obtained shows clearly how rectification current depends upon the temperature distribution in the barrier layer since it containe T_a, T_b, and T_d in addition to the values of D, λ, and Λ at the various positions in the barrier layer. Therefore, if the temperature distribution in the barrier layer changes as rectification current flows through the barrier, thermal creep may be able to occur. Furthermore, owing to a temperature difference between both ends of the barrier, thermoelectric current flows in a circuit or thermoelectromotive force generates at both ends of the barrier according to whether the circuit is closed or not. These effects can not be expected explicitly by the usual isothermal theories. In order to obtain further knowledges on the above effects or to analyse experimental results in detail, it is necessary to solve a differential equation of heat conduction with heat generation source under suitable boundary conditions. But this has not been done in this paper.

The value of Ψ generally depends upon temperature and voltage distributions in the barrier layer and several quantities of the barrier. Hence it is practically not easy to obtain the accurate value of Ψ of a special rectifier under a given applied voltage and ambient temperature. But the tendency of the variation of Ψ may be, in general, similar to those indicated in Figs. 2 and 3 obtained for the special cases of Mott and Schottky barriers. It should be noted that the value of Ψ is larger than 2 over the usual temperature range, and the value of Ψ in the vicinity of zero bias voltage changes rapidly with variation of applied voltage and ambient temperature. These properties of Ψ may affect effectively the low voltage characteristics and zero bias resistance.

As seen from Tables I and II, the values of the dielectric constants determined by Moriguchi and Okazaki are pretty smaller than those of the bulk materials of Cu_2O (10.5, Højendahl(17); and 8, Wright(11)) and Se (6.13, Vonwiller and Mason;(18) 6.60, Schmidt;(19) 7.44, Pirani; and 6.31, Tammann and Boehme,(20) for vitreous Se. 8∼20, Eckart and Rabenhorst;(21) Jaumann and Neckenbürger;(22) and 14.5, Numata and Isami,(23) for hexagonal Se). But taking into account the temperature rise of the barrier, the Tables show that the values of the dielectric constants determined in the present analysis tend to approach those of the bulk materials. This fact seems to be in favour of the present non-isothermal theory.

Finally, the author expresses his sincere thanks to Professor A. Okazaki of Kyusyu University for his continual advice and encouragement and to Mr. Y. Moriguchi for lending of the experimental data. The present investigation was finacially spported by the Scientific Research Expenditure of the Ministry of Education.

Appendix

Making a logarithm of Eq. (54), we obtain

$$\frac{3}{2}\ln y(U)+y(U)=\ln j(U)-\ln J_E(T_b)+\ln\Psi-\int_a^b V\frac{d}{dx}\left(\frac{1}{kT}\right)dx\,, \tag{A.1}$$

under the above-mentioned assumptions.

Expressing $J_E(T_b)$ given by Eq. (45) in terms of the values of the quantities at the plane $x=a$ by using Taylor's theorem, we obtain approximately

$$\ln J_E(T_b)=\ln J_E(T_a)+\frac{V_D}{kT_a^2}\Delta T\,. \tag{A.2}$$

The function $V(x)$ is a monotonous increasing function in the interval $a\leqq x\leqq b$. Hence, if $dT/dx>0$ in the above interval, we have the following inequality relation:

$$0<-\int_a^b V\frac{d}{dx}\left(\frac{1}{kT}\right)dx<-\int_a^b V(b)\frac{d}{dx}\left(\frac{1}{kT}\right)d\,x. \tag{A.3}$$

By Taylor's expansion, Eq. (A.3) can be written as

$$0<-\int_a^b V\frac{d}{dx}\left(\frac{1}{kT}\right)dx<\frac{V(b)}{kT_a^2}\Delta T\,.$$

On the other hand,

$$0<\theta\frac{V(b)}{kT_a^2}\Delta T<\frac{V(b)}{kT_a^2}\Delta T\,,\qquad 0<\theta<1$$

Hence, selecting a suitable value of θ $(0<\theta<1)$, we can obtain

$$-\int_a^b V\frac{d}{dx}\left(\frac{1}{kT}\right)dx=\theta\frac{V(b)}{kT_a^2}\Delta T\,,\qquad 0<\theta<1. \tag{A.4}$$

By Eqs. (A.1), (A.2), and (A.4), we get Eq. (60).

Study on Vacuum Deposition of Metals, I
On the Formation of Alloys by Successive Deposition of Constituent Metal Vapours in Vacuum

By Yoshibumi FUJIKI

Institute of Physics, Kyōto Prefectural Medical College

(Received March 6, 1959)

The formation of alloy phases by successive deposition of constituent metal vapours in vacuum was investigated by electron diffraction method for some binary alloy systems. It was concluded that the temperature of the surface layer of primary deposit is raised by the deposition of secondary metal vapour. This temperature rise, which contributes to the formation of alloy phases, is mainly due to the latent heat of condensation of the metal vapour which deposits on the substrate, and consequently metal pairs which have larger latent heat of condensation may form alloys easier than those which have smaller ones. It was also suggested that some structural defects in the substrate layer would contribute to the formation of alloy phases.

§ 1. Introduction

When the vapours of two metals are deposited successively on any substrate in vacuum, alloys of these two metals are formed for some pairs of metals, but not for other pairs. Michel$^{1)}$ examined Ag–Zn, Ag–Sn, Al–Sb, Al–Cu and other pairs by electron diffraction method and found the formation of alloys for the first two pairs, but not for other pairs. He considered these phenomena as the problem of inter-diffusion similar to the case of bulk specimens, and calculated the depth to which inter-diffusion had occurred for a day using the diffusion constants of the chemical diffusion extrapolated from values at high temperatures to room temperature. His conclusion is that alloy formations are observed for pairs whose diffusion constants at room temperature are larger than the order of 10^{-20} cm^2/sec, and not for pairs whose diffusion constants are smaller than this.

The writer observed almost instantaneous formation of alloy phase by the deposition of secondary metal vapour in electron diffraction camera for Pb–Bi system, and the rate of formation of alloy seemed too large for the order of diffusion constant at room temperature (10^{-16} cm^2/sec). When Sn vapour was deposited on Cu deposit (the weight ratio of Sn and Cu having been 60:40), an alloy of the nickel arsenide type (hexagonal, a=4.19Å, c=5.08Å) was observed. The diffusion constant at room temperature in this case is of the order of 10^{-32} cm^2/sec. The writer supposed that these facts depend upon two main factors, namely, the temperature rise of the surface of primary deposit by the deposition of the secondary constituent metal vapour and the crystal texture or the condition of the surface of the primary deposit. To confirm these conjectures the writer examined some metal pairs by the electron diffraction method.

§ 2. Temperature Rise of the Primary Deposit by the Secondary Vapour Deposition

The temperature of the deposit is supposed to be considerably high just after the deposition of vapour, and then is lowered rapidly to room temperature, and so the temperature of the surface layer of the primary deposit would be risen by the deposition of secondary constituents. The temperature of the secondary deposit should be higher at the surface layer than the bottom during the deposition, and so the diffusion should occur upwards. The alloy thus formed should be those whose composition is rich in secondary element compared with the composition of films as a whole. To assure this the writer examined first the Au–Pb alloy system. Au–Pb alloy system has three intermetallic compounds, Au_2Pb (cubic, a=7.93Å), $AuPb_2$ (tetragonal, a=7.31Å, c=5.644Å) and $AuPb_3$[2] (tetragonal, a=11.958Å, c=5.878Å), and this alloy system is suitable for this aim. Each constituent metal was heated in a spiral of tungsten wire (about 0.22 mm in diameter) and deposited on a Formvar film successively in vacuum (about 2×10^{-5} mm Hg). Total amount of two constituent metals was 10 mg and the distance between filaments and substrate was 6 cm. The rate of evaporation was about 25 mg per minute. After two constituent metals were vaporized, specimen was examined by electron diffraction method. The ratio of the amount of two constituent metals, the alloy phases observed and the intensities of their diffraction patterns are listed in Table I. These results show that compositions of alloys formed are rich in the later deposited element compared with the compositions of films as a whole. These diffraction patterns changed to those which correspond to the alloy phases of the composition of film as a whole when suitably heat-treated in vacuum (see Table I).

When the amount of Pb for the secondary element was reduced to about 2 mg (i.e. 20 wt. % Pb), no alloy phase appeared but only Pb and Au. This specimen showed the diffraction pattern of Au_2Pb and Au after heat-treatment. This phenomenon may be understood by considering that the amount of deposited Pb vapour is very small, so that the latent heat of Pb vapour is insufficient for the temperature rise of the surface of Au necessary to form alloys.

Table I.

Thin films prepared by the deposition of Sn vapour showed the fibre structure which persisted up to the melting point of Sn. But this fibre structure was destroyed by the deposition of Zn vapour on it at room temperature. (Sn–Zn system has no compound but eutectic; eutectic point is 199°C.)

This suggests that the temperature of Sn layer was elevated to near the eutectic point by the deposition of Zn vapour. These results show the temperature rise of films during the deposition of the vapour of the secondary constituent metals.

To estimate the temperature rise, Cd–Sn system was investigated. This system has β-phase (hexagonal) which is stable at temperatures higher than 133°C only. The β-phase was observed when Cd vapour was deposited on Sn layer. It is estimated from this result that the temperature of the surface layer of Sn deposit rose at least above 133°C in this case.

§ 3. Source of the Heat Energy

The source of the heat energy producing the temperature rise should be composed of two parts, namely, the radiation heat from the filament, and the kinetic energy of vapour atoms and the latent heat of condensation by the deposition. To determine which of these is more effective, an experiment of deposition was carried out, shielding the radiation heat. A small rectangular aluminium mirror, whose width was a little larger than the diameter of filament coil, was placed between the filament and substrate at the distance about 1 cm apart from the former. A fraction of Pb vapour swerved in the shadow of radiation shield excepting the case when the vapour density was very low, and thus Pb was deposited on Au film which was prepared by the deposition of Au vapour previously. The formation of alloys was also observed when the vapour density was comparatively high. Compared with the fact that the alloys were not formed when the amount of evaporated Pb was about 2 mg with no radiation shielding because of the insufficiency of the total latent heat as previously mentioned, it is concluded that the latent heat of condensation is more effective for the temperature rise of the surface. If this conclusion is correct, alloys will not be formed if the speed of evaporation of secondary constituent metal is very slow, even though the amount of it is sufficient to form alloys when the evaporation speed is suitably high. To examine this, Pb, 5 mg in weight, was evaporated on Au deposit in about 20 minutes with no radiation shield. The heating current of filament was carefully controlled to keep the uniform evaporation rate. Alloys were not formed in this case.

Then it is presumed that alloys will be formed easier when metals having larger latent heats of evaporation per mole are deposited on the primary deposits than when those having smaller ones are deposited. (Since the kinetic energy of vapour atoms, the latent heat of solidification and the specific heat are small compared with the latent heat of condensation, only the latter has been taken up.) As mentioned above, no alloy was formed when small quantity of Pb vapour was deposited on Au, and therefore it seems suitable for the confirmation of the above-mentioned presumption to examine whether the alloys are formed or not by the deposi-

Table II.

Secondary deposit	Base deposit	Alloy phase formed	Latent heat of vaporization of secondary deposit
Pb	Au	none	42,400 cal/mole
Au	Pb	$AuPb_2$	81,800
Pb	Bi	none	42,400
Bi	Pb	none	42,600
Sn	Ag	γ–Ag–Sn	70,000
Ag	Sn	γ–Ag–Sn	60,720

tion of small quantities of the same mole of the secondary constituents having various latent heats of condensation per mole. The latent heats of condensation of Au, Pb, Bi, Sn and Ag are listed in Table II[3]. Experiments were carried out for Au–Pb, Pb–Bi and Ag–Sn systems. The quantity of each metal used for the second vaporization was between $8\sim10\times10^{-6}$ mole. In the case of Au deposited on Pb layer the alloy phase was formed, but the case of Pb deposited on Au layer showed no alloy formation. The formation of alloy was observed for the Ag–Sn system but no alloy phase was observed for Pb–Bi system independently of the order of evaporation (see Fig. 1). Latent heats of condensation of Pb and Bi are smaller than those of Ag and Sn (see Table II). Considering that diffusion constant at room temperature is of the order of 10^{-16} cm²/sec for Pb–Bi and 10^{-20} cm²/sec for Ag–Sn and the activation energy is 18.6 and 21.4 kcal per mole respectively, it is concluded that the latent heat of condensation is a main cause for the temperature rise of the substrate layer.

§ 4. Effect of the Texture or Surface Condition of Primary Deposit on the Formation of Alloys

As mentioned above, alloys were formed when Au and Pb vapours were deposited successively. But when the Pb vapour was deposited on Au layer which was annealed at 200°C for an hour or at room temperature for a week in vacuum, alloy phases did not appear. These specimens showed no change after annealing for a day at room temperature (see Fig. 2). This was the same when in place of Au deposit the commercial Au foil was used as substrate layer. The diffusion constant at room temperature is about 10^{-10} cm^2/sec in this case and alloy formation should occur according to the interpretation of Michel. To verify that the cause of no alloy formation in the case of annealed Au deposit or foil lies in the contamination of surface or not, the annealed Au deposit or foil was immersed in benzen, distilled water and absolute alcohol successively and the Pb vapour was then deposited on it. No alloy formation was observed yet, however. A fresh Au deposit treated as annealed one was also examined, and in this case the formation of alloy was observed. This shows that a fresh one is not affected by such treatments. These facts show that the cause of no alloy formation in the former case does not lie in the contamination of surface and alloy formation depends not only upon the temperature rise of the surface but also upon the texture or structure of the substrate layer.

To test this, the substrate layers of Ag and Bi were annealed for appropriate time and then the vapour of Sn was deposited on Ag film and Pb vapour on Bi film, respectively. The results are shown in Figs. 3 and 4. As is seen in these figures, alloys were formed contrary to the case of Pb–Au, but the amount of alloys formed diminished as the temperature of annealing became higher. In short, annealing of the substrate layers promotes the tendency to prevent the formation of alloy phases. The grain size of the substrate layer would become large by annealing and as the result the contact area of the substrate with the secondary deposit would diminish, thus reducing the rate of formation of alloys. The tendency of the grain growth would be larger at about these temperatures for Bi and Ag than for Au, but the diminution of the formation of alloy is larger for Au than for Ag or Bi. Especially, the appreciable grain growth of Au by the annealing for a week at room temperature was not observed. Consequently, the grain size is not the ultimate factor, but some structural defects, which have been investigated by many authors, would contribute to the formation of alloy phases.

§ 5. Summary

The formation of alloy phases by successive deposition of constituent metal vapours in vacuum was investigated by electron diffraction method for Au–Pb, Bi–Pb, Cu–Sn, Ag–Sn and Cd–Sn alloy systems. It was concluded that the temperature of the surface layer of the primary deposit is elevated by the deposition of the secondary metal vapour, and this temperature rise contributes to the formation of alloy phases. This temperature rise is mainly due to the latent heat of condensation of the metal vapour which deposits on the substrate layer, and the radiation heat from the filament contributes little to this phenomenon compared with the latent heat of condensation. Consequently, metal pairs having larger latent heat of condensation may form alloys easier than those having smaller ones. The degree of this temperature rise was at least 133°C for Cd–Sn system. It was also suggested that some structural defects in the substrate layer would contribute to the formation of alloys.

Acknowledgement

The writer wishes to express his sincere thanks to Professor K. Tanaka of Kyoto University for his kind advice and discussions and the encouragement throughout the present investigation. The writer is also grateful to Mr. R. Suganuma and Mr. T. Yoshida in our Institute for their assistance.

Effects of Heat Treatment upon the Electrical Properties of Silicon

By Yasuo MATUKURA

Electrotechnical Laboratory, Tokyo, Japan

(Received March 19, 1959)

Experimental studies have been made of the processes in which the changes of the carrier concentration and minority carrier lifetime are introduced into silicon by heat treatment at the temperature range 400–1200°C. In the low temperature heat treatment, the formed denors are less in the vicinity of crystal defects. In the high temperature heat treatment, the decrease of carrier density in *p*- and *n*-type crystals is observed in addition to the annihilation of the formed donors. These behaviors are closely related to the crystal defects. The characteristics of the processes involved are discussed and explained by the introduction of the recombination centers with a capture cross section of 2×10^{-15} cm^2 for hole (at 300°K).

§1. Introduction

It has been observed[1)–4)] that the donor formation is quite large in silicon crystals after heating between 400°C and 500°C, and these denors can be annihilated by a subsequent heat treatment above 600°C. The details of this phenomena depend on the parameters of the crystal growth such as gaseous ambient, rotation rate, and crystal diameter. W. Kaiser[4),5)] has shown that silicon crystals pulled from a quartz crucible contain oxygen as much as 10^{18} cm^{-3}, and some heat treatment effects are caused by the presence of oxygen. Some other investigators have reported[6)–8)] that lifetime of minority carriers in silicon may be influenced by heat treatment, and S. Lederhandler and J. R. Patel[9)] have shown that oxygen atoms can pricipitate at dislocations in crystal. As the correlation between the denor formation, the change in lifetime, and the presence of dislocation has not yet been studied, it is interesting for us to study the electrical properties of heat treated silicon having deliberately introduced defects in order to understand the behaviors of oxygen in silicon.

Here, observations are made on the changes of carrier density and minority carrier lifetime in pulled silicon crystals by heat treatment between 400 and 1200°C, and the results are explained by both the defects in silicon and the recombination centers introduced by heat treatment.

§2. Experimental Results

Several silicon crystals are sulled from a quartz crucible in argon atmosphere with various rotation rates. In order to produce a grain boundary parallel to the pulled axis, some other crystals are pulled with two seeds which have the same ⟨111⟩ axis and are put together side by side.

Samples are ground with silicon carbide powder, and rinsed in a mixture of HNO_3 and HF and then in deionized water. Throughout heat treatment, samples are put upon a quartz boat in a quartz tube using argon as a gas ambient unless stated otherwise.

Resistivity is measured by four point probe method or by potentiometer on the bridge shape samples, and carrier concentration is determined by the value of Hall coefficient or resistivity using the mobility data. Lifetime of minority carriers of the surface treated silicon is measured by Morton Haynes method under an ambient *dc* illumination.

A. *General features*

A typical variation of carrier concentration change measured at room temperature with treating temperature is shown in Fig. 1. This is found in *p*-type specimens cut from the same ingot pulled at 60 rpm. Heating time in hydrogen is about 50 min in each treatment. It is seen that the hole density in silicon decreases by heating at the temperatures in the range of 400 to 600°C and increases at above 600°C. This change results from the donor formation and annihilation. The values of the activation energies of such induced donor centers have been determined by measurements of the variations of Hall coefficient with temperature on arsenic doped silicon which is heated at 470°C for 50 hours. Two levels at 0.14 eV and 0.31 eV below the conduction band are evaluated, in a good agreement with F. J. Morin's data[10]. Since the shallow level may be completely ionized at room temperature, it has been assumed in this work that the change in carrier concentration by heat treatment below 600°C is a measure of the number of the induced donor.

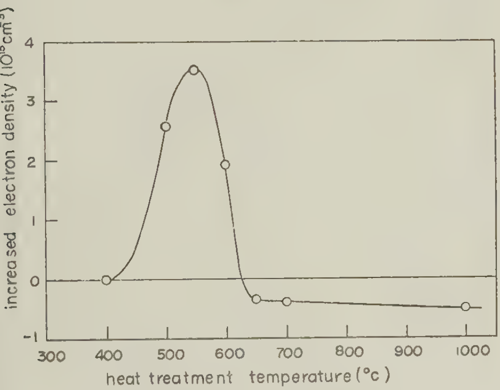

Fig. 1. The change of carier density as a function of heat treatment temperature in p-type silicon pulled at 60 RPM.

The formed donor denters are annihilated by subsequent heat treatment for short period above 600°C, and appeared again below 600°C[2),3)]. It has been known that the donor concentration formed by heating in the temperature range of 400 to 600°C is larger in the crystals pulled at high rotation rate than at low. As the crystal experiences the temperature of the donor formation during the pulling, the formed donors exist originally in every pulled crystal. The decrease in donor density, shown in Fig. 1, by the heat treatment above 600°C is due to the annihilation of the donors formed during the pulling at high rotation rate, 60 rpm.

The formed donor density depends much on the period of heat treatment. It is observed that the denor density induced by heat treatment at 450°C increased with the heating period and approached some value which may be related to the pulling condition. These results agree with Fuller's[3)] and Kaiser's[4)]. The specimens are also heated in various sorts of ambient gas at 500°C. It is seen that the heat treatment in vacuum of 1×10^{-5} mm Hg induces the denors a little less than the other treatments in hydrogen, argon, and air. The induced donor density is not influenced by cooling rate from 500°C. This is examined by the following experiments. The specimens were quickly dropped into the diffusion pump oil at room temperature from the treating temperature and other specimens were slowly cooled. In both treatments, the difference in the formed donor density is not seen.

In the high temperature treatment, it is observed that in addition to the annihilation of the formed donors, both electron density in n-type and hole density in p-type crystal decrease, independent of the crystal growth condition. Such decreases of carrier density are not affected by the variation of cooling rate* from high temperature, but little affected by the sorts of ambient atmosphere including vacuum.

Lifetime of minority carriers decreases by the heat treatment in the temperature range of 400 to 1200°C. This is similar to the characteristic of the decrease of carrier density by the high temperature treatment mentioned above.

B. *Heat treatment at low temperature*

Specimens of about 7×2 mm^2 cross section are cut along the radial direction in some round slices from n-type crystal pulled at 10 rpm. After heat treatment for 30 hours at 450°C, the induced donor concentration varies along the rod. One of these radial variations is shown in Fig. 2, where etch pit density and lifetime of minority carriers before and after the heat treatment are shown together. It is seen that the induced donor concentration decreases at the edge of the slice where the etch pit density is large compared with at the center, and that the decreases of the lifetime are striking at the center.

---

* More rapid cooling experiment were performed by quenching the p-type specimens by dropping into the room temperature oil from 1000°C for about 3 sec. The decrease of hole density in order of 5×10^{14} cm^{-3} was observed. As this results will be related to the lattice defects made by quenching, it will be reasonable to discuss this phenomena in other place.

A *p*-type specimen having an artificial grain boundary pulled at 10 rpm as shown in Fig. 3 is heated at 470°C for 25 hours. The changes of the hole concentration along the rod are also shown in Fig. 3. It is explicitly shown that in the neighbourhood of the grain boundary the formed donor concentration is small compared with that at the other portions.

In order to make precise of the influence of crystal defects on the concentration of the formed donors, the following experiments are also performed. Two specimens are cut along the radial direction from the adjacent slices of the *n*-type ingot. One is etched by CP–4, and another is ground by 600 mesh silicon carbide and carefully rinsed in deionized water. After both specimens are heated for 25 hours at 470°C, the radial variations of increased electron density are measured along the rod. The results are shown in Fig. 4. At the edge where a large number of dislocations are expected, the difference in the formed donor density between both specimens

is not clearly observed, but at the center the formed donor density in the etched specimens is distinctly higher than that in the ground.

From the above mentioned results, it is seen that the donor formation depends strongly on the degree of crystal perfection.

C. *Heat treatment at high temperature*

Both silicon specimens, one cut from a pulled ingot and another from vacuum floating zone refined crystal, exhibit a number of interesting effects by heat treatment in the temperature range of 600 to 1200°C.

Specimens of $7\times2\,\text{mm}^2$ cross section are cut along the radial direction from some round slices of an n-type crystal pulled at 10 rpm. After heat treatment for 8 hours at 1000°C, electron densities decrease as a function of the radial distance as shown by curve (a) in Fig. 5, where the dislocation density along the sample is also shown. Another specimen having the same dimensions is prepared from the adjacent slice of the crystal, and ground by 600 mesh silicon carbide and then carefully rinsed in deionized water. This specimen is heated with the etched one, the results of which is already shown by curve (a). The radial variations of the decreased electron density are shown by curve (b) in Fig. 5. It is seen that the decreases of electron density are contrary to the results caused by a low temperature heat treatment and are striking in the center of the rods where etch pit densities are low. In Fig. 5, it is also seen that the decreases of electron density in the abrased specimen is less than that in the etched one. Such decreases of carrier density are accompanied by the decreases of minority carrier lifetime.

In order to investigate the correlation between the changes of the carrier density and the crystal defects, p-type specimens having a grain boundary are heated for 8 hours at 1000°C. An example of the results is shown by curve (a) in Fig. 6, where the decrease of hole density is plotted along the sample. It is seen that the decreases of hole density are small at the grain boundary. Measurements of thermoelectromotive force by hot probe method show an n-type property along the grain boundary. The similar features are also observed in the following experiments: Among the two p-type specimens cut from a vacuum floating zone refined crystal, one is etched and another is ground, and after a heat treatment at 1000°C for 8 hours, it is observed that only the surface of the abrased specimen has an n-type layer of 1×10^{-2} mm thickness which is determined by angle lapping and hot probe technique. The decreases of the hole density are also observed in these specimens which may be expected to have a lower concentration of oxygen atoms.

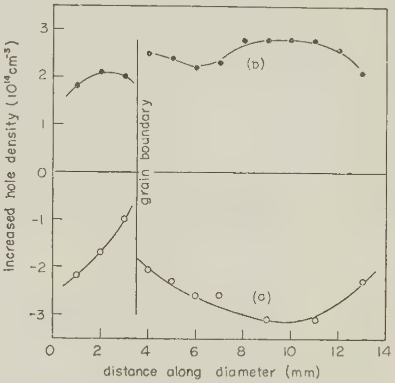

Fig. 6. Changes of hole density as a function of distance along the diameter in p-type silicon having a grain boundary. (a): after heat treatment at 1000°C, (b): after subsequent heat treatment at 470°C.

The p-type sample heated at 1000°C is again heated at 470°C for 25 hours. The change of hole density before and after the heat treatment at 470°C is shown by curve (b) in Fig. 6. In spite of the heat treatment by which the large amount of the donors should be formed, it is observed that the hole density on the contrary increases only in the order of the decreases by the heat treatment at 1000°C.

The decrease of carrier density in p- and n-type silicon by a high temperature heat treatment is accompanied by the decrease of the minority carrier lifetime. Such phenomena depend on the temperature at which the specimens are heated. Some n-type specimens are cut from a crystal pulled at low rotation rate and the values of lifetime are found to be 30 to 50 μsec. These specimens are heated for 6 hours at various temperatures. Fig. 7 shows the variations of the decreased electron density and the lifetime after the heat treatment with the reciprocal of the treating temperature. If it is assumed that the logarithm of the decreased electron density and the lifetime after the heat treatment vary linearly with the reciplocal of the treating temperature, the activation energy may be obtained as 0.36 eV for the changes of electron density and 0.34 eV for the lifetime. It is also observed that the decreases in carrier density and the lifetime after a heat treatment depend neither on the heating period, nor on the resistivity and the lifetime before the heat treatment.

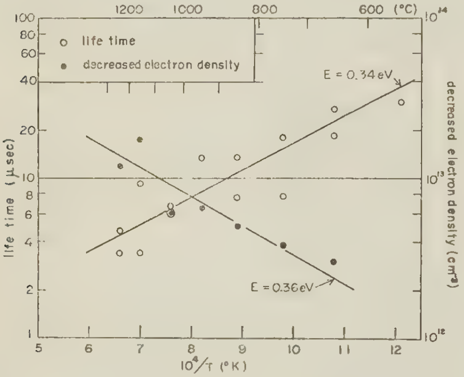

Fig. 7. Lifetime after heat treatment and decreased electron density as a function of reciprocal of heat treatment temperature in *n*-type silicon.

§ 3. Discussion

Discussion is separated into two parts; first, the donor formation by low temperature heat treatment and second, the decreases of carrier density and the annihilation of the formed donors by high temperature's one.

About the phenomena of donor formation, Kaiser[5] has shown that the oxygen atoms included in silicon cause the absorption at 9 μ by Si–O molecular vibration, and that oxygen atoms sensitive with the 9 μ absorption are mostly present at the center of pulled ingot, contributing to the donor formation by a heat treatment at 450°C. The results given in Fig. 2 and 3 show that the formed donor density depends in a very sensitive way on the dislocation density of the materials. Edge portions of pulled crystal and the neighborhood of grain boundary have a higher dislocation density than at the center. The formed donor density is distinctly small at the grain boundary and the edge portion. From these data, it may be reasonable to assume that, when a crystal is cooled during the pulling, the oxygen atoms introduced into the crystal are frozen at the dislocations and the grain boundary, and that the frozen oxygen atoms do not contribute to the donor formation by a low temperature hert treatment. Such assumptions that the oxygen atoms in crystal may be captured by the crystal defects are consistent with the results of low temperature heat treatment on the specimens having an abrased layer as shown in Fig. 4, that is, as the oxygen atoms in crystal diffuse and precipitate in the abrased surface layer, the density of oxygen atoms to contribute to the donor formation is smaller in the abrased specimens than in the etched one. At the edge of crystal, as the oxygen atoms are nearly frozen at dislocations during the pulling, the influence of surface abrasion may be expected to be very small. Lederhandler and Patel[9] have used nearly the same assumption and clearly explained their data on the fast decrease of the absorption coefficient at 9 μ by high temperature heat treatment on the plastically deformed silicon.

The phenomena induced in silicon by a high temperature heat treatment can be explained by the following two processes; (a) annihilation of the formed donors and (b) decrease of carrier density in *p*- and *n*-type silicon. The former may be related to the oxygen atoms included in crystal, but the latter should not be related to oxygen since the decrease of hole density is also observed on a vacuum floating zone refined silicon which is believed to include less oxygen atoms.

Process (a) is explained by Kaiser's assumption that the oxygen atoms, originally active in donor formation, group together into clusters of high oxygen concentration during the heat treatment at 1000°C and then the formed donors are annihilated. In such process, electron density in *n*-type crystal decreases and hole density in *p*-type increases. In Fig. 1, the increases of hole density by a heat treatment at above 600°C show that the donors induced during the pulling are annihilated by this process.

Most of the high temperature heat treatment effects are hardly explained by the process (a). Reduction of the density of majority carriers shown by the curve (a) and (b) in Fig. 5 and the curve (a) in Fig. 6 may be explained by a new assumption that heat treatment introduces some deep trapping centers into both n- and p-type silicons. By further assumption for these trapping centers to play another important role, the recombination center, when the minority carrier is present, the observed reduction of the lifetime after heat treatment may easily be explained. To explain the correlation between the decreased majority carriers density and the lattice imperfection and to explain the n-type character of the grain boundary and the abrased surface, these centers should be assumed to be captured by dislocations quite easily after high temperature heat treatment and to become new donors. If these centers may have a temperature dependent solubility11) and may aggregate each other by low temperature heat treatment, the behavior of the curve (b) in Fig. 6 will be reasonably understood. Also, the facts that the minority carrier lifetime is slightly recovered by the subsequent low temperature heat treatment will be reasonably explained.

If the energy necessary to introduce this center into silicon is E eV, the density of this center Δn, will be given by the following equation,

$$\Delta n = N_0 \exp(-E/kT) .$$

Value of E determined by the slope in Fig. 7 is about 0.35 eV, and N_0 is $2\times10^{14}\,\mathrm{cm}^{-3}$. The lifetime τ_p in the n-type crystal heated at high temperature may be nearly determined by the number and the capture cross section σ of the introduced recombination center,

$$\sigma = \frac{1}{\Delta n \cdot v \cdot \tau_p} .$$

The value of σ obtained from Fig. 7 is $2\times10^{-15}\,\mathrm{cm}^2$ for hole at 300°K. Same estimation of σ for electron in p-type silicon were performed by some experiments. The value of σ is order of about $10^{-15}\,\mathrm{cm}^2$ for electron at 300°K.

The value of the formation energy estimated from the data does not agree with the B. Ross's value6) and the Bemski's one8) which have determined by the quench experiments. It seems that this discrepancy results from the difference in the cooling rate from a treated temperature. Recently, Bemski12) has reported that at high temperature gold is introduced in a concentration of $10^{14}\,\mathrm{cm}^{-3}$ into silicon from the surface and formed a donor level at 0.34 eV from the conduction band. It is interesting to notice that the density of the recombination centers introduced in our experiments is of the order of 10^{12} to $10^{14}\,\mathrm{cm}^{-3}$ at 600 to 1200°C and that the capture cross sections for hole and electron are similar to Bemski's results13). If these centers are introduced from the surface, the concentration of centers must be proportional to the ratio of surface area to volume of the specimen. Studies on the energy level of the centers and on the variation of their concentration with the surface-to-volume ratio seems to be helpful for getting information about what they actually are.

Electronmicroscopic Observations of the Cleavage Plane of KCl Crystal

—the Deformation Zone—

By Tetsuhiko Tomiki*

The Research Institute for Steel, Iron and other Metals,
Tohoku University, Sendai, Japan

(Received February 17, 1959)

The *deformation zone* of KCl single crystal decorated with potassium colloid particles is investigated with electron microscope using a replica technique. The deformation zone is formed independently on the imperfections contained originally in the crystal. The slip lines near the deformation zone observed with light microscope are consisted of a number of fine slip lamellae. The thickness D of the slip lamella, the slip distance s and the height h of the slip step were estimated as $D=720$A, $s=270$A and $h=240$A for three adjacent slip lines. It is suggested that several hundreds of screw type dislocations are attached to every new cleavage step at the deformation zone. The attempts were made for the explanation of the mechanism by which new cleavage steps are formed at the deformation zone.

§ 1. Introduction

When an alkali halide single crystal is coloured either with x-ray[1),2)] or with excess alkali metals introduced additively,[3)] growth of crystallites is observed electronmicroscopically not only on the outer surface, but also in the interior of the crystal. One of the most important markings in analysing the effects induced inside the crystal has been the pattern of steps revealed on the freshly cleaved plane obtained after the colouration, and the characteristic features observed so far with electron microscope are summarized in the following: On the fresh cleavage plane of the coloured crystal, it is observed a zigzag step at the kink site where crystallites grow and, in some cases, a bundle of wavy steps converges at such a kink site. This phenomenon was interpreted as follows: The zigzag step may correspond to a kind of internal surface which was originally straight before colouration and was made to turn into the zigzag shape as a result of ion redistributions caused by the colouring processes. It is also considered that such a motion of the internal surface causes growth of crystallites at kink sites. The bundle of wavy steps attached to the kink site may indicate the internal stress produced by the process stated above.[1),3),4)] These situations are quite similar to those which could be expected on the nonconservative motion of dislocations. At present, we have not a sufficient experimental confirmation to interpret the phenomenon in languages of the current dislocation theory, except for a few remarkable cases.

On the other hand, it has been generally accepted, on the basis of the observations with optical microscope, that when the cleavage crack front travels across a twist boundary, new cleavage steps are formed at screw dislocations whose Burgers vectors are not parallel to the cleavage plane.[5)] Recent investigation by Forty[6)] showed that when the cleavage crack front ceased its propagation, the two halves of the crystal plate have plastically deformed by absorption of the kinetic energy of the crack front, and that the new cleavage steps are formed there when the cleavage crack front is made to move forwards again. He observed also the ⟨100⟩ slip lines attached to every cleavage steps which were created anew, and called this special region "*deformation zone*", which can also be produced when the cleavage crack front propagates with a velocity under a critical value.[6),7)] It was suggested that the array of dislocation loops are nucleated along the deformation zone, and this was proved by decorating the dislocation loops with excess metal particles.[8] Another experiment was carried out independently on LiF single crystal with using a successive etch technique, and this gave the same confirmation, too.[9]

---

* Present Address: *Department of Physics, Faculty of Science, Tohoku University.*

If the above relation between the cleavage step and the screw dislocation were applicable to the bundle of wavy steps which converges at the crystallite grown at the kink site of a zigzag step, there must exist a screw dislocation whose Burgers vector is not parallel to the cleavage plane. But, this would be too favourable to be true. It is desired to observe the deformation zone or a twist boundary with electron microscope, if the attempts are made for the interpretation of the characteristic features of step patterns.

As the first step to see the relationship between the cleavage steps and the crystal imperfections such as dislocations, the deformation zone of KCl single crystal was observed with electron microscope.

§ 2. Experimental

2·1 *KCl crystal employed in the experiment*

KCl specimen employed here was not a

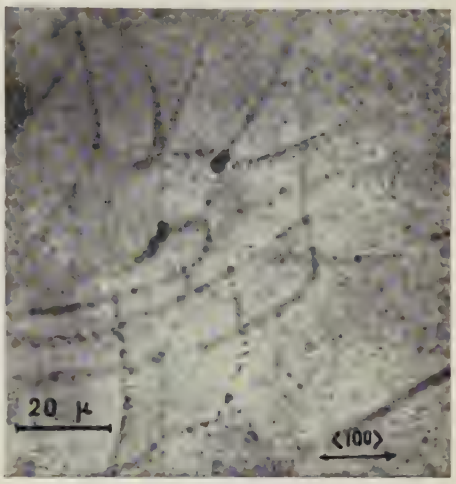

Fig. 1. An optical microscopic image of KCl crystal decorated with colloid particles along dislocation lines.

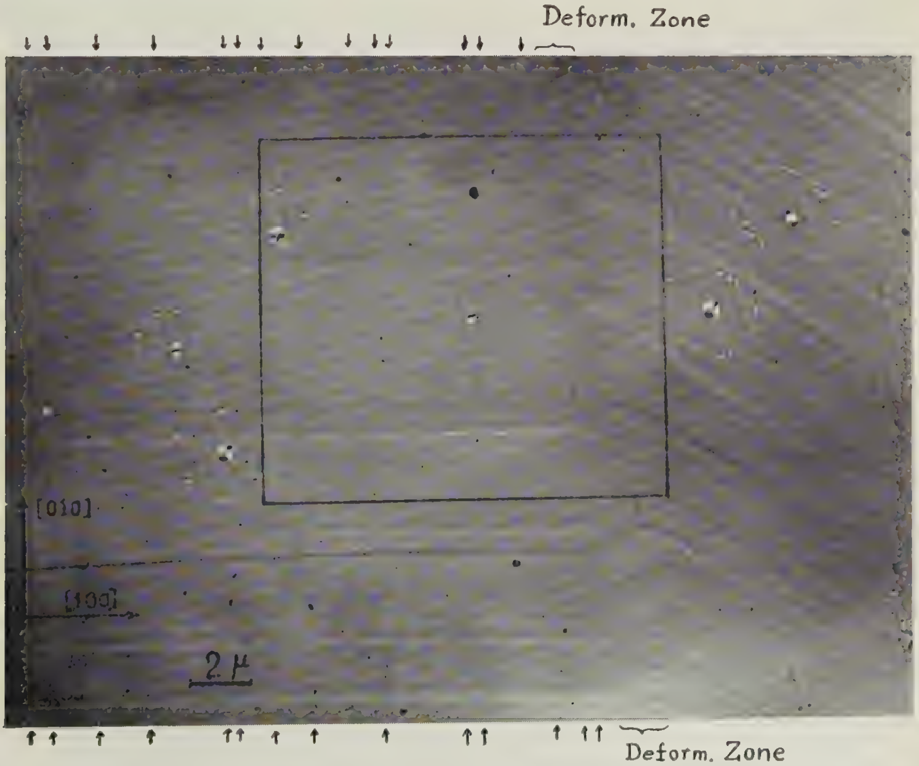

Fig. 2. An electron image of the deformation zone and the cleavage plane adjacent to it. The [100] and [010] direction are chosen as shown in the figure, and the [001] axis is directed upwards normally to the paper. *Cr*-shadow is directed to the [010], and the cleavage crack front propagated from left to right. Every arrow indicates the spots where the slip lamellae are predominant.

pure single crystal cleaved from the block, but was one decorated with potassium colloid particles along the dislocation networks. The reason why the decorated crystal was adopted is based on the following facts: The electronmicroscopic observations on the freshly cleaved {100} planes of the decorated crystal showed that a pit is produced at the spot on the cleavage plane where colloid particle precipitated[10]; this means that we can obtain the surface markings which are closely related to the crystal imperfections without smearing out the fine steps of an electronmicroscopic scale, for the application of the usual etch technique to the fresh cleavage plane to produce the etch pits leads to the simultaneous and inevitable removal of the surface layer of few microns in thickness.

In the present experiment, the undeformed KCl single crystal was heated in the atmosphere of potassium vapour at 550°C for 4 hours, followed by the furnace cooling to room temperature in 12 hours. By this pro-procedure, it was possible to obtain the crystal that was decorated with potassium colloid particles along the dislocation lines as shown in Fig. 1. If the crystal is quenched to room temperature instead of the furnace cooling, it will acquire the atomic dispersed ***F*** centres, as is well known. The procedure adopted in this experiment is slightly different from Rexer's method by which greater parts of the experiments for decorating dislocations of alkali halides with colloid particles were carried out,[11] nevertheless the phenomena that the crystal becomes to contain colloid particles by this procedure are not quite new in themselves.[12]

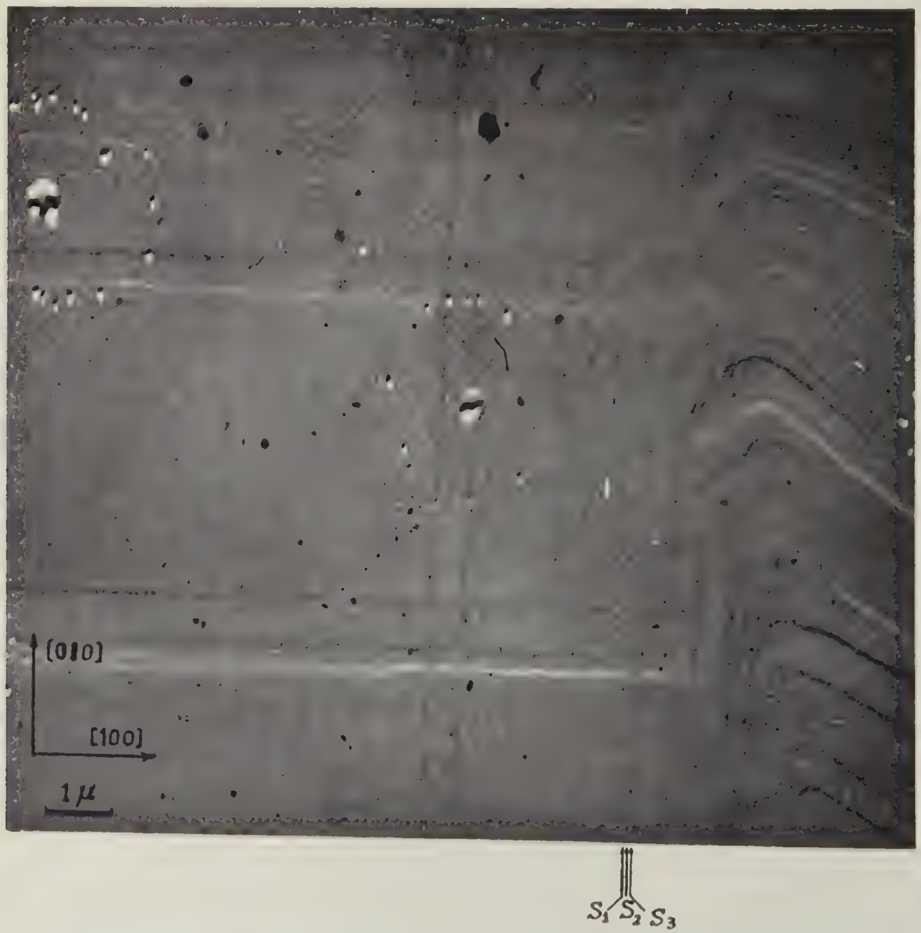

Fig. 3. An electron image of fine slip lamellae on the cleavage plane adjacent to the deformation zone. The coordinate system is identical with that of Fig. 2. The slip lines S_1, S_2 and S_3 are estimated as about 240A in heights.

2·2 *Cleavage planes and a reprica*

The (001) cleavage plane of the crystal was obtained with a sharp razor by tapping it with pincette at room temperature. The special attentions were not put on the cleaving process as were done in the previous workers.[6),7)] This fresh cleavage plane was observed with the electron microscope using the one stage replica which was consisted of obliquely deposited ***Cr*** film subsequently reinforced with ***C*** film in high vacuum, where the ***Cr***-beam was directed parallel to one of the ⟨100⟩ of the specimen and made an angle $\theta = \tan^{-1}(0.4)$ to the cleavage plane to be observed.

§ 3. Experimental Results

The electron image of the deformation zone described above and the surface area adjacent to it are shown in Fig. 2 which illustrates the general features of cleavage steps on this surface area. The shadow direction indicates that the cleavage crack front propagated from left to right leaving the straight cleavage steps directed to the [100] of the basal plane behind, until it reached to the defor-

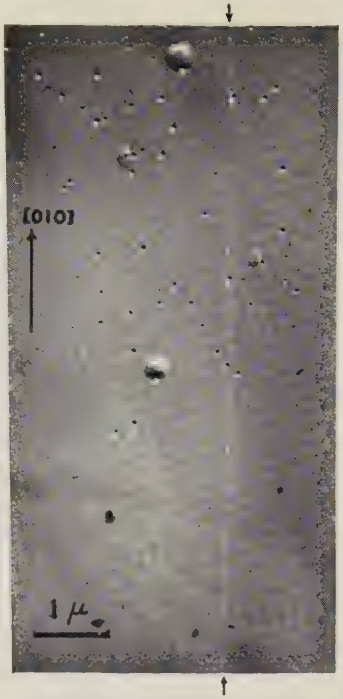

Fig. 4. An electron image showing the single slip line on the flat cleavage plane. The arrow indicates the [010] slip line.

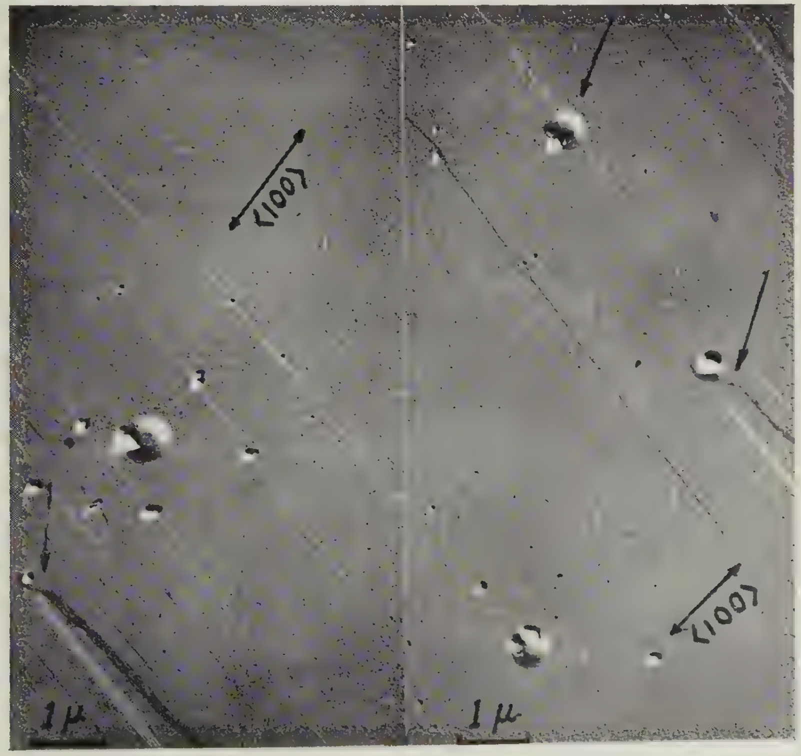

(a) (b)

Fig. 5. An electron micrograph showing the effect of imperfections on the cleavage step.

mation zone. When the cleavage crack front passed across this zone, the new cleavage steps were produced and their running direction was suffered a sudden change from the older [100] to the direction making an angle of about 30° to it after the short passage along the direction making an angle of about 20° to the [010].

The small semispherical pits of about 0.5 microns in diameter encircled with tiny drops are observable on the cleavage plane. They are considered to be resulted from the potassium colloid particles.[10] Since they indicate probably the place where imperfections were located before cleaving process, it is conceivable that a deformation zone can be formed independently of the imperfections contained originally in the crystal, provided that all of the imperfections are to be decorated with colloid particles.

Another interesting phenomenon is that the fine slip lines having the [010] direction of the basal plane are observed chiefly on the surface area where only the [100] cleavage steps appear. Every arrow in the figure indicates the spots where the slip lamellae are predominant.

Fig. 3 shows the detailed structure on the surface region enclosed with black lines in Fig. 2. One sees here clearly a kind of fluctuation in the density and strength of the fine slips. To every new cleavage step a number of fine slip lines whose directions are slightly deviated (about 20°) from the [010] are attached. The sum of their slipped distances represents roughly the height of the new cleavage step to which they are attached. Furthermore, the [100] cleavage step are segmented by the [010] slip lines. The shape of the intersection of the cleavage step and slip planes indicates that the resolved slip processes are mainly due to the (101)/$[10\bar{1}]$ slip system. It should be pointed out, however, that the slip lines are not always so simple as stated above, but mixed with other glide systems.

Fig. 4 is the electron micrograph which shows the single slip line on the cleavage plane. We could occasionally observe slip lines of this type on the cleavage plane.

Finally, it must be mentioned the effect of the "colloid" pit on the cleavage step. Though it is observed that a new cleavage step is rarely created behind the spot where colloid particle precipitated, its definite influences on the cleavage step could not be observed as shown in Figs. 2, 3 and 4. If a fine cleavage step happened to proceed against the pit, its passage was forced to curve leaving a semicircular locus of the cleavage step around the pit. The radius of curvature of the semicircular step was slightly larger than that of the pit by 300 A to 1,000 A. This is considered to be caused by the stress around the imperfection. These phenomena are shown in Fig. 5.

§ 4. Discussion

4·1 *Estimation of the number of screw dislocations*

The resolved [010] slip lines on Figs. 2 and 3 probably correspond to the (101)/$[10\bar{1}]$ slip system, taking the orthogonal coordinates system such as shown in Fig. 2. It is conceivable that this configuration causes the slip lines to have the dark contrast against

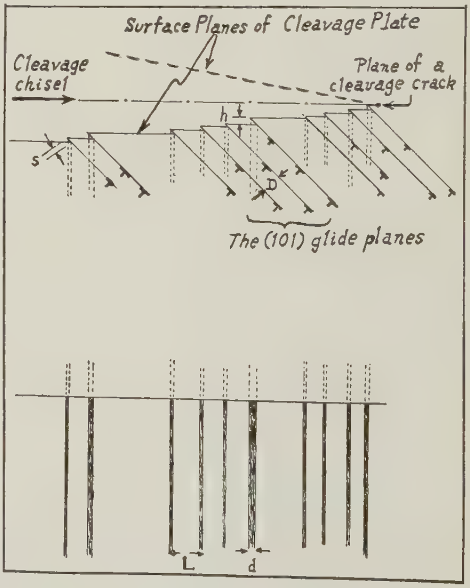

Fig. 6. (a): A schematic diagram of slip lamella and plastic bending of the half crystal. This configuration was obtained on the basis of Fig. 2 (or 3). The slip distance s of a slip lamella, the step height h and the lamella width D are defined. (b): The darkening of an electron image obtained from the replica which casts the surface represented by Fig. 6 (a). The width d of a slip line and the lamella length L measured along the [100] on the (100) are defined.

the slip lamellae even though the ***Cr***-shadow was parallel to the [010] direction. Fig. 6 is the schematic diagram obtained from Fig. 2 (or 3). Then, the step height h due to the slip motion of each lamella is equal to the breadth d of the slip line, and the slip distance s along the [101] is $\sqrt{2}\cdot d$. The thickness D of a slip lammella is given by $L/\sqrt{2}$, where L is the breadth of the lammella measured along the [100] on the (001) plane (see, Fig. 6). For the slip system S_1, S_2 and S_3 indicated in Fig. 2, the following values can be obtained:

	Slip			Lamella	
	S_1	S_2	S_3	S_2S_1	S_3S_2
h	240 A	>240 A	240 A	—	—
s	270 A	>270 A	270 A	—	—
D	—	—	—	720 A	720 A

These values will give a rough picture for the slip system observable in the region near the deformation zone. To each new cleavage step created along the deformation zone five to ten resolved slip lines are attached, so we can calculate the number N of the screw dislocations per new cleavage step according to the next equation:

$$N=(s/\boldsymbol{b})\cdot n \tag{1}$$

where,

n=the number of slip lines attaching to a new cleavage step

$\boldsymbol{b}$=Burgers Vector$=a\cdot[110]/2$

Taking $s=270$ A, the relation $N=120\cdot n$ is obtained. Thus, it is estimated that 5.10^2 to 10^3 screw dislocations are created at or near the every new cleavage step along the deformation zone.

4·2 *The mechanism of the creation of new cleavage steps*

According to the present investigation, the deformation zone was formed independently of the imperfections originally included in the crystal plate, because Fig. 2 shows that the deformation zone is located on the region of the cleavage plane which has not any relationship to the colloid pit. Thus, it is certain that the slip lines observed in Figs. 2 and 3 were produced by the applied external force by which the cleavage crack front was driven.

As to the mechanism of formation of the deformation zone, the previous investigators[6),7)] infered as following: When the cleavage crack was introduced into the crystal and driven by the external force, the elastic energy in the crystal is stored up in addition to the increment of the surface energy accompanied with the crack propagation; this elastic energy is released possibly by the plastic work, hence the dislocation loops are spontaneously introduced into the crystal region near the front of a propagating cleavage crack. This special region is the so called deformation zone, as stated in § **1**. This problem has been investigated on the standpoint of crack propagation. Nevertheless, the mechanism by which new cleavage steps are created along the narrow strip of deformation zone was not taken up so far as we know. In this paragraph, some discussions are given on this point.

When the cleavage crack was introduced into the crystal plate along the {100} so as to obtain two halves of the crystal plate with equal thickness, they separate each other with nearly equal amount of a plastic bending which is partly caused with glide processes extensively occurred on the deformation zone. In the other case when the thinner crystal plate was cleaved off from the thicker one, the former is severely deformed. It is considered here, therefore, the mechanism by which the new cleavage steps are created along the deformation zone only in the case when the two halves of the crystal plate are cleaved with equal thickness and under the same plastic bending. This may be applicable to the other cases with a slight modification.

Fig. 7 shows that the cleavage crack ***ABNM*** is introduced into the crystal plate to produce two halves of crystal plate ***I*** and ***II*** with equal thickness, here a cleavage crack front is located along the curve ***ASB***. It is assumed that the crystal plates ***I*** and ***II*** are equivalent in all respects. Now, let us suppose that the elastic energy in the crystal is stored up and happens to be elevated at a critical value at the instant when the cleavage crack front is located along the ***ASB***, and that the crystal plates ***I*** and ***II*** are consequently deformed by slip by the high stress concentration at the point, for example S, on the **ASB** in order to release it. For the easy comparison between Fig. 2 (or 3) with Fig. 7, the same coordinate system was adopted in both figures. The family of the [100] cleavage steps in Fig. 2 is considered to exist on the cleavage crack **ABNM** in Fig. 7. If the slip process in **I** is due to the $(101)/[10\bar{1}]$ system, as in Fig. 3, the crystal plate **II** must slip along the [101] on the $(\bar{1}01)$ at the same instance because of the assumption of equivalency. Consequently, dislocation loops may be nucleated both on the (101) and on the $(\bar{1}01)$, where the dislocation loops on the (101) may be easily located downwards in the region of the crystal plate **I**, and those on the $(\bar{1}01)$ upwards in the crystal plate **II**. The parts of dislocation loops near the free surface **ASBNM** may move to the surface, then cut it leaving the slip steps along the [010] to release the stress field. The configuration of the dislocation loops at this instance is represented in the figure as the curves of $SP_{\text{I}}E_{\text{I}}$ and $SP_{\text{II}}E_{\text{II}}$. The character P indicates that they have the positive edge character, and the character E for the end point of the dislocation loop. The shaded part in the figure indicates the slipped region. Near the point S, the excess of screw dislocations of the same sign may be concentrated locally. If the dislocation loop $SP_{\text{II}}E_{\text{II}}$ have a screw component near the region S whose sign is reverse to that of the $SP_{\text{I}}E_{\text{I}}$, the high concentration of the stress at the region S could not be released, thus such kind of combination of slip processes is meaningless. These special situations lead to raise the elastic energy in the neighbourhood of S, and give rise to the additional force $\boldsymbol{F}$ directed towards interior the crystal along the [010]. In accordance with Fig. 2, if we suppose the applied external force $\boldsymbol{f}$ to be directed along the [100], the cleavage crack front near the point S may be driven by the resultant force $(\boldsymbol{F}+\boldsymbol{f})$. This mechanism appears to explain the facts that the slip steps serve as the starting lamellae of every new cleavage step to which they are attached and that their directions are deviated slightly from the [010] direction (see § **3**; Fig. 3, for example). After the additional spontaneous force $\boldsymbol{F}$ around the point S as well as the other points along the deformation zone under the same condition as S vanishes by the movement of the crack front along the special direction stated above, the crack front should be driven solely by the external force along the direction favourable to it. Thus, the cleavage step may change its running direction suddenly. It is conceivable that the abrupt change of the direction of cleavage steps from that of the slip lamella making an angle 20° to the [010] in Fig. 3 may correspond to the above state of affairs.

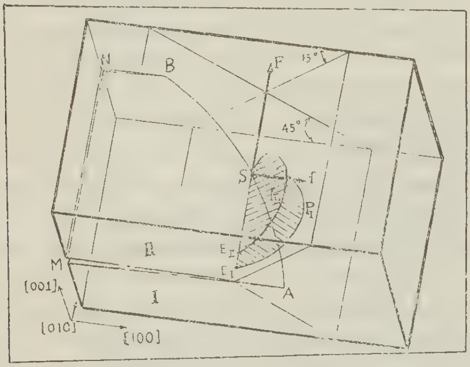

Fig. 7. Schematic diagram for the propagation of a cleavage crack front. **ABNM** is the cleavage crack, **ASB** is the front of a cleavage crack. The curve $SP_{\text{II}}E_{\text{II}}$ corresponds to a dislocation loop on the $(\bar{1}01)$ and $SP_{\text{I}}E_{\text{I}}$ to that on the (101). Shaded regions represent the slipped area (See the text).

Now, according to the above mechanism, it appears possible to understand the reason why the new cleavage steps are formed and suffered to the abrupt change of their running directions at the deformation zone **ASB** nearly independent of the older cleavage steps. As estimated in § **4·1**, it is easy to make the older cleavage steps of 0.1 microns or less in heights vanish by the slipping process. If any cleavage step is sufficiently high so that it is not made vanish by the slip process, it can across the deformation zone. However, its running direction is forced to change at the deformation zone to the direction which was determined by the force $\boldsymbol{F}$ to relieve the strain energy of the screw dislocations with same sign.

§ 5. Summaries

The cleavage plane of KCl single crystal containing colloid particles was investigated with electron microscope using one stage replica technique. The important results are summarized as follows:

(1) The deformation zone is formed independently of the imperfections contained originally in the crystal.

(2) The slip lines near the deformation zone observed with light microscope are consisted of a number of fine slip lamellae. Measurements were made on the thickness D of the slip lamella, the slip distance s and the height h of the slip step for three examples. They gave the following values: $D=720$ A, $s=270$ A and $h=240$ A. Thus, it was estimated that several hundreds of screw dislocation are attached to every new cleavage step at the deformation zone.

(3) It was found that new cleavage steps are created independent of the older cleavage steps at the deformation zone and that the height of a new cleavage step at the defortion zone and that the height of a new cleavage step is nearly equal to the sum of the slip lamellae attaching to it. Attempts were made for the explanation of the mechanism by which new cleavage steps are formed and made to change near the deformation zone their running direction from that of the older one.

(4) Some effects of crystal imperfection on the passage of a cleavage step was detected (Fig. 5).

Acknowledgements

This experiment was made in 1956 during the course of the experiment of the additively coloured crystal with the electron microscope[3),10)] at the *Research Institute for Scientific Measurement, Tohoku University*. The author would like to express his cordial thanks to Prof. S. Ogawa, *the Research Institute for Steel, Iron and other Metals*, who made this possible. He is very greateful to Prof. T. Hibi for his kind and instructive guidances to electronmicroscopy through experiments. His gratitudes are also due to Dr. T. Suzuki who kindly suggested the mechanism of the production of new cleavage steps and criticized the manuscript.

β-Ferric Oxyhydroxide and Green Rust

By D. R. Dasgupta and A. L. Mackay

Birkbeck College Crystallographic Laboratory,
21, Torrington Square, London, W. C. 1

Evidence that the existence of crystalline $Fe(OH)_3$ has not been demonstrated by Abe[1)] is presented and doubts cast on the existence of β-FeOOH are dispelled. The green rust observed by Yoshioka[9)] is shown to be identical with that found by Keller[6)] and outline structures are suggested for these compounds.

§ 1. Introduction

In the course of a programme of work on magnetic iron minerals we have studied as many iron oxides and hydroxides as have been reported in the literature and in most cases have been able to characterise the various phases and elucidate their mutual relationships. Our experiments lead us to results which conflict with those of Yoshioka[9),10)] and Abe[1)] which are reported in Structure Reports, **15** (1951).

§ 2. β-FeOOH

Data on the material precipitated when ferric chloride solution is hydrolysed at about 90°C have been published by several authors, for example, Weiser and Milligan[3)], Kratky and Nowotny[7)] and ASTM cards numbers 1–0669, 3–0429 and 3–0446. All these observations are in substantial agreement with our own (Table I), except that Weiser and Milligan, presumably because of instrumental deficiencies, did not record the highest spacing in the diffraction pattern (at 7.40Å). Within experimental error our pattern can be indexed on the basis of a body-centred tetragonal unit cell with the dimensions $a=10.48\pm0.01$ and $c=3.023\pm0.005$Å. Small distortions from this symmetry are, of course, not excluded by a powder photograph.

We prepared our specimen by the hydrolysis of $FeCl_3$ but examined also the hydrolysis products of a number of other ferric salts. We found that FeF_3 gave a product identical with β-FeOOH. Ferric bromide, nitrate and sulphate, however, gave α-FeOOH on hydrolysis. Ferric alum gave jarosite, $(NH_4)Fe_3(OH)_6(SO_4)_2$. From a mixed solution of chloride or fluoride and sulphate, β-FeOOH was precipitated in preference to jarosite. All methods of preparation gave, to within 1%, the same spacings which did not vary with the Cl′ content. On very prolonged hydrolysis at 90° (for 144 hours) β-FeOOH transformed to α-Fe_2O_3 and not to α-FeOOH.

We think that the structure should be compared with that of hollandite or α-MnO_2 (Byström[3)]) where the unit cell is very similar (space group I4/m and cell dimensions $a=9.8$ and $c=2.86$Å) and where extra large ions are necessary for stabilising the structure. In the manganese oxide Ba^{++} ions occur statistically and analyses of β-FeOOH show variable quantities (up to 4%) of Cl′ ions. The Cl′ (or F′) cannot occur stoichiometrically as the diameter of the Cl′ ion (3.62Å) is greater than the c-dimension of the cell. Analysis also confirms that all the iron is in the ferric state.

On heating, β-FeOOH loses water and transforms to α-Fe_2O_3 at about 200° depending on the Cl′ content. (With less Cl′ the temperature of the decomposition is lowered). It is difficult to estimate the significance of the water loss, about 20% above 100°, because of the adsorption of water on small particles. The loss if the composition were FeOOH would be 10% and if $Fe(OH)_3$, 25%. There are good reasons for not believing the material to be $Fe(OH)_3$ because the latter is well known as a gel which on drying at room temperature goes to α-Fe_2O_3 and on ageing may give α-FeOOH. No reliable observations of crystalline $Fe(OH)_3$ have been made before.

Abe's data seem to correspond to a mixture of β-FeOOH and $FeCl_3\cdot 6H_2O$ (see Table I). Decomposition of the ferric chloride hydrate by the electron beam would account for the difference between the X-ray and electron diffraction observations.

The agreement between the observed and calculated values using the hydrargillite-type

* X=X-ray diffraction E=electron diffraction.

structure is certainly remarkable but if the latter really obtained the intensities should be similar to those in the powder pattern of $Al(OH)_3$. The extremely strong reflexion (002) corresponding to the layer structure should be outstanding but it appears to be only moderate while there are other serious intensity differences.

We conclude therefore, that the existence of crystalline $Fe(OH)_3$ has not been demonstrated and that the β-FeOH remains as a well-characterised and established compound.

§ 3. Green Rust

We have prepared green rust (Feitknecht and Keller[5]) in quantity both chemically, by the controlled oxidation of buffered ferrous solutions, and electrolytically. In the presence of Cl′ ions the rust produced has a rhombohedral cell with $a=3.198\pm0.01$ and $c=24.2\pm0.1$Å. This is called "green rust I" and has been described by Keller[6]. In the presence of SO_4'' ions the same material is also formed (with dimensions $a=3.23$ and $c=22.5$) but at a later stage another phase, which we have called "green rust II" appears. This has a hexagonal cell with dimensions $a=3.174$ and $c=10.94$Å. The green rust II is also formed in the electrolysis of N/10 $(NH_4)_2SO_4$ between iron electrodes at a high current density, air being excluded from the solution. Further details are in the press elsewhere.

$1/d^2$ is calculated for a rhombohedral cell with hexagonal cell dimensions $a=3.15$ and $c=22.6$Å. In the X-ray powder photograph the reflexion 0003 is very strong and 0006 is strong. There are other intensity differences consequent on the preferred orientation in the electron diffraction camera.

The material reported by Yoshioka[9] appears to differ from these two forms. Nevertheless spacings recorded by electron diffraction can be very satisfactorily indexed on a rhomdohedral cell with $a=3.15$ and $c=22.6$Å (see Table II). It is thus seen to be substantially the same as the green rust I which would be expected in the electrolysis of dilute NaCl with iron electrodes. However, the strongest lines, 0003 and 0006, found in the X-ray pattern are missing. It is also noticable that the 1 indices do not exceed 10. These observations would be consistent with the orientation of flakes of rust parallel to the mounting film and perpendicular to the electron beam.

There seems to be no simple transformation between Yoshioka's cell (body-centred orthorhombic with $a=5.30$, $b=3.16$ and $c=7.83$Å) and ours. This orthorhombic cell is not, therefore, an alternative description and coincidences between certain key spacing explain the satisfactory indexing of the spacings. It would be possible to use a monoclinic cell with $a=5.45$, $b=3.15$, $b=7.75$ and $\beta=103.6°$ ($d_{100}=5.30$ and $d_{001}=7.53$Å) which was centred on the c-face.

Some speculations can be made as to the structure of the green rusts I and II in terms of the packings of equal spheres, if some simplifying assumptions are made:

a) Hexagonal layers of anions (O″, OH′ or H_2O) are stacked so that regular tetrahedra fill space. The interlayer distance is thus 0.817a where a is the anion diameter.

b) There will be tetrahedral and octahedral vacancies available for cations. Assume that no great distortion of the structure is caused by filling these and restrict consideration to the octahedral holes.

c) Restrict consideration to hexagonal cells (P or R) with one anion per layer (a=approx.

3.16Å).

d) Reject as unlikely the sharing of faces by coordination octahedra (or tetrahedra) round the cations (Pauling's rules).

e) Assume the compounds are stoichiometric. There are then, only the following stackings for the numbers of layers indicated: (A, B, C denote anions at 0, 0, z; 1/3, 2/3, z; 2/3, 1/3, z and a, b, c denote cations with the same coordinates)

2-layers

Composition AO_2. Sequence A–BcA. ($c=1.633a$, hexagonal cell).

3-layers

Composition AO. Sequence AcBaCbA. (cubic with $a_{cub.}=1.414a$).

Composition A_2O_3. Sequence AcBaC–A. ($c=2.45a$, hexagonal).

Composition AO_3. Sequence AcB–C–A. ($c=2.45a$, hexagonal).

4-layers

Composition A_2O_4. Sequence AcB–AbC–A or A–BcAbC–A. ($c=3.27a$, hexagonal).

6-layer rhombohedral

Composition AO_2. Sequence AcB–CbA–BaC–A. ($c=4.90a$, rhombohedral)

9-layer rhombohedral

Composition A_2O_3. Sequence AcBaC–BaCbA–CbAcB–A

Composition AO_3. Sequence AcB–C–BaC–A–CbA–B–A or A–B–CaB–C–AbC–BcA. ($c=7.35a$, rhombohedral).

We suggest that as a first approximation the green rust I has the 9 layer rhombohedral structure (c/a obs.=7.2) and that the green rust II has the 4 layer structure A–BcAbC–A (c/a obs.=3.4). The 2 and 6 layer structures are exemplified by $Fe(OH)_2$ and $CdCl_2$ respectively⁴⁾.

The formula $Fe^{++}Fe^{+++}O_2''\cdot OH'$ suggested by Deiss and Schikorr as the composition of the green rust I seems, therefore, not only compatible with the structure but likely, if the above assumptions are correct.

Anti-Phase Domains in Gold-Copper-Zinc Ordered Alloys Revealed by Electron Microscope

By Shiro OGAWA, Denjiro WATANABE

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

Hiroshi WATANABE and Tsutomu KOMODA

Hitachi Central Research Laboratory,
Kokubunji, Tokyo

(Received March 7, 1959)

Using thin evaporated films of gold-copper-zinc ternary ordered alloys, the line-up of anti-phase domains has been observed as parallel lines on transmission electron micrographs of bright field, down to a domain size of about 8Å.

The lattice modulation accompanying anti-phase domains, i.e. the periodic error of lattice spacing or scattering factor with the same period as a domain size, has again been verified to play an important role in forming the satellites around the direct spot on a diffraction pattern, and hence, in forming the parallel lines on electron-microscopic images. Two-thirds of the intensity of the satellites have been estimated in the present alloy films to arise from the modulation, and the rest probably from double diffraction.

§ 1. Introduction

In our previous work[1] it was reported that parallel lines spaced at intervals of about 20Å were observed on transmission electron micrographs from evaporated films of CuAu II and that they revealed the line-up of stable anti-phase domains in this ordered alloy. There are many ordered alloys with long period, i.e. with anti-phase domains of definite size[2], and most of them have considerably smaller domains than CuAu II. It is interesting and desirable to observe the domain structures also in such alloys with smaller domain size by means of electron microscopy. This observation will be useful in the following two points. First, it enables us to investigate into the details of distribution of anti-phase domains in many examples, and secondly, it affords data to the problem how far the fine structure of metals and alloys can be resolved by an electron microscope with the high resolving power.

K. Schubert *et al*[3],[4] studied many ordered alloys with long period by means of X-ray diffraction, especially, in detail those in the gold-copper-zinc system. According to them, the addition of zinc to CuAu makes a domain size smaller, keeping the crystal structure almost isomorphous to CuAuII. For example, an alloy containing 42.5 gold, 42.5 copper and 5 zinc in atomic per cent has a domain size of 3.7 a, i.e. about 14.7Å, a being the lattice constant along the line-up direction of domains. The more the zinc content is, the smaller this size, and for an alloy containing 31 gold, 31 copper and 38 zinc in atomic per cent a domain size is 1.4 a, i.e. about 5.5Å. Thus, the addition of a divalent metal makes the occurrence of out-of-steps more frequent and gives rise to a continuous decrease of the domain size. The present authors undertook to utilize this fact and to observe anti-phase domains far smaller than those in CuAuII. The observation was made on several ternary alloy films with different contents of zinc, and the line structures corresponding to the line-up of domains were successfully observed, the least resolved distance being 8Å. The details of observation and the discussion on them will be given in § 3 and § 4, respectively.

§ 2. Experimental

Specimen films were prepared as follows: Gold was first evaporated on to cleavage surfaces of rocksalt heated at 400°C and then equivalent copper in number of atoms was evaporated on gold films at room temperature. Composite films were homogenized and alloy-

Table I. Lattice constants and domain sizes of the Au–Cu–Zn alloy films.

No.	a (Å)	b (Å)	c (Å)	domain size (Å)	M=domain size/a

2	3.96		3.68	11.8	3.0
3	4.01	3.96	3.68	9.4	2.3
4	4.02	3.94	3.68	8.0	2.0

ed at 350°C, and after having been detached from the substrates, they were mounted on titanium plates with pin holes 0.1 mm in diameter. Electron diffraction proved these films to be composed of single-crystalline CuAu I. They were again put into the evaporation chamber, and after preheating at 350°C a small quantity of zinc was evaporated on to them, the temperature being maintained at about 100°C. The alloy films consisting of the three elements were then heated up to 350°C, kept at this temperature for 2 hours and slowly cooled. This treatment was sufficient to produce single-crystalline ternary alloy films of the crystal structure isomorphous to CuAuII. Thus, four kinds of specimens with different compositions were prepared, but the compositions were not immediately known. Domain sizes estimated from separations of split superlattice reflections of diffraction patterns were 13.3Å, 11.8Å, 9.4Å and 8.0Å, corresponding to 3.4 a, 3.0 a, 2.3 a and 2.0 a, respectively. According to X-ray measurements by Schubert *et al*, these data show compositions of the films to range between 47gold-47copper-6zinc and 38gold-38copper-24zinc in atomic composition. The lattice constants of these alloys are tabulated in Table I with the above data. Specimens No. 3 and 4 have orthorhombic unit cells, while No. 1 and 2 were observed from electron diffraction patterns not to be orthorhombic but to be tetragonal. The film thickness was always about 300Å.

The electron microscope of Hitachi HU-10 type was used, as in the previous work[1]. The operating voltage, the focal length of the objective lens and the aperture size were 75 KV, 3 mm and 50 $\mu\phi$, respectively. The images were recorded on Fuji Process plates (hard) at a magnification of 80,000~120,000 x.

§ 3. Results

Electron diffraction patterns of four kinds of single-crystalline alloy films are shown in Figs. 1(a), 2(a), 3(a) and 4(a), respectively. They are quite similar to the pattern of CuAuII[5], the main difference between one another consisting in the separations of split superlattice reflections and of satellites around the direct spot and main reflections. The smaller the domain size is, the larger the separations, and the satellites of the first order which are very much close to the direct spot in case of CuAuII are here sufficiently separated from it. Some special remarks should be made about Fig. 4(a). First, spots in a {001} group of supperlattice reflections, Miller's indices being used in terms of the

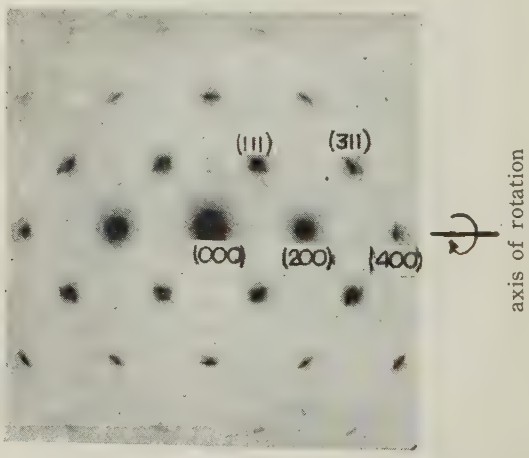

Fig. 5. Electron diffraction pattern of the same film as in Fig. 3 (a), [110] incidence.

disordered cubic lattice, appear to be doubled. The fact is, however, that there occurs nothing unusual. That is to say, owing to the special value of domain size, $2a$, both the second order splits of {110} superlattice reflections, A, and the second order satellite of the direct spot, B, just accompany the original three component spots of {001} group, C. Secondly, the nearest neighbors among four component spots forming a {110} cross are connected with each other by lines of fairly strong intensity, as indicated by arrows, and moreover, there are seen unusually diffuse spots, D, immediately inside the two inner component spots. The origin of these phenomena is not clear at present.

Utilizing the satellites around the direct spot to image formation, it was tried to observe the line structures on electron micrographs of the present alloy films of four kinds. The micrographs obtained are shown in Figs. 1(b), 2(b), 3(b) and 4(b) and are of very high magnification. Equally spaced parallel lines are seen on each of them. The instrumental magnification was calibrated against the $(20\bar{1})$ spacing of copper phthalocyanine. The mean spacings of the lines agree within about 10 per cent with the values deduced from the diffraction patterns, 13.3Å, 11.8Å, 9.4Å and 8.0Å, respectively.

The line structures were found only at a few places in the image on one photographic plate, and so the above electron micrographs were selected from not many examples. The little frequency of visibility of the line structure is probably caused by the lack of uniformity in the thickness of the present specimens. As shown on micrographs, they have a patch-like structure, and there may be appreciable unevenness even in one agglomeration. The preparation method of films by Bassett, Menter and Pashley⁶⁾ is probably better in obtaining the uniform thickness.

In Fig. 1(b) two sets of parallel lines are seen, one consisting of the lines with a smaller spacing and the other with a larger spacing. The former set is understood from the value of its spacing to correspond to the line-up of anti-phase domains, while the latter is inclined by 45° to the former and its spacing is about $\sqrt{2}$ times as large as the former. The nature of the set with the larger spacing will be elucidated in § 4. Any of the line structures seen on the micrographs except Fig. 1(b) is interpreted to represent the line-up of domains. As it is known from the diffraction patterns that there are two orthogonal directions of the line-up of domains in the film plane, the lines should be observed along two orthogonal directions also on the micrographs. These micrographs, however, do not show such two directions owing to the limited area where the lines are visible, although such two orthogonal sets of the lines were surely seen at some distance from each other on one photographic plate.

§ 4. Discussion

In the previous work¹⁾ the present authors ascribed the origin of the satellites around the main reflections to some periodic lattice modulation, accompanying anti-phase domains, with the same period as a domain size, provided that the modulation meant not the periodic occurrence of out-of-steps but the formation of a periodic error of lattice spacing or of scattering factor. There may be some contribution of secondary diffraction to the intensity of the satellites, but the present authors concluded experimentally that a greater part of the intensity is caused by the above modulation of the lattice. Glossop and Pashley⁷⁾ also tried to observe anti-phase domain boundaries in CuAuII by means of electron microscope and obtained the similar line structure in bright field images as well as in dark field images. According to them, the latter image is formed directly as a result of the phase change itself by utilizing two pairs of two component spots in a {110} cross, while the former is formed by combination between the direct spot and the satellites which are produced by double diffraction of two component spots in a cross. Thus, they neglected the effect of the periodic modulation in explanation of the image. Although the present authors were convinced that the said modulation plays an important role in producing the satellites, the experiment which involved the tilting of the specimen and was done in the previous work was repeated in the present case, in order to examine quantitatively the contribution of double diffraction. Fig. 5 shows that the satellites remained even when the film producing the diffraction pattern in Fig. 3(a) at normal incidence was tilted about the principal axis lying in the film plane until {110} groups of superlattice reflections vanished and {111} main reflections appeared. In this condition there are no split superlattice reflections located close to the sphere of reflection in reciprocal space, except those of the considerably higher order. It is highly improbable, therefore, that the remaining satellites are caused by double diffraction, and they should be considered as originated entirely from the periodic lattice modulation. They appear fairly strong, but a microphotometry showed their intensity to be about two-thirds of the original intensity in Fig. 3(a), {400} reflections on the tilting axis being taken as standard. The intensity of the remaining satellites was sensitive to an error in the direction of the tilting axis, and the above value is the maximum one in several examinations. Similar results were obtained also from the other kinds of films. About one-third of the original intensity, therefore, depends upon the appearance of split superlattice reflections and might arise from double diffraction. Double diffraction considered here, however, may mean not such one as given by two incoherent layers, which were previously discussed, but a dynamical one occurring in a coherent lattice, as suggested by Glossop and Pashley⁷⁾.

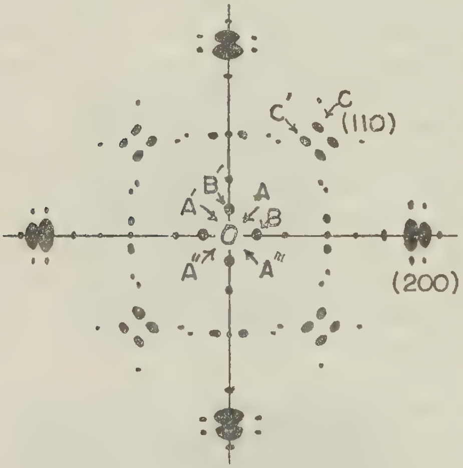

Fig. 6. Illustration of Fig. 1 (a).

Next, the lines with the larger spacing seen in Fig. 1(b) will be explained. In Fig. 6, which is an illustration of Fig. 1(a), OA corresponds to the spacing $\sqrt{2}$ times as large as the domain size which is represented by OB and OB', if a diffraction spot were observable at A. As OA is equal to CC' which is a distance between two neighboring spots in a {110} cross, it may be conceivable that A would be produced by double diffraction. However, diffraction spots, C and C', belong to different systems of anti-phase domains, and hence this double diffraction is caused not by dynamical interaction in a coherent lattice but by successive diffraction through two overlapped layers of different systems of anti-phase domains whose line-up directions are orthogonal to each other in the film plane. This idea explains well both the spacing and the direction of the lines in question which are thought as a kind of a rotational moiré pattern. Such lines as these have already been observed in CuAuII by Glossop and Pashley⁷⁾ and explained in the above-mentioned way by them. In their case, however, two sets of the lines crossing each other were observed. These sets are thought to be due to the occurrence of two component diffraction beams, e. g. A and A' in Fig. 6, at the same time by double diffraction. In the present case, however, only one of the two component diffraction beams was probably formed and hence only one set of the lines was observed. The fact is, however, that in the present diffraction patterns the diffracted intensity has never been observed at any of A, A', A'' and A'''. If the overlapping of two different systems of domains is so rare that it contributes very little intensity to the diffraction pattern, however, the circumstances will fully be understood.

The number M, a size of anti-phase domains measured in atomic distance, is given in general as a fractional number from diffraction patterns. This fact can be understood, if different domain sizes are assumed to be mixed in a coherent crystal lattice. This assumption was verified in the previous work¹⁾, where the line structure on electron micrographs of CuAuII was observed to contain surely two kinds of the spacing, i.e. two kinds of M values. The same should hold also for some of the present alloys, i.e. for those with M values, 3.4 and 2.3. Measurements of the spacing were carefully done on the line structures of the four kinds of alloys by means of a comparator as well as of a microphotometer. A positive evidence for a mixture of M values, however, could not be obtained from the electron micrographs in the present case, probably due to the obscurity based on too large magnification. But it will be worth while saying that the fluctuation of the measured spacing is larger in the alloys with M values of 3.4 and 2.3 and amounts to about ±15 per cent, while it is smaller in the alloys with M values of 3.0 and 2.0 and amounts to about ±8 per cent. The latter fluctuation is an error of measurements, because there should be the uniform spacing in the latter alloys. Thus, if further examples are required for a mixture of different domain sizes to be observed on electron micrographs, it may be disadvantageous to use ordered alloys with small domain sizes such as in the present work.

Proton Magnetic Resonance in Hydrates of Halogen Compounds of Mg, Ca, Sr and Ba

By Syukuro YANO

Faculty of Engineering, Kyoto University, Kyoto

(Received September 12, 1958)

Proton resonance in crystal water of $Mg(H_2O)_6Cl_2$, $Mg(H_2O)_6Br_2$, CaI_26H_2O, SrI_26H_2O and MgI_28H_2O was studied in temperature range from −90°C to +110°C and the same in $CaCl_26H_2O$, $CaBr_26H_2O$, $SrCl_26H_2O$ and $SrBr_26H_2O$ was studied in the range above room temperature, all in powdered states. Line shapes were recorded by the radiofrequency spectrometer with an automatic field scanning apparatus connected to the sweeping coils of a permanent magnet. Transitions of second moment and line shapes were observed for all the above salts. Experiments on single crystals of $Mg(H_2O)_6Cl_2$ and CaI_26H_2O were also carried out at room temperature. In $Mg(H_2O)_6Cl_2$, $Mg(H_2O)_6Br_2$, CaI_26H_2O, SrI_26H_2O and BaI_26H_2O, water molecules of hydration have the states of hindered rotational motion below melting point, but in $CaCl_26H_2O$, $CaBr_26H_2O$, $SrCl_26H_2O$ and $SrBr_26H_2O$, these rotational states were not observed. The angle between the rotational axis of a water molecule and its inter-proton direction was estimated to be about 90° in the case of $Mg(H_2O)_6Cl_2$. In the cases of CaI_26H_2O and SrI_26H_2O these angles are calculated to be 45° or 60°, and these results suggest the precession of the rotational axis, if rotational motion of water molecules is assumed to occur about an axis perpendicular to the inter-proton axis. Sharp peaks appearing in chlorides and bromides of Ca and Sr are interpreted as the narrowing due to random re-orientation of the rotational axis.

§ 1. Introduction

The studies of structure and motion of water molecules in hydrated crystals are important for the information about the hydrogen bonds and chemical properties of compounds. The halogen compounds of the group II elements, Mg, Ca, Sr and Ba, have six water molecules as hydrates at normal temperature, and their chemical properties can be compared with each other because they are of the varied combinations of the metallic ions and halogen ions. One of the characteristic properties of these salts is the strongly hygroscopic nature in the dehydrated state and the strong deliquescence in the hydrated state. Therefore, it is interesting to obtain some informations about the state of the water molecules in these hydrates.

Nuclear magnetic resonance method in solid state explored by E. M. Purcell *et al.*[1] has been applied to the structural investigation of water molecules in hydrates by G. E. Pake[2] and others[3], or to the study of hindered rotational motion in solids[4]. The rotational motion of NH_4[4], or CH_4[5] molecules in solid has been observed by many workers. Since these molecules are non-polar and have symmetrical shapes, their hindering potentials are in general not high. However, water molecules are not expected to rotate easily because of larger electric dipole moment and less symmetrical shape. Therefore, the rotational motion of water molecules in solid has not been found yet as far as the author knows. Translational motion of proton along the hydrogen bonds in solid was found in several substances involving ferroelectric substances[6], and small torsional oscillation of water molecules in $K_2HgCl_4H_2O$ was also studied by J. Itoh *et al*[7].

It is reported, in the present paper, that proton magnetic resonance in hydrates examined here has been found to show two types of line shape transitions when temperature changes, and these will be discussed by rotational model of water molecules. Although the complex structure and strong deliquescence have not permitted the precise determination of hydrogen positions in these salts, experiments on small single crystals were used for the determination of motional state of water molecules. Besides above salts, resonance research has been made on beryllium salts, the results of which are not reported here because they are only on $BeCl_2 4H_2O$ and $BeSO_4 4H_2O$.

§ 2. Experimental Apparatus and Procedure

Experiments were performed using the modulation technique described by Bloembergen, Purcell and Pound[1]. A block diagram of the apparatus is shown in Fig. 1. The first measurement was made in $Mg(H_2O)_6Cl_2$ by the Weiss type electromagnet which was excited by currents from 24 volts batteries to give the gap field of about 3000 gauss with pole pieces 10 cm in diameter and 25 mm air gap length. The homogeneity of magnetic field within 0.2 gauss over the sample volume was obtained by providing the ring shim of 3 mm wide and 0.7 mm high around the periphery of each pole face, adjusting carefully parallelism and coaxiality of both pole caps with three brass spacers. For cooling experiments this magnet was not suited because of the intervening of the spacers and smallness of gap length.

A permanent magnet with pole face diameter of 140 mm and air gap length of 40 mm was constructed, which produces the magnetic field of 4140 gauss by NKS-3*, with a uniformity of 2×10^{-5} over the sample volume. Continuous variation of the static magnetic field linear with time was achieved by an automatic current scanning apparatus[8], which supplied current by ten 807 control tubes to the ten coils connected in series each coil having 250 turn windings around a pole. An error voltage which is the difference of the potential between that across the standard resistor R_S and that across reference rheostat, is amplified by a direct current amplifier and applied to the control tubes in such a phase that the error voltage may be reduced to zero. The rheostat is a 15-revolutions helipot which is driven continuously with time by a clock motor. The accuracy of the sweeping rate is larger than 10^{-4} and static stability is higher than 10^{-5} over 10 minutes.

* This magnet was constructed by Sumitomo Metal Industries, Ltd., Osaka.

6J6 cathode coupled oscillator developed by Pound and Knight[9] and an autodyne oscillating detector similar to Hopkins' circuit[10] were used. To study the temperature variation of resonance, cooling or heating of the high frequency probe was made by thermal conduction. A brass pipe for shielding of a radiofrequency coil was tightly inserted into a hole of the copper block to which a long copper rod was connected as shown in Fig. 2. This rod was inserted into a dewar vessel containing liquid oxygen or into a long heater coil. By suitably enclosing the air gap of the magnet, high temperature stablity was secured throughout a long period of time.

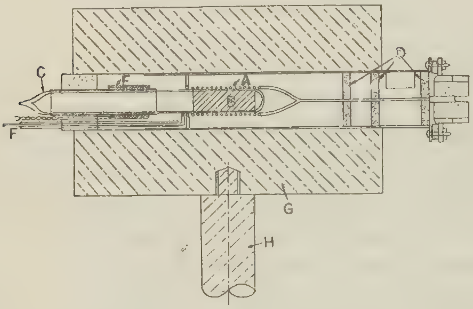

Fig. 2. Sample coil assembly.
A. Rf coil, B. Sample, C. Glass tube containing sample, D. Daiflon spacers, E. Coil for compensation, F. Cupper-constantan thermocouple, G. Cupper block, H. Cupper rod.

Sample temperature was varied by adjusting the position of the dewar or the current of the heater coil. Use of such conduction method is of great advantage in preventing noise generated by boiling of liquid oxygen or by both electric induction and mechanical vibrations produced by the heating current. A radiofrequency lead from the sample coil is supported by Daiflon spacers and the probe part within the shielding cylinder can be easily interchanged by removing it at a coaxial cable connector. The small coil inserted coaxially into this part was used to deliver ac voltage into the radiofrequency coil for the cancellation of constant zero drift due to the residual voltage induced directly by ac modulation which remains after careful positioning of this probe in the magnet gap. In most cases, however, signals obtained were strong enough at low level of magnetic field modulation, 0.5~1 gauss peak to peak, so that the use of this cancellation unit is not always necessary.

Samples were obtained from Maruwaka Chemical Company almost in powdered states. Iodides of Ca, Sr and Ba have the strongest deliquescence and magnesium salts come next to this. A small crystal of CaI_26H_2O with the size of about 1×1×1 mm^3 deliquesces and becomes liquid after exposed in ordinary atmosphere for several seconds. Instead of making a fine powder of CaI_26H_2O and $SrI_2 \cdot 6H_2O$, small crystals in a glass tube were dried by pumping in vacuum until it became transparent and sealed in vacuum, then these samples were heated to their melting point and quenched quickly. Slowly cooled samples of these salts show different shapes in their absorption curves when they are rotated in magnetic field, although their shape has a good symmetry. These effects are due to the crystallization by slow cooling. Chlorides and bromides of Ca, Sr and Ba have not so strong deliquescence that fine powders are easily compressed to form a small circular tablet and sealed in a glass tube after pumping in vacuum.

Single crystals of $Mg(H_2O)_6Cl_2$ were grown from aqueous solution by evaporation method or slow cooling method. A needle-like single crystal having the size of 25×3×3 mm^3 was grown by the latter method. This crystal was fixed in a test tube and sealed in vacuum. A plate-type crystal of CaI_26H_2O of the size of 1×5×7 mm^3 was selected from many crystals made by Maruwaka Co.

Resonance curves were recorded automatically every 3°~5°C in temperature range from −90°C to +110°C in almost all powdered samples, but for CaI_26H_2O and SrI_26H_2O a hundred curves were recorded. Temperature was measured by a copper-constantan thermocouple attached to the sample tube wall.

Melting point of the samples was measured in vacuum sealed test tube immersed in a water bath except in case of the magnesium salts, and the result was in good agreement with the values described in text-books on chemistry.

§ 3. Experimental Results and Discussion

In general proton resonance absorption derivatives in these hydrates have a line shape similar to Fig. 3. In some of them, however, the separation between peaks of doublet becomes narrower below room temperature, and in others a single peak appears overlapping the line at its center. The experimental results obtained in powdered samples are summarized in Table I with three characteristic separations and second moments calculated from experimental derivative curves. Chloride and bromide of Ca and Sr show rather broad absorption curves of two spin system with second moments of nearly 30 gauss² at room temperature. Chloride and bromide of Mg and iodide of Ca, Sr and Ba have very

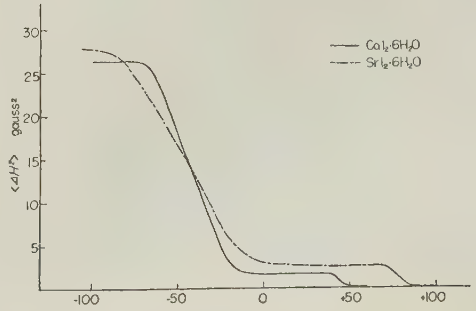

Fig. 7. Variation of second moments with temperature in CaI_26H_2O and SrI_26H_2O.

narrow curves with small second moments at room temperature. A narrow curve observed at room temperature seems to be due to some motion of water molecules, so the resonance curves were taken at different temperatures. At lower temperatures they became a broad and definite two spin system structure with second moments of about 26~28 gauss². Fig. 4 shows two photographs of absorption derivatives at two different temperatures selected from curves recorded by millivoltmeter charts in $Mg(H_2O)_6Br_2$. Nearly the same results had been obtained in $Mg(H_2O)_6Cl_2$[11].

Second moment variation with temperature of $Mg(H_2O)_6Cl_2$, $Mg(H_2O)_6Br_2$ and MgI_28H_2O is shown in Fig. 5. Chloride and bromide exhibit line width and second moment transitions at about 0°C and it seems to become rigid at about −30°C and −50°C respectively. At lower temperatures MgI_28H_2O has a broad and nearly flat resonance curve, but a sharp peak appears at −55°C which becomes larger as temperature rises, as shown in Fig. 6. The gradual decrease of second moment in Fig. 4 is due to the mixing of this sharp part. Strong signals with narrower separation between doublet than in the magnesium salts were observed in both iodide of Ca and that of Sr at room temperature. Variation of second moment and line shapes with temperature are also given in Figs. 7 and 8.

a) *Hindered rotation of water molecules in* $Mg(H_2O)_6Cl_2$ *and* $Mg(H_2O)_6Br_2$

The formula derived theoretically by Van Vleck[12] may be written for the case of these powdered hydrates as

$$\begin{aligned}\langle \varDelta H^2\rangle &= \langle \varDelta H^2\rangle_0 + \langle \varDelta H^2\rangle_1 \\ \langle \varDelta H^2\rangle_0 &= (4/5)\alpha^2 = 358.1\times10^{-48} r^{-6} \qquad (1) \\ \langle \varDelta H^2\rangle_1 &= 358.1\times10^{-48}\sum_j r_j^{-6} \\ &\quad + (4/15)\sum_k I_k(I_k+1) g_k^2 \beta^2 r_k^{-6}\end{aligned}$$

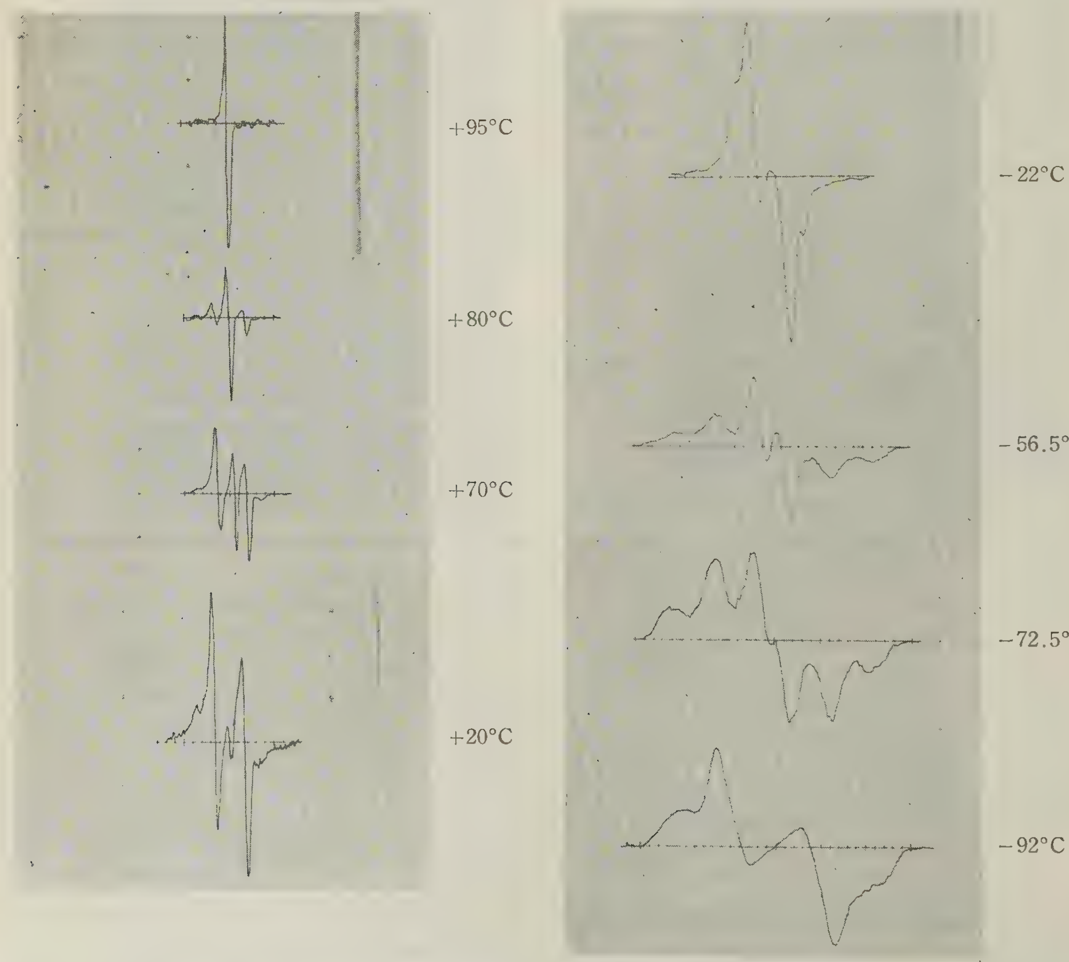

Fig. 8. Recorded derivatives of proton resonance in powdered SrI_26H_2O.

that is, total second moment, $\langle \Delta H^2 \rangle$, is divided into two parts, the intra-water molecular part $\langle \Delta H^2 \rangle_0$ and the interaction part due to other molecules $\langle \Delta H^2 \rangle_1$. r is the inter-proton distance in a given water molecule, $\alpha = (3/2)\mu r^{-3}$, $\mu = gI\beta$, r_j's are the distances to other protons, r_k's are the ones to other magnetic nuclei with the spin and the gyromagnetic ratio of I_k and g_k respectively, and β is the nuclear magneton. Eq. (1) is valid when the lattice is rigid. The structure of hexahydrated magnesium chloride and the corresponding bromide has the same type, but it is different from the one of $SrCl_2 6H_2O$ type. The unit cell contains two molecules: $a_0 = 9.90$A, $b_0 = 7.15$A, $c_0 = 6.10$A with the angle $\beta = 94°$ between positive a and c axes for the chloric salt, and $a_0 = 10.25$A, $b_0 = 7.40$A, $c_0 = 6.30$A, $\beta = 93°30'$ for the bromic salt. In both salts the magnesium ion is surrounded by six water molecules in the form of a regular octahedron and each halogen ion has eight H_2O neighbors. Projections of $Mg(H_2O)_6Cl_2$ on a b-face and an a-face are shown in Fig. 9[13].

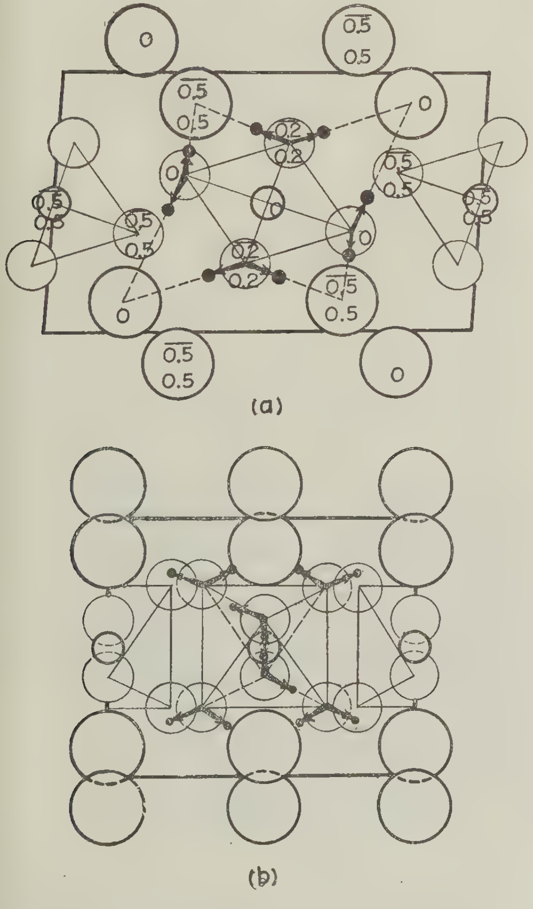

Fig. 9. (a) A projection of the monoclinic $Mg(H_2O)_6Cl_2$ structure on a b-face. The chlorine atoms are shown as the largest circles, the water molecules as middle-sized circles which surround octahedrally the central magnesium atom shown by the smallest circles. The assumed positions of hydrogens of water molecules are shown by the small black circles.
(b) A projection on an a-face.

Considering distances from water molecules to chlorine atoms or to other water molecules and also directions to chlorine atoms from oxygen positions, probable hydrogen bonds locations considered here are shown in Fig. 9 by arrows with black circles which indicate each hydrogen position. In this configuration the bond angles of H-O-H are 130°~140°. However, the bond angle of water molecule is to be nearly equal to tetrahedral angle. Therefore the intermolecular part of the second moment was calculated by assuming the water molecule which had the tetrahedral bond angle and the direction of one O-H coinciding with one of the directions of O-H····Cl shown in the figure. There are two possible arrangements for each of two water molecules just lying on b-plane, and also two for each of four water molecules which are lying above or below b-plane. By averaging the values of $\langle \Delta H^2 \rangle_1$ calculated for the combination of these configurations, we obtained the value of $\langle \Delta H^2 \rangle_1 = 5.95 \pm 0.6$ gauss^2. Using the value of $\langle \Delta H^2 \rangle_0$ which is obtained by subtracting $\langle \Delta H^2 \rangle_1$ from the observed value of the second moment 26.0 ± 0.5 gauss^2, the inter-proton distance in these water molecules is calculated to be 1.615 ± 0.015A.

The second moment obtained from the experimental records shows a transition at −30°~0°C as in Fig. 5. The data on the solubility of $MgCl_2$ in water show that twelve-hydrate is stable below −16.4°C, eight-hydrate is stable between −16.4°C and −3.4°C, and that hexahydrate is stable above −3.4°C to 117°C. The temperature of phase change, −16.4°C and −3.4°C, is nearly equal to the temperature of the second moment transition. However, it is not reasonable to consider that the transition of the second moment at −30°C~0°C originates from a phase change of the crystal or the change of the hydration

* These salts are listed for comparison. ** Central peak.

number. But instead we regard it as originating from the onset of some motion of the water molecules. The reasons are as follows. (1) Because the samples used are the dried hexahydrated powder sealed at room temperature and absolute number of water molecules must be unchanged, some fraction of the hexahydrated molecules must be dehydrated below −30°C, if eight- or twelve-hydrate is produced by cooling. However, dehydration temperature of hexahydrates is about 117°C from the solubility data. Then our sample must keep a form of hexahydrate below −30°C. (2) If the inter-proton distance is calculated on the assumption that the doublet line with second moment of 6.0 gauss^2 observed at room temperature originates from rigid lattice, it becomes 1.96A or longer, and this is nearly equal to twice 0.98A of O-H distance in a water molecule in a gas phase. Also as seen in Table I, second moments for $SrI_2 6H_2O$, $CaI_2 6H_2O$ and $BaI_2 6H_2O$ are much smaller than those of magnesium salts at room temperature, so that the resulting inter-proton distance from rigid lattice model becomes longer than 2A. It is difficult to believe that the water molecule is distorted in these salts, although the structure of a water molecule in a solid is affected by their surrounding ions. (3) In the case of phase transformation, variations in second moment associated with a change of crystal structure cannot be so large as those observed. For example, $CuCl_2 2H_2O$ and $CaSO_4 2H_2O$ have nearly equal second moments and the same line shape. For iodide of barium, our experiment shows independence of line shape and second moment on the hydration number as seen in Table I. (4) The assumption of rotational motion of water molecule is consistent with other results obtained so far, as will be described below. Tunneling motion of the proton between an oxygen atom and a halogen ion is also discussed later.

The second moment for a proton pair in rotational motion about an arbitrary axis may be derived by the method used by Gutowsky and Pake⁴⁾,

$$\begin{aligned} \langle \Delta H^2 \rangle_0 &= (4/5)\alpha'^2 , \\ \langle \Delta H^2 \rangle_1 &= 358.1\times 10^{-48}[\langle r_j^{-3}\rangle_{\mathrm{AV}}]^2 \\ &\quad +(4/15)\sum_k I_k(I_k+1)g_k^2\beta^2[\langle r_k^{-3}\rangle_{\mathrm{AV}}]^2 . \end{aligned} \tag{2}$$

Here, $\alpha'=\alpha P_2(\cos\gamma)$, γ is the angle between the radius r and the axis of rotation of r and $\langle r_j^{-3}\rangle_{\mathrm{AV}}$ and $\langle r_k^{-3}\rangle_{\mathrm{AV}}$ denote the average value over the rotational position of the molecule. Eq. (2) may apply to the second moment for a powder on the assumptions that the rotation permit the use of a classical average over this motion and that the reorientational frequency of this motion is higher than the frequency width of the absorption curve.

To distinguish exactly $\langle \Delta H^2\rangle_0$ from $\langle \Delta H^2\rangle_1$ in the observed value of $\langle \Delta H^2\rangle$, the result of the experiment on single crystal is used. When a single crystal involving a proton pair P—P rotating about an axis OR is measured in various orientations, keeping external magnetic field H_0 in the xy-plane as shown in Fig. 10, the observed doublet separation δH of the proton signal may be written as

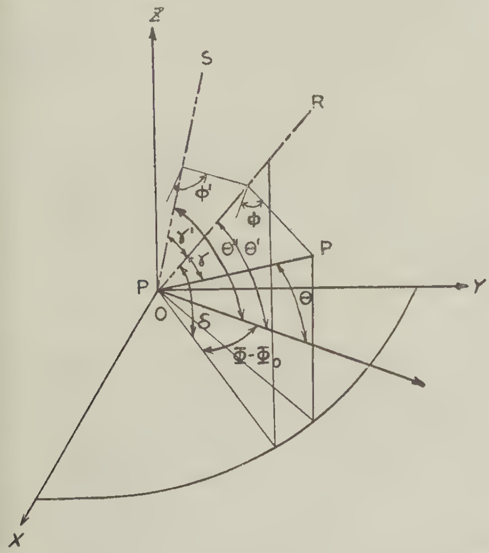

Fig. 10. Definition of various angles for the model of a rotating proton pair.

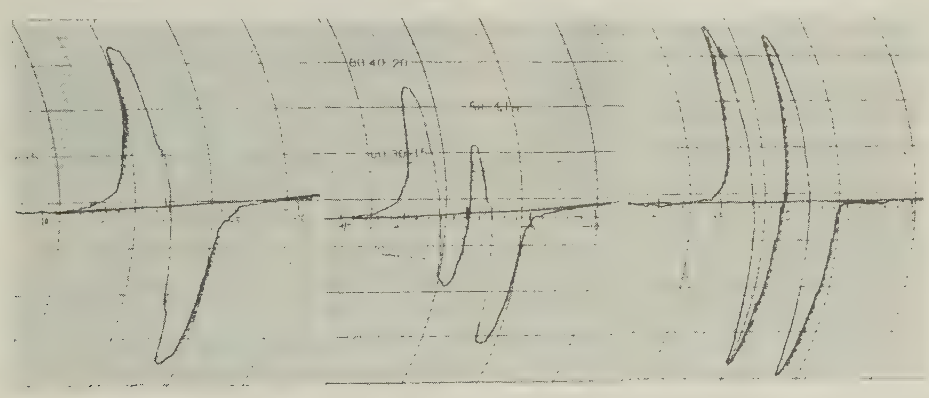
$$\begin{aligned}\delta H &= 4\alpha P_2(\cos\gamma)P_2(\cos\theta')\\ &= 2\alpha'\{3\cos^2\delta\cos^2(\Phi-\Phi_0)-1\}\,, \qquad (3)\end{aligned}$$

where θ', $\Phi-\Phi_0$ and δ are as shown in the figure. If δH is measured for various $\Phi-\Phi_0$, with a constant angle δ, and α' can be determined. Then from the known values of δ, γ will also be given.

Experimental plot of δH is shown in Fig. 11a, and the derivative curves for the special three orientations are reproduced in Fig. 11b. These experiments were performed using a needle-like single crystal with its long axis perpendicular to the static external magnetic field. Since the smaller one of the extreme values of δH is $2\alpha'$, the experiment gives $2\alpha'=5.10$ gauss, which is compared with $2\alpha=10.0$ gauss derived from $\langle \Delta H^2\rangle_0$ for the rigid lattice value. Two possible values 88°±2° and 35°±0.5° for γ follow. The former is easily accepted. The width of a component line of the doublet shown in Fig. 11b can be considered to originate from isotropic contribution of neighboring molecules. The smallest value among them is 2.2 gauss at room temperature. As the result, $\langle \Delta H^2\rangle_1$ becomes 0.60 gauss². $\langle \Delta H^2\rangle_0$ for the rotational motion can be calculated to be 5.05±0.28 gauss², using $r=1.615\pm0.015$A and $P_2(\cos\gamma)=0.5$. The sum of the two values, 5.65 gauss², is within the experimental error



(b)

Table II.

salt	state	$\langle \Delta H^2 \rangle_0$	$\langle \Delta H^2 \rangle_1$	r	γ
$Mg(H_2O)_6Cl_2$	rigid	20.2±1.10	5.95	1.615±0.015	—
$Mg(H_2O)_6Cl_2$	rotation	5.2	0.8	—	88°±2°
$Mg(H_2O)_6Br_2$	rigid	20.5	5.2	1.61±0.02	—
$Mg(H_2O)_3Br_2$	rotation	5.0	0.5	—	88°±3°

of the observed value for the powder, 6.0±0.5 gauss^2.

Nearly the same results were obtained for $Mg(H_2O)_6Br_2$. Although the difference from the resuts of $Mg(H_2O)_6Cl_2$ was almost within experimental errors, it is quite certain that the second moment for Br-salt is a little smaller than that for Cl-salt. This fact corresponds to the expanded structure of Br-salt due to the larger size of Br ions. The second moment increase due to Br-nuclei in place of Cl-nuclei is about 0.4 gauss^2 and gives little contribution. These results are summarized in Table II.

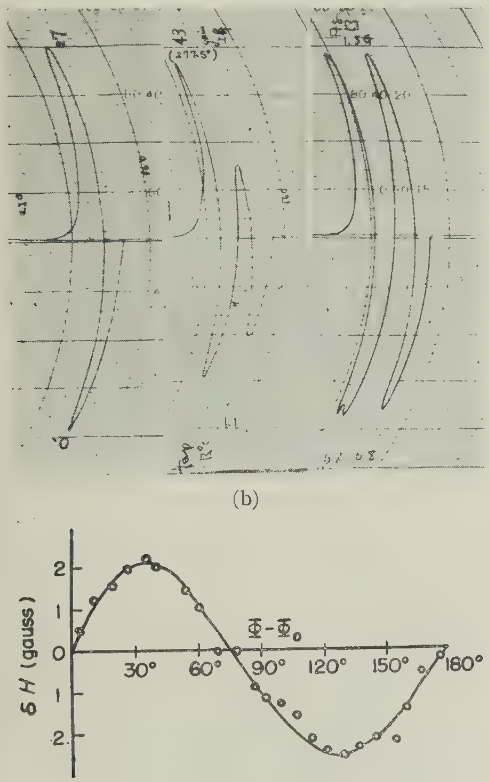
b) *Hindered rotation of water molecules in* CaI_26H_2O *and* SrI_26H_2O

The crystal structure of CaI_26H_2O and SrI_26H_2O is determined by X-ray and this has a type of layer structure isomorphous with that of $SrCl_26H_2O$, in which the position parameters of oxygens of water molecules are also known. In these crystals a metallic ion is surrounded by nine water molecules, three of them in the equivalent positions on the same plane with the metallic ion, three on the upper and three on the lower planes respectively[15]. From various considerations on these crystals, the position of water molecules is determined, although it is not definitely known by the X-ray analysis, assuming that the distance from metallic ion to water molecule is the sum of ionic radii, for Ca^{++} and H_2O, being 2.39A, and for Sr^{++} and H_2O, being 2.53A. The distance between water molecules becomes equal to the sum of an ionic radius of the nearest neighbor halogen and the radius of the water molecules, using the same relative position for halogen as in $SrCl_26H_2O$. By the same method used previously for $Mg(H_2O)_6Cl_2$, experimental rigid lattice second moments 26.1 and 27.7 gauss^2 for CaI_26H_2O and SrI_26H_2O respectively, give the values of the intra-molecular part as $\langle \Delta H^2 \rangle_0 = 23.0$ and 25.0 gauss^2. The values of $\langle \Delta H^2 \rangle_1 = 3.0$ and 2.7 gauss^2, calculated for the Ca-salt and the Sr-salt respectively, consist of the part of proton-proton interaction between neighboring water molecules, 2.5 and 2.3 gauss^2, and that of proton-halogen interaction part of 0.5 and 0.4 gauss^2 respectively.

The inter-proton distance in the water molecule becomes 1.595±0.02 for the Ca-salt and 1.576±0.02A for the Sr-salt. Second moment transitions to very small value from rigid lattice value which occur at about −70°C∼−15°C and −85°C∼−5°C for the Ca-salt and the Sr-salt respectively as seen in Fig. 7, are considered to be also due to the motional narrowing as in the case of the Mg-salts. In these iodides the values of second moment at room temperature are about 6.5% and 9.5% of the rigid values respectively, while in $Mg(H_2O)_6Cl_2$ and $Mg(H_2O)_6Br_2$ the corresponding reductions have been 22% and 15% respectively.

Two types of experiments were performed at room temperature on the single crystal of a small plate type CaI_26H_2O. In one case resonance curves were recorded in various directions 7.5° apart, rotating the plane parallel to the crystal plate, keeping one axis on it perpendicular to the static magnetic field. In another case the axis normal to the crystal plate was held perpendicular to the external field, and the crystal was rotated about this axis. In the former case the maximum number of component lines resolved was 2 and these component lines of the doublets have maximum separation of 2.45 gauss and interchange their positions to give another extreme separation of 2.20 gauss after the rotation by 90°, as seen in Figs. 12a. and b. In the latter experiment maximum splitting number was 3. The further splittings with incomplete resolution were observed ambiguously at a certain angle of crystal rotation. The splitting shown in Fig. 12a indicates $2\alpha' = 2.2$ gauss. Using the same procedure in Eqs. (2) and (3), the angle γ

becomes about 63.5° or 46°. The inter-contribution $\langle\Delta H^2\rangle_1=0.6$ gauss² between neighboring molecules obtained by subtracting $\langle\Delta H^2\rangle_0=1.0\pm0.1$ gauss² from the experimental value $\langle\Delta H^2\rangle=1.6$ gauss² at room temperature is not so different from the value expected from $\langle\Delta H^2\rangle_1=2.5$ gauss² at rigid lattice. The minimum observed width of the component line is 0.6 gauss from Fig. 12b, which amounts to $\langle\Delta H^2\rangle_1$ of 0.05 gauss². In powdered $CaI_2 6H_2O$, two types of resonance were observed in samples of two kinds which differ mainly in the rate of evaporation at precipitation. One type has a central peak, and the second moment is 1.6 gauss². The other is a doublet and has the second moment of 0.6 gauss², but this was observed about the sample which later dissociated and could not be tested again. It is not certain that this type can exist always in a stable form. Although it is probable that HI molecules remained in these powders from chemical point of view, it is not reasonable to regard the central peak as originating from the HI molecules in so far as the resonance signal is taken into consideration, because the disappearance of central peak at low temperature may not correspond to HI model and the vacuum puming treatment would remove the residual HI molecules if they are adsorbed on the surfaces of these powders.



(b)

(a)

Fig. 12. (a) Line pair separation as a function of the angle $\Phi-\Phi_0$ as shown in Fig. 10 for a single crystal of $CaI_2 6H_2O$.
(b) Recorded derivatives of proton resonance in a single crystal of $CaI_2 6H_2O$ for three directions of $\Phi-\Phi_0$.

In $SrI_2 6H_2O$ the second moment observed at room temperature can be separated to $\langle\Delta H^2\rangle_0=2.0$ gauss² and $\langle\Delta H^2\rangle_1=0.5$ gauss², by assuming the model of rotating water molecules with $\gamma=67.5°$ or 43.5°. The variation of the selection of the ratio of $\langle\Delta H^2\rangle_0$ to $\langle\Delta H^2\rangle_1$ from 2.5/0 to 1.5/1.0 may change the angle by ±2° about the above values.

To avoid difficulties exist in the model of rotational motion of water molecules with such a value of the angle γ, the precessional motion of rotational axis around a definite direction is considered as a new model. In Fig. 10, if the rotational axis of OR precesses around an arbitrary axis OS with a constant angle between OR and OS, we have, denoting

$$\alpha''=\alpha' P_2(\cos\gamma')=\alpha P_2(\cos\gamma)P_2(\cos\gamma'),$$
$$\delta H=2\alpha''\{3\cos^2\delta'\cdot\cos^2(\Phi-\Phi_0)-1\}, \qquad (4)$$

since the average of $P_2(\cos\theta')$ over the angle ϕ' becomes $P_2(\cos\theta'')P_2(\cos\gamma')$ by the addition theorem of the Legendre functions. Therefore, the doublet separation in this case is given by writting α'' in place of α' in Eq. (3). Here δ' and $\Phi'-\Phi_0'$ are the angles for OS corresponding to δ and $\Phi-\Phi_0$ for OR.

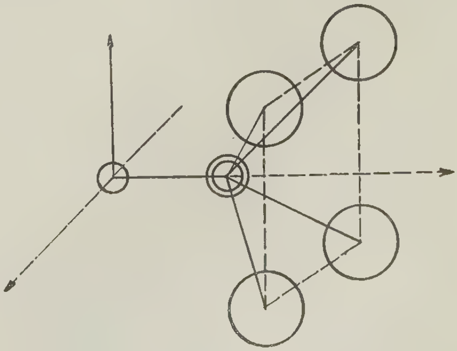


Fig. 13. Drawings showing the relative position of H_2O and the halogen ions in $CaI_2 6H_2O$ and $SrI_2 6H_2O$. Larger circles represent the iodine ions, a small circle represents a Ca or Sr ion, and a double circle shows a water molecule.

Table III.

salt	state	$\langle \Delta H^2 \rangle_0$	$\langle \Delta H^2 \rangle_1$	γ	γ'
$CaI_2 6H_2O$	rigid	23.0	3.0	1.595±0.02	—
$CaI_2 6H_2O$	rotation	1.0	0.6	—	40°
$SrI_2 6H_2O$	rigid	25.0	2.7	1.576±0.02	—
$SrI_2 6H_2O$	rotation	2.0	0.5	—	33°

The second moment for such a powder is given by the modification of Eq. (2) as follows:

$$\langle \Delta H^2 \rangle_0 = (4/5)\alpha''^2 = (4/5)\alpha^2\{P_2(\cos\gamma')P_2(\cos\gamma)\}^2 \,. \qquad (5)$$

In crystals having the structure of $SrCl_2 6H_2O$ type, the positions of water molecules can be shown by Fig. 13. This structure suggests the precessional motion of rotating axis, without discarding the model of rotational motion about C_2-axis of water molecules, because the second moment in this case takes a reduction due to $\{P_2(\cos\gamma')\}^2$ with $P_2(\cos\gamma)=0.5$. Thus γ' becomes 40° for $CaI_2 6H_2O$ and 33° for $SrI_2 6H_2O$. Theses results are tabulated in Table III.

c) *Results on other hydrates*

Powdered $CaCl_2 6H_2O$, $CaBr_2 6H_2O$, $SrCl_2 6H_2O$ and $SrBr_2 6H_2O$ have broad resonance lines of almost two spin type at room temperature, which correspond to the rigid lattice with second moment of about 30 gauss². Signal to noise ratios for these resonances are not so high as for the salts discussed in a) and b) because very low level of oscillation of the rf oscillator is used to avoid distortion of signals by a slight saturation. Although a sharp overlapping central peak with the broad line which originates from the adsorbed moisture on the surface of powders or from remaining HCI or HBr was eliminated by vacuum drying as much as possible, resonance signals in $CaCl_2 6H_2O$ and $CaBr_2 6H_2O$ had nevertheless a faint central peak, but those in $SrCl_2 6H_2O$ and $SrBr_2 6H_2O$ showed hardly any peaks. However, in enough lower temperature ranges which is above room temperature but under the melting points, a peak appeared at the center of the broad line in the latter salts, and it became large at elevated temperature with the decrease in intensity of broad lines. In the former salts the nearly same things occurred. This state must correspond to the transitions of resonance in $Mg(H_2O)_6Cl_2$ or $SrI_2 6H_2O$ at higher temperatures, but these hydrates melt into their own water without passing the state in which the water of hydration can rotate in their lattice. It is often said in chemistry that hydrogens will escape from these crystals as molecules HCI or HBr at melting. If it is assumed in this model that the hydrogen belonging to a water molecule is shifted to the neighboring halogen ion and forms a molecule HCl or HBr before melting, then this state must correspond to the narrower line. However, in $SrCl_2 6H_2O$, for example, when one proton of a water molecule moves to the chlorine atom to form HCI, interatomic distance of which is taken to be 1.27A, the second moment for such a model of the distorted water molecule is calculated to be 2.1 gauss², and the line becomes a doublet having a peak separation of 3.22 gauss. This is different from the observed one in $SrCl_2 6H_2O$, but it is similar to the reasonance of $SrI_2 6H_2O$ in the room temperature range. On the other hand, if HI molecules are formed in solid state of $SrI_2 6H_2O$ in the room temperature range, the bond formation of I–H····O–H gives the second moment of 2.65 gauss² for hydrogen-iodine interaction and 4.42 gauss² for proton-proton interaction. The sum of these two values is much larger than the observed value of the second moment at room temperature for $SrI_2 6H_2O$. The motion of the proton between two potential minima along O–H····I bond makes the second moment assume an intermediate value between the rigid lattice value, 23.5 gauss², and the above distorted value, 7.07 gauss². Thus in all cases, the reasonable account can be made only on the model that the proton moves out of the line joining the oxygen and the halogen ion.

As an explanation for a central peak, the following motional narrowing is considered. If the precessional motion occurs varying the angle between the axis of rotation and the axis of precession from γ_1' to γ_2', then the eduction of the approximate doublet separaion δH is shown to be proportional to the verage value of $P_2(\cos\gamma')$ over γ' from γ_1' o γ_2'. For example, a doublet separation of bout 10 gauss reduces to 0.65 gauss taking $_1'=45°$ and $\gamma_2'=60°$, and the doublet line nay not be distinguished from a single peak, vhen $\langle \Delta H^2\rangle_1 \geqq 0.2$ gauss². Moreover, the second noment can be reduced to zero, if the average of $P_2(\cos\gamma')$ is taken over the angle γ' rom 0° to 90°. Thus the rotational motion pproaches in such a manner to random rerientational motion, then the resonance line ives rise to a sharp central peak. Without assing the rotational motion or precession f a definite angle, the hydrates discussed in) go into the liquid-like structure.

4. Concluding Remarks

It should be concluded, from the above reults, that the water molecules of hydration n some halogen compounds of the second roup elements go into the hindered rotationl motion. However, detailed behavior of his motion such as rotational frequency, or he reasons why these motion should occur n some salts and not in others, is not certain, nd must be studied further.

Little is known about the thermal properies of these hydrates and we know the data bout the hydration of magnesium chloride nly. Energies of hydration of Mg^{++} ion nd $[Mg(H_2O)_6]^{++}$ ion are estimated to be 52 kcal/g.ion and 210 kcal/g.ion respectively16), nd heat of solution of $Mg(H_2O)_6Cl_2$ crystal s known to be 2.94 kcal/mole17). We may neglect the energies associated with entropy hanges in the reactions, because they are mall compared to these energies. By subracting the heat of solution of $Mg(H_2O)_6Cl_2$ rom the sum of hydration energies of $Mg(H_2O)_6]^{++}$ ion and two Cl^- ions, we obained 345 kcal/g.ion as the binding energies etween two Cl^- ion and $[Mg(H_2O)_6]^{++}$ ion. On the other hand, the energy of formation f $[Mg(H_2O)_6]^{++}$ ion from Mg^{++} ion and six H_2O molecules can be calculated as the diference between the energies of hydration f Mg^{++} ion and $[Mg(H_2O)_6]^{++}$ ion. This mounts to be 242 kcal/g.ion. Although hese values show that the attractive forces etween electric dipoles of the water moleules and chlorine negative ions are not so small, the arrangement of negative ions does not make the suitable angle of H–O–H as well as sufficiently shorter O–H····Cl distance for Cl····H–O–H····Cl binding to be possible, therefore the water molecule may take two or more equilibrium directions. Moreover, we believe that the coordination of water molecules to the central small metallic ion makes the interaction between charges of the electric dipoles reduce appreciably the hindering potential for rotation in the case of magnesium salts.

Possibility of hindered rotational motion of water molecules for the iodides will be due to the small electronegativity of iodine ion and it represents little contribution of covalency to these binding.

Acknowledgement

The author wishes to express his sincere thanks to Professor Tunahiko Sidei for his continual guidance and encouragement throughout this study. He is also indebted to Mr. Takenobu Higashimura for his invaluable advice, to Mr. Tadao Matsunami for preparing a single crystal of $Mg(H_2O)_6Cl_2$, and to Mr. Sōji Sasaki for his assistance in construction of the experimental apparatus.

Radiofrequency Spectroscopy Using Three-Level Maser Action

By Koichi SHIMODA

Department of Physics, Faculty of Science, University of Tokyo

(Received April 3, 1959)

A direct transition between l-type doublet of OCS molecule was observed either as emission or absorption using the three-level maser action. The pumping radiation was supplied by a klystron 2K33 at the frequency correspanding to $J=2\leftarrow1$, and the l-type doubling transition at 12.78 Mc/sec for $J=1$ was observed by a modified Pound-Knight circuit. Generally the low frequency transition of molecules is shown to be detectable using the bandwidth of about $1\,\mathrm{s}^{-1}$, if the corresponding microwave transition at 24,000 Mc/sec has the absorption coefficient larger than $10^{-8}\,\mathrm{cm}^{-1}$. The line-width can possibly be reduced to several kc/sec at the sacrifice of sensitivity. The application of this type of spectrometer is also discussed.

§ 1. General Considerations

The absorption of electromagnetic waves by molecules in gases has widely been observed in the infrared and microwave range, but it has never been observed in the lower radiofrequency range. This is only because the absorption by molecules is approximately proportional to the square of the frequency and it becomes very weak at lower frequencies. Thus the radiofrequency spectroscopy of gases by conventional methods of microwave spectroscopy is not practicable in the range below 1000 Mc/sec, where only a few lines have been observed[1].

However, a variety of transitions is known to fall in still lower radiofrequency range which is too weak to be detected by a conventional absoption technique. It is the purpose of this paper to report the first success of observing low frequency transitions of molecules by the application of three-level maser technique[2][3].

Consider a three-level system where the low frequency transition to be observed may either be $\nu_0=(E_3-E_2)/h$ as in Fig. 1 (a) or $\nu_0=(E_2-E_1)/h$ as in Fig. 1 (b). In order to simplify the discussion only the case of Fig. 1 (a) will be described.

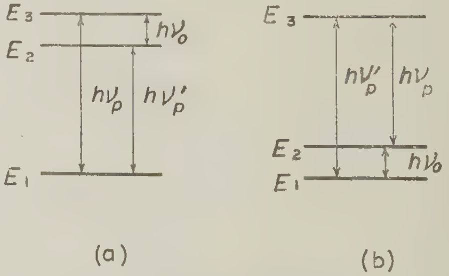

Fig. 1. Three level systems.

The power absorption coefficient at the frequency $\nu=\nu_0$ is given by

$$\alpha=(n_2-n_3)\frac{8\pi^2\nu_0}{3hc}\frac{|\mu_0|^2}{\Delta\nu}, \qquad (1)$$

where n_2 and n_3 are the number density of molecules in the energy levels E_2 and E_3 respectively, μ_0 the dipole matrix element between states E_2 and E_3, and $\Delta\nu$ the half-half-width of the line which is assumed to be mostly due to pressure broadening. In thermal equilibrium at temperature T, the Boltzmann distribution shows

$$n_2-n_3=\frac{h\nu_0}{kT}n_2 \qquad (2)$$

and the absorption coefficient is given by

$$\alpha_0=\frac{8\pi^2\nu_0^2 n_2}{3ckT}\frac{|\mu_0|^2}{\Delta\nu}. \qquad (3)$$

Therefore the absorption coefficient is proportional to the square of the frequency, assuming that other factors are constant.

If the transition between states E_1 and E_3 is allowed, pumping power at the frequency $\nu_p=(E_3-E_1)/h$ is used to saturate the transition, and then the induced emission at the frequency ν_0 will be observed. On the other hand, if the transition between states E_1 and E_2 is allowed, the pumping power at the frequency $\nu_p'=(E_2-E_1)/h$ will enhance the induced absorption at the frequency ν_0. In either case for complete saturation one obtains

$$|n_2-n_3|\cong\frac{h\nu_p}{2kT}n_2. \qquad (4)$$

The absorption coefficient or the coefficient of induced emission in this case becomes

$$\alpha_{0,\text{pump}}\cong\frac{4\pi^2\nu_0\nu_p n_2}{3ckT}\frac{|\mu_0|^2}{\Delta\nu} \qquad (5)$$

which is $\nu_p/2\nu_0$ times larger than α_0.

Since the low frequency transition can more conveniently be observed with a resonator cell than a transmission line cell, a better measure of the intensity is the quality factor of the molecules. It is denoted by $Q_m(\nu)$ and is given by

$$Q_m(\nu)=\frac{2\pi\nu_0}{c\alpha(\nu)} \qquad (6)$$

as a function of frequency. For $\nu=\nu_0$, $Q_m(\nu_0)$ will be simply written as Q_m, but it may be noted that Q^{-1} of the molecule in this paper does not represent the line-width but is equal to the loss factor of the gas.

When the molecule is completely saturated by the pumping radiation, the following equation is obtained from Eqs. (5) and (6).

$$\frac{1}{Q_m}=\frac{2\pi\nu_p n_2}{3kT}\frac{|\mu_0|^2}{\Delta\nu} \qquad (7a)$$

This equation may be expressed as

$$\frac{1}{Q_m}=\frac{\lambda_p\alpha_p}{4\pi}\left|\frac{\mu_0}{\mu_p}\right|^2 \qquad (7b)$$

where μ_p is the dipole matrix element of the pumping transition and α_p is the absorption coefficient at ν_p. It is noticeable that Eq. (7) is independent of ν_0. Assuming that the pumping frequency is about 24 Gc/sec and $\mu_0\approx\mu_p$, Eq. (7) can be written as

$$\frac{1}{Q_m}\approx\frac{\alpha_p}{10}. \qquad (8)$$

As the typical value of microwave absorption coefficient which has been measured arround 24 Gc/sec is $\alpha_p=10^{-5}\sim10^{-8}$ cm^{-1}, the above equation shows that Q of the molecule at the low frequency transition should be such that $1/Q_m=10^{-6}\sim10^{-9}$, which is of detectable magnitude as will be shown below.

§ 2. Line-Width and Sensitivity of Three-Level Maser Spectrometer

If the radiofrequency spectral lines are as broad as those in the microwave range, direct observation of low frequency transitions would be less worthy of study. The resolution of microwave spectrometer is largely limited by Doppler broadening, which is proportional to the transition frequency and the velocity of molecules. The Doppler width is approximately given by

$$\Delta\nu_D\approx\frac{v_m}{c}\nu_0\approx10^{-6}\nu_0, \qquad (9)$$

where v_m is the average velocity of molecules. For low frequencies, $\nu_0\approx10$ Mc/sec, the Doppler width, $\Delta\nu_D\approx0.01$ kc/sec, is so small as to allow very high resolution. However, other broadening factors will dominate in usual experimental conditions.

The broadening by collisions of molecules with cell walls or electrodes is given approximately by[4)]

$$\Delta\nu_w\cong\frac{0.1}{d}\sqrt{\frac{2RT}{M}}, \qquad (10)$$

where d is the distance between opposite walls, R the gas constant, and M the molecular weight. As an example take $d=2$ cm, $M=60$, and then Eq. (10) gives $\Delta\nu_w=1.45$ kc/sec.

The broadening by collisions of molecules with each other is known to be proportional to the gas pressure. In order to reduce it to 1 kc/sec for example, the gas pressure must be of the order of 10^{-4} mm Hg.

Saturation effect will be appreciable, when the field intensity at the frequency ν_0 is larger than the critical value E_c which is approximately given by

$$E_c^2 = 3h^2 \frac{(\varDelta\nu_0)^2}{|\mu_0|^2} \tag{11}$$

where $\varDelta\nu_0$ is the total line-width and h the Planck's constant. The critical field E_c may be written as

$$E_c(\text{V/cm}) = 3.44 \times 10^{-3} \frac{\varDelta\nu_0(\text{kc/sec})}{|\mu_0|(\text{Debye})} . \tag{12}$$

Therefore, the field intensity must be very weak in order to obtain high resolution. For example, when $\varDelta\nu_0 = 3$ kc/sec and $\mu_0 = 1$ Debye, the field intensity must be less than 10 mV/cm.

Now the sensitivity of the spectrometer is calculated. In order to detect electric dipole transition, the molecules of gas must be put in the r.f. electric field. The cell acts as a capacitor C, which forms a resonant circuit with an external inductance L. Assuming that the quality factor of the LC resonator is Q_0 at the absence of molecules in the capacitor, the impedance at the resonant frequancy is $R_0 = Q_0/2\pi\nu_0 C$. At the presence of molecular transition having Q_m the impedance at resonance becomes

$$R = \frac{Q_0 Q_m}{2\pi\nu_0 C(Q_0 + Q_m)} .$$

Therefore, when the LC resonator is driven by a constant current generator, the resonator r.f. voltage $V_0 = iR_0$ will change by $\varDelta V_0 = i(R - R_0)$ at the presence of molecules. For $Q_m \gg Q_0$ the signal voltage due to the transition of molecules is

$$\varDelta V_0 = K \frac{Q_0}{Q_m} V_0 , \tag{13}$$

where K is the filling factor.

On the other hand the effective noise voltage is expressed as

$$\overline{v_n^2} = 4FR_0 kT\varDelta f ,$$

where F is the noise figure of the r.f. spectrometer, and $\varDelta f$ the effective bandwidth of the detecting system.

Assume for simplicity that the signal voltage larger than r.m.s. noise voltage can be detected. Then the minimum detectable $1/Q_m$ is

$$\left(\frac{1}{Q_m}\right)_{\min} = \frac{2}{KV_0} \sqrt{\frac{FkT\varDelta f}{2\pi\nu_0 C Q_0}} . \tag{14}$$

This equation shows that the larger the r.f. voltage the higher the sensitivity, while equation (11) or (12) requires the lower r.f. voltage for the higher resolution.

As an example of high sensitivity let us take $V_0 = 0.2$V, $F = 2$, $\varDelta f = 1\,\text{s}^{-1}$, $K = 0.8$, $\nu_0 = 10$ Mc/sec $= 10^7\text{s}^{-1}$, $Q_0 = 100$, and $C = 200$ pF, one obtains

$$\left(\frac{1}{Q_m}\right)_{\min} = 1 \times 10^{-9} .$$

This sensitivity assures observation of r.f. transition having the intensity corresponding to the microwave absorption coefficient of $10^{-8}\,\text{cm}^{-1}$ as can be seen from Eq. (8).

However, higher resolution must be attained at the sacrifice of high sensitivity. The resonator voltage should be smaller than $V_0 = 3.44 \times 10^{-3} \varDelta\nu_0 d/\mu_0$ volts from Eq. (12), where d is the separation of r.f. electrodes in centimeters. For example, take $\varDelta\nu_0 = 3$ kc/sec, $\mu_0 = 1$ Debye, $d = 2$ cm, and $V_0 = 2 \times 10^{-2}$V is obtained. This results in the sensitivity as

$$\left(\frac{1}{Q_m}\right)_{\min} = 1 \times 10^{-8} ,$$

if other factors are the same as before.

§ 3. Experimental Results

A three-level radiofrequency spectrometer has been constructed and tested to observe direct l-type doubling transitions of ICN and OCS. The spectrometer was first operated for ICN. The rotational spectrum of ICN, corresponding to the transition $J = 2 \leftarrow 1$, shows l-type doublets, which were measured by Oka, Hirakawa, and Miyahara, although they were not reported in their paper[5] because of the inadequacy of these lines in determining the quadrupole coupling constants.

The rotational transition of ICN at 13,094 Mc/sec or 13,083 Mc/sec, corresponding to $J = 2 \leftarrow 1$, $F = 9/2 \leftarrow 7/2$, and $v_2 = 1$, was employed to increase the intensity of direct l-type doubling transition at 5.4 Mc/sec, for $J = 1$. The experiment turned out to be a failure, and the reasons of its negative result are considered as follows. The pumping radiation supplied by a crystal doubler was not sufficiently strong to achieve appreciable saturation. Moreover, the presence of hyperfine structures due to I^{127} and N^{14} made each component weaker, and the sample used was not pure.

Then the three-level spectrometer was

tested with carbonyl sulfide which shows no hyperfine structure. The pumping transition was $J=2\leftarrow1$ in $v_2=1$ state, and the direct l-type doubling transition for $J=1$ could be observed either as emission or as absorption at 12.78 Mc/sec. The accurate frequency was not measured, but it seemed to be only a little smaller than this value.

The energy level diagram of OCS for $J=1$ and 2 is shown in Fig. 2, and the frequencies of allowed transitions between these levels are:

$\nu_{12}=12.78$ Mc/sec
$\nu_{34}=38.35$ Mc/sec
$\nu_{13}=24{,}355.50$ Mc/sec
$\nu_{24}=24{,}381.07$ Mc/sec

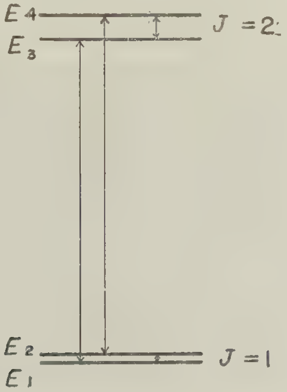

Fig. 2. Energy level diagram of OCS in the first bending vibrational mode.

In thermal equlibrium at room temperature the absorption coefficient of $J=1$ line at 12.78 Mc/sec is calculated to be $\alpha_0=4.0\times10^{-13}\,\mathrm{cm}^{-1}$, which is many orders of magnitude smaller than the detectable absorption without pumping.

The dipole matrix element[6] for the transition $J+1\leftrightarrow J$ is

$$|\mu_{ij}|^2=\mu^2\frac{(J+1)^2-l^2}{(J+1)(2J+1)} \tag{15}$$

and for $\Delta J=0$

$$|\mu_{ij}|^2=\mu^2\frac{l^2}{(J+1)(2J+1)}\,. \tag{16}$$

Thus for the pumping transition $J=2\leftarrow1$ at the frequency ν_{13} or ν_{24}, $|\mu_p|^2=\frac{1}{2}\mu^2$, and for direct l-type doubling transition of $J=1$ $|\mu_0|^2=\frac{1}{6}\mu^2$. As the absorption coefficient at the frequency ν_p is $\alpha_p=4.4\times10^{-6}\,\mathrm{cm}^{-1}$, the intensity of l-type doubling transition under complete saturation by pumping at the frequency $\nu_p=\nu_{13}$ or ν_{24} is calculated from Eq. (7b) as

$$\frac{1}{Q_m}=1.4\times10^{-7}\,. \tag{17}$$

The calculated intensity of the $J=2$ line is $1/Q_m=5.7\times10^{-8}$ because $|\mu_0|^2=\frac{1}{15}\mu^2$ in this case.

To achieve high resolution as well as high sensitivity, the separation of r.f. electrodes must be large, but then large pumping power is required. The optimum pumping power of a plane polarized wave can be approximately expressed as

$$P_{\mathrm{opt}}=\frac{3ch^2}{4\pi}\frac{(\Delta\nu_p)^2}{|\mu_p|^2}S\,, \tag{18}^*$$

where the relaxation time is taken as $\nu=1/2\pi\Delta\nu_p$, $\Delta\nu_p$ is the total line-width including Doppler effect of the pumping transition, and S is the cross-sectional area of the cell. It may be noted that although the Doppler broadening is not a power dissipating process, it must be taken into the calculation of saturation power, because only during the time interval $1/2\pi\Delta\nu_D$ the phase difference between molecules and waves is kept within one radian.

Taking the following values, $|\mu_p|^2=\frac{1}{2}(0.709)^2$, $\Delta\nu_p=70$ kc/sec, and $S=23\,\mathrm{cm}^2$, the optimum pumping power is calculated as

$$P_{\mathrm{opt}}=14\,\mathrm{mW}\,.$$

Microwave power of this order of magnitude at 24 Gc/sec was supplied by a klystron 2K33.

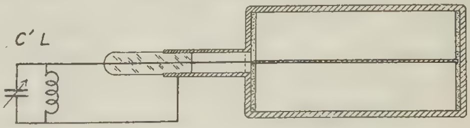

Fig. 3. Cross-section of the waveguide cell.

The absorption cell is made of 3,000 Mc/sec band waveguide of 2 meters length, whose cross-section is 72.0 mm×34.0 mm I.D. and the r.f. center electrode has been inserted in the same way as the Stark septum as shown in Fig. 3.

The r.f. voltage is applied to the center electrode which is connected to an external inductance L and a small variable capacitor to tune the resonant frequency.

---

* This corresponds exactly to $|y|^2\tau^2=\frac{1}{2}$ in ref. (7) or $|\mu_p|_x E\tau=h$, where E is the r.m.s. field intensity of the pumping radiation.

The r.f. oscillator and detector employed is of a modified Pound-Knight circuit.[8] The pumping radiation is frequency modulated at the frequency of $175\,\mathrm{s}^{-1}$, and the r.f. amplifier and detector is followed by a tuned $175\,\mathrm{s}^{-1}$ amplifier and a phase-sensitive detector. The time constant of the filter in the detector output can be varied from 0.005 to 0.25 sec. The output of the spectrometer can be observed with a d.c. oscilloscope as well as with a pen-and-ink recorder. A block diagram of the spectrometer is shown in Fig. 4.

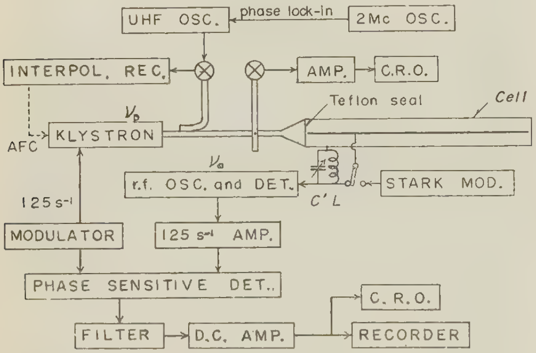

Fig. 4. Block diagram of the three level r.f. spectrometer. $125\,\mathrm{s}^{-1}$ should read $175\,\mathrm{s}^{-1}$.

The absorption cell is used as a Stark cell to observe and monitor the pumping transition by a crystal detector in an auxiliary waveguide.

The klystron 2K33 might be automatically frequency controlled with respect to the UHF oscillator at 358 Mc/sec which is locked in the harmonic of a 2 Mc/sec crystal oscillator[9], but actually it was manually tuned with respect to the 358 Mc/sec oscillator. To sweep the microwave frequency for pumping, frequency of the interpolation receiver was changed with time. When the pumping frequency was ν_{13}, emission of r.f. signal at $\nu_0=\nu_{12}$ could be observed, and when it was ν_{24}, absorption of r.f. signal could be observed.

The capacitance of the r.f. electrode of the cell is about 300 pF including capacitance of the lead, and Q of the resonant circuit is fairly low. Because the r.f. field is stronger at the edge of the electrode, the filling factor is supposed to be also small. Using the values, $\Delta\nu_0=10$ kc/sec, $|\mu_0|=0.709/6^{1/2}$ Debye, and $d=1.66$ cm, it is found from Eq. (12) or (15) that the resonator voltage should not exceed $V_0=0.2$ V. Then the minimum detectable intensity is calculated from Eq. (14), assuming $\nu_0=12.78$ Mc/sec, $C=3\times10^{-10}$ F, $Q_0=20$, $K=0.5$, $F=3$, and $\Delta f=1.3\,\mathrm{s}^{-1}$, corresponding to the filter time constant of 0.25 seconds, as

$$\left(\frac{1}{Q_{\mathrm{m}}}\right)_{\min}=3.6\times10^{-9}\,.$$

Therefore, the l-type doubling transition having the intensity as shown by Eq. (17) must be observed with the signal to noise ratio of

$$\frac{S}{N}=\frac{1.4\times10^{-7}}{3.6\times10^{-9}}=39\,.$$

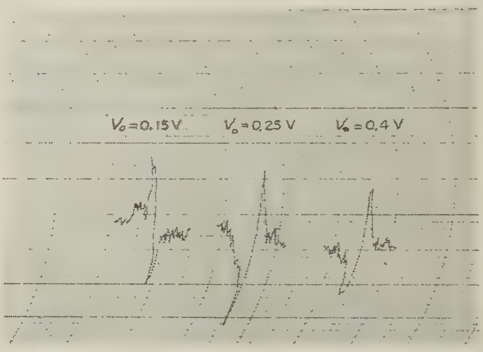

Fig. 5. Traces of records of the direct l-type doubling transition of OCS, where the left one was taken with sweep in the reverse direction.

By sweeping the pumping frequency through ν_{p}, the direct l-type doubling transition was observed and recorded as shown in Fig. 5, using the filter time constant of 0.25 seconds. The observed intensity of the line agrees fairly well with the calculated value, thus confirming the theoretical considerations given above. Saturation effect by r.f. field was observed when the r.f. amplitude was increased above 0.1 volt.

The spectrum could also be recorded by sweeping the r.f. frequency. However, the record was disturbed and blotted by interferences from other laboratories. The observed line-width at a pressure of about 10^{-3} mm Hg and with r.f. amplitude of about 0.25 volts was nearly 40 kc/sec. The line-width was found to decrease by reducing the pressure, but then the signal intensity also decreased and the pumping power could not considerably be reduced. It can be supposed that much higher sensitivity with slower sweep as well as smaller r.f. amplitude must be used in order to reduce the line-width below 10 kc/sec and observe the line with good signal to noise ratio.

§ 4. Applications

Most of the low frequency transitions of simple molecules might be studied by the three-level technique described above.

1. Direct transitions between K-type doublets, corresponding to $\Delta J=0$ and $\Delta K_1=1$ in case of a nearly symmetric prolate rotor, can be detected. The transition $\Delta J=1$ is used for pumping. A slightly asymmetric molecule such as CH_2CO or CH_2DC1 seems to be a good example of this type, and larger signal intensity than for l-type doubling transition is generally expected.
2. Direct hyperfine transitions corresponding to $\Delta J=0$ and $\Delta F=\pm1$ for a symmetric molecule may be studied. But the intensity is expected to be smaller, because the magnitude of the dipole matrix element is rather small in this case.
3. Transitions between Stark or Zeeman components under d.c. external field, corresponding to $\Delta J=0$ and $\Delta M=\pm1$, may also be observed.
4. Other low frequency transitions due to l-type doubling, inversion, or internal rotation may possibly be observed, if both the observation frequency and the pumping frequency fall in some convenient ranges.

In conclusion the author would like to express his thanks for the assistance of Messrs H. Takuma and T. Shimizu in carrying out the experiment. He also thanks for the financial help of the Ministry of Education.

Stationäre Temperaturverteilung in der Wand vielschichtiger Röhrenleitungen

Von Václav VODIČKA

Pilsen, ČSR

(Eingegangen am 19. März 1959)

The present paper solves completely the problem of stationary temperature distribution in a hollow n-layerd circular cylinder whose boundaries are kept at given temperatures varying both in the tangential and in the longitudinal direction. The first part of the paper takes into account heat transfer at the surfaces of separation, and the second part treats the case of a continuous variation of temperature at each surface of separation. The results are very complicated.

Dieser Aufsatz bringt fertige Formeln für stationäre Temperaturfelder in einem hohlen n-schichtigen Kreiszylinder, dessen beide Oberflächen auf vorgeschriebener Temperatur gehalten werden. Trotz ihrer technischen Bedeutung hat der Verfasser die fertigen Formeln in der Literatur nicht finden können.

Der ganze Aufsatz zerfällt in zwei Teile.

Im ersten rechnen wir mit endlichen Wärmeübergangsfaktoren an den Trennflächen einzelner Körperschichten, der zweite Teil setzt überall stetige Aenderung sowohl der Temperatur als auch des Wärmeflusses voraus.

I. Wärmesprünge an den Trennflächen

§ 1. Problemstellung. **Es seien**

$$0<\rho_1<\rho_2<\cdots<\rho_{n+1}\,, \quad h_i>0\,, \quad h_i'>0 \qquad (i=2,\,3,\,\cdots,\,n) \tag{1}$$

gegebene Konstanten, $f(\varphi, z)$ und $F(\varphi, z)$ zwei für alle reellen φ, z definierte Funktionen mit der Periode 2π bezüglich φ. Im Bereich $0\le\varphi\le 2\pi$ lassen sich $f(\varphi, z)$ und $F(\varphi, z)$ in Fourierreihen entwickeln, als Funktionen von z seien beide mit Hilfe vom Fourierschen Integraltheorem ausdrückbar.

Unter diesen Verhältnissen geht es um die in φ periodische Lösun $u_i(\rho, \varphi, z)$ folgender technisch und physikalisch leicht verständlichen Aufgabe:

$$\frac{\partial^2 u_i}{\partial\rho^2}+\frac{1}{\rho}\frac{\partial u_i}{\partial\rho}+\frac{1}{\rho^2}\frac{\partial^2 u_i}{\partial\varphi^2}+\frac{\partial^2 u_i}{\partial z^2}=0$$

$$(\rho_i<\rho<\rho_{i+1},\ 0\le\varphi\le 2\pi,\ -\infty<z<+\infty;\ i=1,\,2,\,\cdots,\,n)\,, \tag{2}$$

$$u_1(\rho_1, \varphi, z)=f(\varphi, z) \qquad (0\le\varphi\le 2\pi,\ -\infty<z<+\infty)\,, \tag{3.1}$$

$$\frac{\partial u_i}{\partial\rho}+h_{i+1}(u_i-u_{i+1})=\frac{\partial u_{i+1}}{\partial\rho}+h_{i+1}'(u_i-u_{i+1})=0$$

$$(\rho=\rho_{i+1},\ 0\le\varphi\le 2\pi,\ -\infty<z<+\infty;\ i=1,\,2,\,\cdots,\,n-1)\,, \tag{3.2}$$

$$u_n(\rho_{n+1}, \varphi, z)=F(\varphi, z) \qquad (0\le\varphi\le 2\pi,\ -\infty<z<+\infty)\,. \tag{3.3}$$

§ 2. Zurückführung auf zwei einfachere Fälle

Die Lösung unseres Problems (2)–(3.3) ergibt sich augenscheinlich durch Summierung der Lösungen zweier einfacheren Aufgaben, die dadurch zustandekommen, dass man sich in (2)–(3.3) das eine mal $F(\varphi, z)$ und das andere mal $f(\varphi, z)$ durch Null ersetzt denkt.

Ist $u_i^{(1)}(\rho, \varphi, z)$; $i=1, 2, \cdots, n$ die Lösung des ersten und $u_i^{(2)}(\rho, \varphi, z)$; $i=1, 2‘ \cdots, n$ des zweiten Teilproblems, so hat man also in

$$u_i(\rho, \varphi, z)=u_i^{(1)}(\rho, \varphi, z)+u_i^{(2)}(\rho, \varphi, z) \qquad (i=1,\,2,\,\cdots,\,n) \tag{4}$$

das verlangte Ergebnis für die Anfangsaufgabe (2)–(3.3).

§ 3. Die Bestimmung von $u_i^{(1)}(\rho, \varphi, z)$; $i=1, 2, \cdots, n$

Die mit noch unbestimmten Parametern β, γ und mit /im allgemeinen freilich von β, γ abhängigen/ beliebigen Konstanten A_{ik}, B_{ik}, C_{ik} und D_{ik} gebildeten Ausdrücke

$$\left.\begin{aligned}
&v_{ik}=R_{ik}(\beta\rho)(A_{ik}\cos k\varphi+B_{ik}\sin k\varphi)\cos\beta(\gamma-z) && (i=1,\,2,\,\cdots,\,n)\\
&R_{ik}(\beta\rho)=C_{ik}I_k(\beta\rho)+D_{ik}K_k(\beta\rho) && (i=1,\,2,\,\cdots,\,n-1)\,,\\
&R_{nk}(\beta\rho)=K_k(\beta\rho_{n+1})I_k(\beta\rho)-I_k(\beta\rho_{n+1})K_n(\beta\rho) && (k=0,\,1,\,2,\,\cdots)
\end{aligned}\right\} \tag{5}$$

sind für jedes k Lösungen von (2), haben die Periode 2π besüglich φ und darüber hinaus ist $v_{nk}(\rho_{n+1}, \varphi, z)=0$

Es ist leicht zu erzielen, dass auch noch die Uebergangsbedingungen (3.2) von den v_{ik} erfüllt werden. Dies wird dann und nur dann der Fall, wenn

$$\left.\begin{aligned}
&h_{i+1}(A_{i+1,k}\cos k\varphi+B_{i+1,k}\sin k\varphi)R_{i+1,k}'(\beta\rho_{i+1})=h_{i+i}'(A_{ik}\cos k\varphi+B_{ik}\sin k\varphi)R_{ik}'(\beta\rho_{i+1})\,,\\
&h_{i+1}\frac{R_{ik}(\beta\rho_{i+1})}{R_{ik}'(\beta\rho_{i+1})}=h_{i+1}'\frac{R_{i+1,k}(\beta\rho_{i+1})}{R_{i+1,k}'(\beta\rho_{i+1})}-1;\ R_{mk}'(\beta\rho_n)=\left[\frac{d}{d\rho}R_{mk}(\beta\rho)\right]_{\rho=\rho_n}\\
&\qquad\qquad(0\le\varphi\le 2\pi;\ i=1,\,2,\,\cdots,\,n-1,\ k=0,\,1,\,2,\,\cdots)\,.
\end{aligned}\right\} \tag{6}$$

Gebraucht man die Tatsache, dass sich aus

$$\frac{a+bx}{A+Bx}=\frac{1}{p}\left(-1+q\,\frac{a+by}{A+By}\right)$$

nach einiger Rechenarbeit

$$x=\frac{1}{N}\left(P-\frac{pq\Delta^2}{M+Ny}\right)$$

mit

$$\begin{aligned} &M=aBq-A(B+bp)\,, && N=-B[B+b(p-q)]\,,\\ &P=A[B+b(p-q)]+p\Delta\,, && \Delta=aB-Ab \end{aligned}$$

ergibt, so folgt aus der zweiten Gleichungsgruppe (6)-unter gleichzeitiger Berücksichtigung von (5) und von bekannten Wronskischen Beziehungen aus der Theorie der Zylinderfunktionen-leicht

$$D_{ik}=q_{ik}C_{ik} \qquad (i=1,\,2,\,\cdots,\,n-1;\ k=0,\,1,\,2,\,\cdots) \tag{7}$$

$$\left.\begin{aligned} q_{ik}=q_{ik}(\beta)= &\ \frac{1}{N_{i+1,k}(\beta)}\left\{P_{i+1,k}(\beta)-\frac{h_{i+1}h'_{i+1}}{\rho_{i+1}^2[M_{i+1,k}(\beta)+N_{i+1,k}(\beta)q_{i+1,k}(\beta)]}\right\},\\ &M_{i+1,k}(\beta)=-I_k'(\beta\rho_{i+1})K_k'(\beta\rho_{i+1})-h_{i+1}I_k'(\beta\rho_{i+1})K_k(\beta\rho_{i+1})+h'_{i+1}I_k(\beta\rho_{i+1})K_k'(\beta\rho_{i+1})\,,\\ &N_{i+1,k}(\beta)=-K_k'(\beta\rho_{i+1})[K_k'(\beta\rho_{i+1})+(h_{i+1}-h'_{i+1})K_k(\beta\rho_{i+1})]\,,\\ &P_{i+1,k}(\beta)=-\frac{h_{i+1}}{\rho_{i+1}}+I_k'(\beta\rho_{i+1})[K_k'(\beta\rho_{i+1})+(h_{i+1}-h'_{i+1})K_k(\beta\rho_{i+1}]\\ &\qquad\qquad\qquad\qquad\qquad\qquad (i=1,\,2,\,\cdots,\,n-2;\ k=0,\,1,\,2,\,\cdots)\\ q_{n-1,k}=q_{n-1,k}(\beta) = &-\frac{1}{\rho_nK_k'(\beta\rho_n)}\left\{\rho_nI_k'(\beta\rho_n)\right.\\ &\left.+\frac{h_n}{-h_nK_k(\beta\rho_n)+K_k'(\beta\rho_n)\left[-1+h_n'\,\dfrac{K_k(\beta\rho_{n+1})I_k(\beta\rho_n)-I_k(\beta\rho_{n+1})K_k(\beta\rho_n)}{K_k(\beta\rho_{n+1})I_k'(\beta\rho_n)-I_k(\beta\rho_{n+1})K_k'(\beta\rho_n)}\right]}\right\}\\ &\qquad\qquad\qquad\qquad\qquad\qquad (k=0,\,1,\,2,\,\cdots)\,. \end{aligned}\right\} \tag{7.1}$$

Geht man mit (7) und (7.1) in die erste Gleichungsgruppe (6) ein, so bekommt man daraus durch leichte Rechnung

$$\left.\begin{aligned} &A_{i+1,k}C_{i+1,k}=\delta_{i+1,k}A_{1k}C_{1k}\,, \qquad B_{i+1,k}C_{i+1,k}=\delta_{i+1,k}B_{1k}C_{1k}\\ &\qquad\qquad\qquad\qquad (i=1,\,2,\,\cdots,\,n-2;\ k=0,\,1,\,2,\,\cdots)\\ &\delta_{i+1,k}=\delta_{i+1,k}(\beta)=\frac{h_2'h_3'\cdots h'_{i+1}}{h_2h_3\cdots h_{i+1}}\prod_{\nu=1}^{i}\frac{I_k'(\beta\rho_{\nu+1})+q_{\nu k}K_k'(\beta\rho_{\nu+1})}{I_k'(\beta\rho_{\nu+1})+q_{\nu+1,k}K_k'(\beta\rho_{\nu+1})}\\ &A_{nk}=\delta_{nk}A_{1k}C_{1k}\,, \qquad B_{nk}=\delta_{nk}B_{1k}C_{1k} \qquad (k=0,\,1,\,2,\,\cdots)\\ &\delta_{nk}=\delta_{nk}(\beta)=\frac{h_n'}{h_k}\cdot\frac{I_k'(\beta\rho_n)+q_{n-1,k}K_k'(\beta\rho_n)}{K_k(\beta\rho_{n+1})I_k'(\beta\rho_n)-I_k(\beta\rho_{n+1})K_k'(\beta\rho_n)}\delta_{n-1,k}(\beta)\,. \end{aligned}\right\} \tag{8}$$

Unter Zuhilfenahme von bisherigen Ergebnissen erscheinen unsere partikuläre Lösungen (5) in der Form

$$v_{ik}=\delta_{ik}(\beta)C_{1k}V_{ik}(\beta\rho)\Phi_k(\varphi)\cos\beta(\gamma-z) \qquad (i=1,\,2,\,\cdots n;\ k=0,\,1,\,2,\,\cdots) \tag{9}$$

worin $\delta_{1k}=1$ $(k=0,\,1,\,2,\,\cdots)$ und die übrigen $\delta_{ik}(\beta)$ nach (8) zu berechnen sind. Weiter ist mit den durch (7.1) bestimmten Grössen q_{ik}

$$V_{ik}(\beta\rho)=I_k(\beta\rho)+q_{ik}K_k(\beta\rho)\,, \qquad V_{nk}(\beta\rho)=K_k(\beta\rho_{n+1})I_k(\beta\rho)-I_k(\beta\rho_{n+1})K_k(\beta\rho) \tag{9.1}$$
$$(i=1,\,2,\,\cdots,\,n-1;\;\; k=0,\,1,\,2,\,\cdots)$$

und endlich

$$\Phi_k(\varphi)=A_{1k}\cos k\varphi+B_{1k}\sin k\varphi \qquad (k=0,\,1,\,2,\,\cdots) \tag{9.2}$$

Die durch (9)–(9.2) definierten Ausdrücke $v_{ik}=v_{ik}(\rho,\,\varphi,\,z;\;\beta,\,\gamma)$ genügen allen Forderungen unseres ersten Teilproblems, bis auf (3.1). Dasselbe gilt dann natürlich auch für die Funktionen

$$u_{ik}(\rho,\,\varphi,\,z)=\int_0^\infty d\beta\int_{-\infty}^\infty v_{ik}(\rho,\,\varphi,\,z;\;\beta,\,\gamma)d\gamma \qquad (i=1,\,2,\,\cdots,\,n;\;\; k=0,\,1,\,2,\,\cdots)\,. \tag{10}$$

Die letzte noch zu befriedigende Bedingung (3.1) drückt sich mit geläufigem Ansatz

$$u_i^{(1)}(\rho,\,\varphi,\,z)=\sum_{k=0}^\infty u_{ik}(\rho,\,\varphi,\,z) \qquad (i=1,\,2,\,\cdots,\,n) \tag{11}$$

aus durch die Gleichung

$$\left.\begin{aligned}
&\frac{1}{\pi}\sum_{k=0}^\infty\int_0^\infty d\beta\int_{-\infty}^\infty[f_{k1}(\gamma)\cos k\varphi+f_{k2}(\gamma)\sin k\varphi]\cos\beta(\gamma-z)d\gamma\\
&=\sum_{k=0}^\infty\int_0^\infty[I_k(\beta\rho_1)+q_{1k}K_k(\beta\rho_1)]d\beta\int_{-\infty}^\infty C_{1k}(A_{1k}\cos k\varphi+B_{1k}\sin k\varphi)\cos\beta(\gamma-z)d\gamma\,,\\
&f_{01}(\gamma)=\frac{1}{2\pi}\int_0^{2\pi}f(\alpha,\,\gamma)d\alpha\,, \qquad \begin{matrix}f_{k1}(\gamma)\\ f_{k2}(\gamma)\end{matrix}=\frac{1}{\pi}\int_0^{2\pi}f(\alpha,\,\gamma)\cdot\begin{matrix}\cos k\alpha\\ \sin k\alpha\end{matrix}d\alpha \qquad (k\geq 1)\,.
\end{aligned}\right\} \tag{12}$$

Daraus entnimmt man sofort

$$\begin{matrix}A_{1k}C_{1k}\\ B_{1k}C_{1k}\end{matrix}=\frac{1}{\pi\Lambda_k}\cdot\begin{matrix}f_{k1}(\gamma)\\ f_{k2}(\gamma)\end{matrix}\,, \qquad \Lambda_k=\Lambda_k(\beta)=I_k(\beta\rho_1)+q_{1k}K_k(\beta\rho_1) \qquad (k=0,\,1,\,2,\,\cdots)\,, \tag{13}$$

wobei natürlich für das Endergebnis ganz belanglos ist, dass der Ausdruck $B_{10}C_{10}$ unbestimmt bleibt.

Fasst man die bisherigen Teilergebnisse (11), (10), (9)–(9.2) zusammen, so gelangt man zur folgenden fertigen Lösung unseres ersten Teilproblems:

$$u_i^{(1)}(\rho,\,\varphi,\,z)=\frac{1}{\pi}\sum_{k=0}^\infty\int_0^\infty\frac{\delta_{ik}(\beta)}{\Lambda_k(\beta)}V_{ik}(\beta\rho)\,d\beta\int_{-\infty}^\infty[f_{k1}(\gamma)\cos k\varphi+f_{k2}(\gamma)\sin k\varphi]\cos\beta(\gamma-z)d\gamma$$
$$(i=1,\,2,\,\cdots,\,n)\,. \tag{14}$$

Die in den Lösungsformeln (14) vorkommenden Grössen und Ausdrücke berechnen sich wie folgt: q_{ik} nach (7.1), $\Lambda_k(\beta)$ nach (13), $V_{ik}(\beta\rho)$ nach (9.1), $f_{k1}(\gamma)$ und $f_{k2}(\gamma)$ nach (12), $\delta_{1k}(\beta)=1$ und die anderen $\delta_{ik}(\beta)$ sind in (8) erklärt; I_k und K_k bedeuten modifizierte Besselsche Funktionen, mit Strich werden überall die Ableitungen nach ρ bezeichnet, sodass z. B.

$$I_k'(\beta\rho_n)=\left[\frac{d}{d\rho}I_k(\beta\rho)\right]_{\rho=\rho_n}\,.$$

§ 4. Die Bestimmung von $u_i^{(2)}(\rho,\,\varphi,\,z)$; $i=1,\,2,\,\cdots,\,n$

Nach dem, was im Abschnitt 2 gesagt wurde, geht es hier bloss um eine unwesentliche Abänderung der vorigen Aufgabe. Die gewünschte Lösung kann angenscheinlich direkt nach (14) ohne jede Rechnung aufgeschrieben werden, indem man in (14) die alten Symbole durch neue nach dem leicht verständlichen Schema

$$\left.\begin{array}{lllll} u_i^{(1)}(\rho, \varphi, z)\,, & \rho_i\,, & f(\varphi, z)\,, & h_i\,, & k_i' \\ u_{n+1-i}^{(2)}(\rho, \varphi, z)\,, & \rho_{n+2-i}\,, & F(\varphi, z)\,. & -h_{n+2-i}'\,, & -h_{n+2-i} \end{array}\right\} \tag{15}$$

ersetzt.

Dadurch erhält man

$$u_i^{(2)} = \frac{1}{\pi}\sum_{k=0}^{\infty}\int_0^{\infty}\frac{d_{ik}(\beta)}{L_k(\beta)}W_{ik}(\beta\rho)d\beta\int_{-\infty}^{\infty}[F_{k1}(\gamma)\cos k\varphi + F_{k2}(\gamma)\sin k\varphi]\cos\beta(\gamma - z)d\gamma$$

$$(i=1, 2, \cdots, n) \tag{16}$$

wobei die hier vorkommenden Abkürzungen folgende Bedeutung haben:

$$\left.\begin{array}{l} d_{1k}(\beta) = \dfrac{h_2}{h_2'}\cdot\dfrac{I_k'(\beta\rho_2) + r_{2k}K_k'(\beta\rho_2)}{K_k(\beta\rho_1)I_k'(\beta\rho_2) - I_k(\beta\rho_1)K_k'(\beta\rho_2)}d_{2k}(\beta)\,, \\ d_{i+1,k}(\beta) = \dfrac{h_{i+2}h_{i+3}\cdots h_n}{h_{i+2}'h_{i+3}'\cdots h_n'}\displaystyle\prod_{\nu=1}^{n-i-1}\dfrac{I_k'(\beta\rho_{n+1-\nu}) + r_{n+1-\nu,k}K_k'(\beta\rho_{n+1-\nu})}{I_k'(\beta\rho_{n+1-\nu}) + r_{n-\nu,k}K_k'(\beta\rho_{n+1-\nu})} \\ \qquad\qquad (i=1, 2, \cdots, n-2),\ d_{nk}(\beta) = 1;\ (k=0, 1, 2, \cdots) \end{array}\right\} \tag{16.1}$$

$$L_k(\beta) = I_k(\beta\rho_{n+1}) + r_{nk}K_k(\beta\rho_{n+1}) \qquad (k=0, 1, 2, \cdots) \tag{16.2}$$

$$W_{1k}(\beta\rho) = K_k(\beta\rho_i)I_k(\beta\rho) - I_k(\beta\rho_1)K_k(\beta\rho)\,, \qquad W_{ik}(\beta\rho) = I_k(\beta\rho) + r_{ik}K_k(\beta\rho)$$

$$(i=2, 3, \cdots, n;\ k=0, 1, 2, \cdots) \tag{16.3}$$

$$\left.\begin{array}{l} r_{2k} = r_{2k}(\beta) = -\dfrac{1}{\rho_2K_k'(\beta\rho_2)}\left\{\rho_2I_k'(\beta\rho_2) + \dfrac{h_2'}{-h_2'K_k(\beta\rho_2) + K_k'(\beta\rho_2)\left[1 + h_2\dfrac{K_k(\beta\rho_1)I_k(\beta\rho_2) - I_k(\beta\rho_1)K_k(\beta\rho_2)}{K_k(\beta\rho_1)I_k'(\beta\rho_2) - I_k(\beta\rho_1)K_k'(\beta\rho_2)}\right]}\right\}\,, \\ r_{ik} = r_{ik}(\beta) = \dfrac{1}{T_{ik}(\beta)}\left\{U_{ik}(\beta) - \dfrac{h_ih_i'}{\rho_i^2[S_{ik}(\beta) + r_{i-1,k}T_{ik}(\beta)]}\right\}\,. \\ \quad S_{ik}(\beta) = -I_k'(\beta\rho_i)K_k'(\beta\rho_i) - h_iI_k(\beta\rho_i)K_k'(\beta\rho_i) + h_i'I_k'(\beta\rho_i)K_k(\beta\rho_i)\,, \\ \quad T_{ik}(\beta) = -K_k'(\beta\rho_i)[K_k'(\beta\rho_i) + (h_i - h_i')K_k(\beta\rho_i)]\,, \\ \quad U_{ik}(\beta) = \dfrac{h_i'}{\rho_i} + I_k'(\beta\rho_i)[K_k'(\beta\rho_i) + (h_i - -h_i')K_k(\beta\rho_i)] \\ \qquad\qquad (i=3, 4, \cdots, n;\ k=0, 1, 2, \cdots) \end{array}\right\} \tag{16.4}$$

$$F_{01}(\gamma) = \frac{1}{2\pi}\int_0^{2\pi}(F(\alpha, \gamma)d\alpha\,, \qquad \begin{matrix}F_{k1}(\gamma)\\F_{k2}(\gamma)\end{matrix} = \frac{1}{\pi}\int^{2\pi}F(\alpha\gamma)\begin{matrix}\cos k\alpha\\ \sin k\alpha\end{matrix}d\alpha \qquad (k=1, 2, \cdots)\,. \tag{16.5}$$

§ 5. Die Lösung des ursprünglichen Problems (2)–(3.3)

Nach der Vorschrift (4) ergibt sich die gewünschte Lösung durch Summierung der beiden Teillösungen (14) und (16). Der Leser möge sich vom neuen direkt überzeugen, dass die so erhaltenen $u_i(\rho, \varphi, z)$ wirklich unsere ursprüngliche Aufgabe (2)–(3.3) befriedigen.

II. Stetige Aenderung der Temperatur und des Wärmeflusses

Das jetzige Problem unterscheidet sich von dem vorhergehenden nur in den Bedingungen (3.2), die jetzt durch die geläufigen Beziehungen

$$u_i = u_{i+1}\,, \qquad \lambda_i\frac{\partial u_i}{\partial\rho} = \lambda_{i+1}\frac{\partial u_{i+1}}{\partial\rho}(\rho = \rho_{i+1},\ 0 \leq \varphi \leq 2\pi,\ -\infty < z < +\infty;\ i=1, 2, \cdots, n-1) \tag{17}$$

zu ersetzen sind.

Die Lösung ergibt sich augenscheinlich aus dem Ergebnis des ersten Teiles durch den Grenzübergang

$$h_{i+1}\to+\infty\,,\qquad h'_{i+1}\to+\infty\,,\qquad \frac{h'_{i+1}}{h_{i+1}}=\frac{\lambda_i}{\lambda_{i+1}}\qquad (i=1,\,2,\,\cdots,\,n-1)\,,\tag{18}$$

wenn man wie üblich unter λ_i $(i=1,\,2,\,\cdots,\,n)$ die Wärmeleitfähigkeit der i-ten Körperschicht versteht.

Nach einiger Rechenarbeit kommt man so zum Ergebnis

$$\begin{aligned}u_i(\rho,\,\varphi,\,z)=&\frac{1}{\pi}\sum_{k=0}^{\infty}\int_0^\infty\frac{\delta_{ik}(\beta)}{\Lambda_k(\beta)}V_{ik}(\beta\rho)d\beta\int_{-\infty}^{\infty}[f_{k1}(\gamma)\cos k\varphi+f_{k2}(\gamma)\sin k\varphi]\cos\beta(\gamma-z)d\gamma\\&+\frac{1}{\pi}\sum_{k=0}^{\infty}\int_0^\infty\frac{d_{ik}(\beta)}{L_{1k}(\beta)}W_{ik}(\beta\rho)d\beta\int_{-\infty}^{\infty}[F_{k1}(\gamma)\cos k\varphi+F_{k2}(\gamma)\sin k\varphi]\cos\beta(\gamma-z)d\gamma\\&\qquad\qquad(i=1,\,2,,\,\cdots,\,n);\end{aligned}\tag{19}$$

$$\left.\begin{aligned}&\delta_{1k}(\beta)=1\,,\qquad \delta_{i+1,k}(\beta)=\frac{\lambda_1}{\lambda_{i+1}}\prod_{\nu=1}^{i}\frac{I_k'(\beta\rho_{\nu+1})+q_{\nu k}(\beta)K_k'(\beta\rho_{\nu+1})}{I_k'(\beta\rho_{\nu+1})+q_{\nu+1,k}(\beta)K_k'(\beta\rho_{\nu+1})}\\&\qquad\qquad\qquad(i=1,\,2,\,\cdots,\,n-2)\,,\\&\delta_{nk}(\beta)=\kappa_n\frac{I_k'(\beta\rho_n)+q_{n-1,k}(\beta)K_k'(\beta\rho_n)}{K_k(\beta\rho_{n+1})I_k'(\beta\rho_n)-I_k(\beta\rho_{n+1})K_k'(\beta\rho_n)}\delta_{n-1,k}(\beta)\\&\Lambda_k(\beta)=I_k(\beta\rho_1)+q_{1k}(\beta)K_k(\beta\rho_1)\,,\qquad V_{ik}(\beta\rho)=I_k(\beta\rho)+q_{ik}(\beta)K_k(\beta\rho)\\&V_{nk}(\beta\rho)=K_k(\beta\rho_{n+1})I_k(\beta\rho)-I_k(\beta\rho_{n+1})K_k(\beta\rho)\qquad(i=1,\,2,\,\cdots,\,n-1)\\&q_{ik}(\beta)=\frac{1}{N_{i+1,k}(\beta)}\left\{-P_{i+1,k}(\beta)+\frac{\kappa_{i+1}}{\rho_{i+1}^2[M_{i+1,k}(\beta)-q_{i+1,k}(\beta)N_{i+1,k}(\beta)]}\right\}\,,\\&\qquad M_{i+1,k}(\beta)=\kappa_{i+1}I_k(\beta\rho_{i+1})K_k'(\beta\rho_{i+1})-I_k'(\beta\rho_{i+1})K_k(\beta\rho_{i+1})\\&\qquad N_{i+1,k}(\beta)=(1-\kappa_{i+1})K_k(\beta\rho_{i+1})K_k'(\beta\rho_{i+1})\\&\qquad P_{i+1,k}(\beta)=-\frac{1}{\rho_{i+1}}+(1-\kappa_{i+1})I_k'(\beta\rho_{i+1})K_k(\beta\rho_{i+1})\qquad(i=1,\,2,\,\cdots,\,n-2)\,,\\&q_{n-1,k}(\beta)=-\frac{1}{\rho_nK_k'(\beta\rho_n)}\Bigg[\rho_nI_k'(\beta\rho_n)\\&\qquad+\frac{1}{-K_k(\beta\rho_n)+\kappa_nK_k'(\beta\rho_n)\dfrac{K_k(\beta\rho_{n+1})I_k(\beta\rho_n)-I_k(\beta\rho_{n-1})K_k(\beta\rho_n)}{K_k(\beta\rho_{n+1})I_k'(\beta\rho_n)-I_k(\beta\rho_{n+1})K_k'(\beta\rho_n)}}\Bigg]\\&\kappa_{i+1}=\frac{\lambda_i}{\lambda_{i+1}}\qquad(i=1,\,2,\,\cdots,\,n-1)\end{aligned}\right\}\tag{19.1}$$

$$\left.\begin{aligned}&d_{1k}(\beta)=\frac{1}{\kappa_2}\cdot\frac{I_k'(\beta\rho_2)+r_{2k}(\beta)K_k'(\beta\rho_2)}{K_k(\beta\rho_1)I_k'(\beta\rho_2)-I_k(\beta\rho_1)K_k'(\beta\rho_2)}d_{2k}(\beta)\,,\qquad d_{nk}(\beta)=1\,,\\&d_{i+1,k}(\beta)=\frac{\lambda_n}{\lambda_{i+1}}\prod_{\nu=1}^{n-i-1}\frac{I_k'(\beta\rho_{n+1-\nu})+r_{n+1-\nu,k}(\beta)K_k'(\beta\rho_{n+1-\nu})}{I_k'(\beta\rho_{n+1-\nu})+r_{n-\nu,k}(\beta)K_k'(\beta\rho_{n+1-\nu})}\\&\qquad\qquad\qquad(i=1,\,2,\,\cdots,\,n-2)\\&L_k(\beta)=I_k(\beta\rho_{n+1})+r_{nk}(\beta)K_k(\beta\rho_{n+1})\\&W_{1k}(\beta\rho)=K_k(\beta\rho_1)I_k(\beta\rho)-I_k(\beta\rho_1)K_k(\beta\rho)\,,\qquad W_{ik}(\beta\rho)=I_k(\beta\rho)+r_{ik}(\beta)K_k(\beta\rho)\\&\qquad\qquad\qquad(i=2,\,3,\,\cdots,\,n)\end{aligned}\right|$$

$$\left.\begin{aligned}
r_{2k}(\beta) &= -\frac{1}{\rho_2 K_k'(\beta\rho_2)}\Bigg[\rho_2 I_k'(\beta\rho_2) \\
&\quad + \frac{\kappa_2}{-\kappa_2 K_k(\beta\rho_2) + K_k'(\beta\rho_2)\dfrac{K_k(\beta\rho_1)I_k(\beta\rho_2) - I_k(\beta\rho_1)K_k(\beta\rho_2)}{K_k(\beta\rho_1)I_k'(\beta\rho_2) - I_k(\beta\rho_1)K_k'(\beta\rho_2)}}\Bigg], \\
r_{ik}(\beta) &= \frac{1}{T_{ik}(\beta)}\left\{-U_{ik}(\beta) + \frac{\kappa_i}{\rho_i^2[S_{ik}(\beta) - r_{i-1,k}(\beta)T_{ik}(\beta)]}\right\}, \\
S_{ik}(\beta) &= -I_k(\beta\rho_i)K_k'(\beta\rho_i) + \kappa_i I_k'(\beta\rho_i)K_k(\beta\rho_i) \\
T_{ik}(\beta) &= (1-\kappa_i)K_k(\beta\rho_i)K_k'(\beta\rho_i) \\
U_{ik}(\beta) &= \frac{\kappa_i}{\rho_i} + (1-\kappa_i)I_k'(\beta\rho_i)K_k(\beta\rho_i) \qquad (i=3, 4, \cdots n)\,.
\end{aligned}\right\} \quad (19.2)$$

Was endlich die in der Lösung (19) noch vorkommenden Fourierkoeffizienten $f_{k1}(\gamma)$, $f_{k2}(\gamma)$, $F_{k1}(\gamma)$ und $F_{k2}(\gamma)$ betrifft, so behalten diese ihre früheren Werte (12) und (16.5).

Three-Level Maser Detector for Ultramicrowaves

By Koichi SHIMODA

Deparment of Physics, Faculty of Science, University of Tokyo

(Received May 12, 1959)

Conventional electronic detectors such as silicon diodes lose their sensitivity in the millimeter and sub-millimeter ranges. A device which was proposed by the author as a three-level maser detector* is described in this note.

Consider a system of molecules which have energy levels as shown in Fig. 1. Here a transition between levels E_2 and E_3 falls in the conventional microwave range where a good sensitivity is feasible. When the other transition between levels E_1 and either E_2 or E_3 is allowed, the system can be used to detect high frequency waves written as ν_p or ν_p' in Fig. 1.

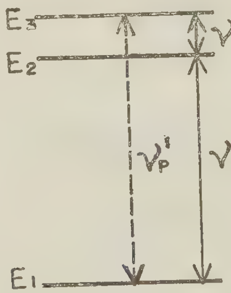

Fig. 1. Three levels.

Absorption of ultra-microwaves at the frequency ν_p or ν_p' changes the population of levels and results in the increase or decrease of microwave absorption at the frequency ν_0. The system is similar to that which has been studied as a three-level maser spectrometer[1] except that all transitions lie in much higher frequencies in this case.

Because the gas absorption coefficient is very large at higher frequencies, the ultra-microwaves at the frequency ν_p will be appreciably absorbed by a small amount of gas. Increase of population of the level E_2 is given by

$$\Delta n_2 = \frac{\tau}{Vh\nu_p}\Delta P\,, \tag{1}$$

where ΔP is the absorbed ultra-microwave power, V the volume of the gas, and $\tau \approx (2\pi\,\Delta\nu_p)^{-1}$ the time of relaxation. The microwave gas absorption coefficient at the frequency ν_0 is given by

$$\alpha_0 = (n_2 - n_3)\frac{8\pi^2\nu_0}{3hc}\frac{|\mu_0|^2}{\Delta\nu_0}\,, \tag{2}$$

where μ_0 is the dipole matrix element, and $\Delta\nu_0$ the half-width of the line. The change of α_0 when the ultra-microwave power is absorbed by ΔP is

$$\Delta\alpha_0 = \Delta n_2\frac{8\pi^2\nu_0}{3hc}\frac{|\mu_0|^2}{\Delta\nu_0} = \frac{\Delta P}{V}\frac{8\pi^2\nu_0\tau}{3h^2c\nu_p}\frac{|\mu_0|^2}{\Delta\nu_0}\,. \tag{3}$$

Then the absorbed ultra-microwave power is expressed as

$$\Delta P = \frac{3h^2c}{4\pi}\frac{\nu_p}{\nu_0}\frac{\Delta\nu_0\Delta\nu_p}{|\mu_0|^2}V\Delta\alpha_0\,. \tag{4}$$

It may be noted that this equation does not include n_2 nor n_3, and hence for the sensitive detection one choose molecules which have large $|\mu_0|$ and considerable absorption coefficient at the frequency ν_p.

Taking values as $\Delta\nu_0 = \Delta\nu_p = 100$ kc/sec, $|\mu_0|^2=$ D^2, Eq. (4) becomes

$$\Delta P = 10^{-4}V\frac{\nu_p}{\nu_0}\Delta\alpha_0 \text{ watts.}$$

A typical microwave spectrometer can observe the change of absorption as small as 10^{-8} cm^{-1}. Thus the minimum detectable power at $\lambda_p = \frac{c}{\nu_p} = 0.4$ mm is

$$\frac{\Delta P}{V} = 3 \times 10^{-11} \text{ W/cm}^3\,.$$

A long waveguide cell should not be used, since the ultra-microwave is absorbed in a short length of the path. A compromise is the use of a cavity cell tuned to the frequency ν_0, in which the ultra-microwave is radiated. With the cell volume of 10 cm^3 the ultra-microwave power of 3×10^{-10} watts might be detected.

It may be impossible to reduce the line-width of the ultra-microwave line to 100 kc/sec and may perhaps be some ten times larger. Nevertheless the three level maser detector is expected to be more sensitive than crystal detectors, minimum detectable power of which is estimated as 10^{-6} watt at the wavelength of 0.4 mm.

---

Polaron Mobility in Potassium Bromide

By Masami Onuki and Hajimu Kawamura

Department of Applied Physics, Osaka City University, Osaka

(Received May 19, 1959)

The reliable value of electron mobility in alkali halide crystal have been desired in connection with the polaron problem.[1][2] We made experiment on the KBr crystal of high purity obtained by the recrystalization technique. The conductivity was afforded by illuminating the additive coloured crystal with 500 watts tungsten lamp through water filter. For the measurment we adopted the ac method after Macdonald,[3] in order to avoid the space charge effect, the frequency being 330 cycles/sec. The detecting device is composed of pre-amplifier, difference amplifier, main band pass amplifier, dc detector and cathode ray oscilloscope. The input impedance of the pre-amplifier was about 80 $M\Omega$ for 330 cycles/sec, the input capacitance being eliminated by feed back system. The push-pull output of about 100 volts from an oscillator is supplied to each current electrode. The relative amplitude and phase are adjusted so that the voltage at two Hall electrodes are just balanced when the magnetic field is absent. The temperature range was from 85°K to room temperature. The maximum intensity of the magnetic field was 4500 oersted.

Since the impedance between Hall electrodes which is about $1\sim3\times10^9\Omega$ under illumination at room temperature is much higher than the input impedance, the detected Hall voltage is reduced by the factor Z_{cry}/Z_{in}, where Z_{in} and Z_{cry} are the input and crystal impedance respectively. Hence it is necessary to measure Z_{cry} as well as appearent Hall voltage V'_H in order to get the true Hall voltage V_H. Fig. 1 shows the photoconductivity σ which is the reciprocal of Z_{cry}, V'_H and V_H in arbitrary scale as the function of temperature. The mobility μ is given by $(V_H/t)/(KV_l/l)=\mu H\cdot10^{-8}$, where l is the length of the specimen, t the width, V_l its applied voltge and K the numerical factor due to the non-uniformity of electric field near the Hall electrode. We determined this value to be 0.83 by mapping the pattern of the electric field by making use of conducting sheet.

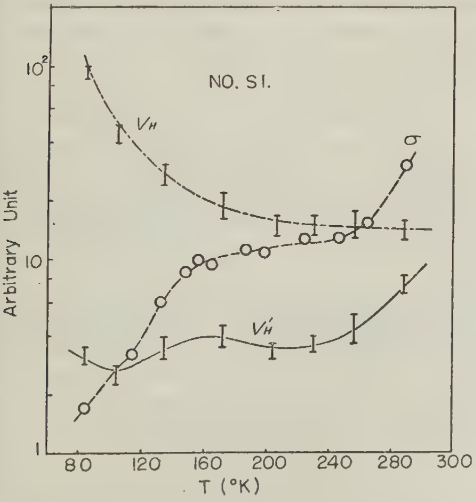

Fig. 1. V'_H, σ and V_H *vs* temperature, the ordinate being arbitrary scale.

The average values of μ for about ten specimens are plotted as the function of temperature in Fig. 2.

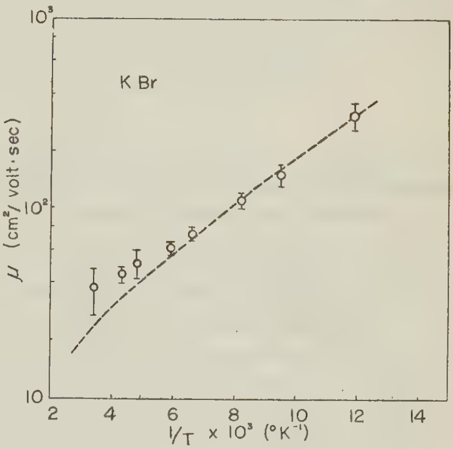

Fig. 2. Mobility in KBr as a function of temperature. The dotted line shows the theoretical curve $\mu=A$ $(\exp\Theta/T-1)$, with $A=16.4$ cm²/volt sec and $\Theta=255$°K.

These points better fit to $\mu=A$ $(\exp\Theta/T-1)$ rather than $\mu=BT^{-n}$. The best fit was obtained for $A=16.4$ cm²/volt sec and $\Theta=255$°K. According to Low and Pines,[1] μ is given by

$$\mu=\frac{1}{2\alpha\omega}\,\frac{e}{m^*}\left(\frac{m^*}{m_p}\right)^3 f(\alpha)\cdot(\exp\Theta/T-1),\ \Theta>T,$$

$$m_p=m^*\left(1+\frac{\alpha}{6}\right),\ \alpha=\frac{e^2}{\hbar}\left(\frac{m}{2\hbar\,\omega}\right)^{\frac{1}{2}}\frac{\varepsilon_s-\varepsilon_0}{\varepsilon_s\varepsilon_0}\left(\frac{m^*}{m}\right)^{\frac{1}{2}},$$

where m^* and m_p are the effective masses of conduction electron and polaron respectively. From the measured value of A we have $m_p=0.33m$, $m^*=0.23m$ and $\alpha=2.65$, where m is the free electron mass. The Debye temperature associated with the longitudinal optical vibration Θ is calculated from Reststrahl frequency ω_t by making use of the relation $k\Theta=\sqrt{\varepsilon_s/\varepsilon_0}\ \hbar\omega_t$ where ε_s and ε_0 are the static and optical dielectric constant respectively. We get $\Theta=246$°K for KBr, which is to be compared with the experimental value of 255°K. From this work we can conclude that the interaction of electron with the optical phonon is more dominant than with the acoustical phonon as well as with the impurity centers above 80°K. The acoustical mode may become effective below 50°K, if the deformation potential of KBr is the same order with that of KCl which was calculated by one of us.[4)]

It is our pleasure to thank Mr. H. Okura who furnished specimens and gave many valuable discussions.

Connection Formulas for WKB Solutions with Two Turning Points

By Haruo MORIGUCHI

Department of Physics, Faculty of Liberal Arts, Shizuoka University, Shizuoka

(Received April 27, 1959)

In this note we shall give the connection formulas for the WKB solutions of a differential eqation

$$\frac{d^2y}{dx^2}+f(x)y=0\,, \tag{1}$$

where $f(x)$ is a smooth function of x which satisfies the following conditions:

$$f(a)=f(-a)=0\,, \tag{2}$$

$$f(x)<0 \qquad \text{for } x<-a \text{ and } x>a\,, \tag{3}$$

and for $b<x<c$, $f(x)$ can be approximated as

$$f(x)\sim\nu+\frac{1}{2}-\frac{x^2}{4}\,, \tag{4}$$

where

$$a=2(\nu+\tfrac{1}{2})^{1/2}\,, \qquad \nu\geqq-\tfrac{1}{2}\,,$$

and

$$b\ll-a\,, \qquad c\gg a\,.$$

Under these conditions, let us write the WKB approximate solutions for $|x|\gg a$ as

$$y\sim y_{\substack{1\\2}}=|f(x)|^{-1/4}\exp\left(\pm\int_x^{-a}\sqrt{|f(x)|}dx\right) \quad (x\ll-a)\,, \tag{5}$$

and

$$y\sim y_{\substack{3\\4}}=|f(x)|^{-1/4}\exp\left(\pm\int_a^{x}\sqrt{|f(x)|}dx\right) \quad (x\gg a) \tag{6}$$

Then we have the connection formulas

$$y_1\leftrightarrow-\cos\nu\pi\, y_3-\sqrt{\frac{\pi}{2}}\frac{\sin\nu\pi}{\Gamma(\nu+1)}(\nu+\tfrac{1}{2})^{\nu+1/2}e^{-\nu-1/2}y_4\,, \tag{7}$$

$$y_2\leftrightarrow\cos\nu\pi\, y_4-\sqrt{\frac{2}{\pi}}\sin\nu\pi\,\Gamma(\nu+1)(\nu+\tfrac{1}{2})^{-\nu-1/2}e^{\nu+1/2}y_3, \tag{8}$$

$$y_3\leftrightarrow-\cos\nu\pi\, y_1-\sqrt{\frac{2}{\pi}}\frac{\sin\nu\pi}{\Gamma(\nu+1)}(\nu+\tfrac{1}{2})^{\nu+1/2}e^{-\nu-1/2}y_2\,, \tag{9}$$

and

$$y_4\leftrightarrow\cos\nu\pi\, y_2-\sqrt{\frac{2}{\pi}}\sin\nu\pi\,\Gamma(\nu+1)(\nu+\tfrac{1}{2})^{-\nu-1/2}e^{\nu+1/2}y_1 \tag{10}$$

For the deduction of these formulas, let us consider an approximate solution

$$y\sim y_0=D_\nu(x) \tag{11}$$

in the region $b<x<c$. Here $D_\nu(x)$ is the parabolic cylinder function, for which we have the asymptotic expression

$$D_\nu(x)\sim\begin{cases} x^\nu\exp(-x^2/4) & (x\gg a)\\ \cos\nu\pi\,|x|^\nu\exp(-x^2/4) & \\ \quad -\sqrt{2/\pi}\,\Gamma(\nu+1)\sin\nu\pi\,|x|^{-\nu-1}\exp(x^2/4)\,. & (x\ll-a)\end{cases} \tag{12}$$

On the other hand, substituting (4) into (5) and (6) and expanding them, we have, for large values of $|x|$,

$$\begin{cases} y_1\sim\sqrt{2}(\nu+\tfrac{1}{2})^{\nu/2+1/4}e^{-\nu/2-1/4}|x|^{-\nu-1}\exp(x^2/4) \\ \hfill (x\ll-a) \\ y_2\sim\sqrt{2}(\nu+\tfrac{1}{2})^{-\nu/2-1/4}e^{\nu/2+1/4}|x|^{\nu}\exp(-x^2/4)\,, \end{cases}$$

and (13)

$$\begin{cases} y_3\sim\sqrt{2}(\nu+\tfrac{1}{2})^{\nu/2+1/4}e^{-\nu/2-1/4}x^{-\nu-1}\exp(x^2/4) \\ \hfill (x\gg a) \\ y_4\sim\sqrt{2}(\nu+\tfrac{1}{2})^{-\nu/2-1/4}e^{\nu/2+1/4}x^{\nu}\exp(-x^2/4)\,. \end{cases}$$

Now (12) and (13) should be the approximate solutions of the same order of accuracy for $b<x\ll-a$ or $a\ll x<c$. Hence, comparing them with each other we have the connection formula (10), and inverting the role of the sign of x we have (8). Other formulas (7) and (9) can be derived from (8) and (10). When ν is large, we have, for the coefficients in the expressions (7)—(10),

$$\sqrt{\frac{2}{\pi}}\Gamma(\nu+1)\sin\nu\pi(\nu+\tfrac{1}{2})^{-\nu-1/2}e^{\nu+1/2}\sim2\sin\nu\pi\,. \tag{14}$$

The corresponding formulas, in which the coefficients have such a simple asymptotic form can also be obtained by repeated use of the usual connection formula at the linear turning points a and $-a$.

More rigorous and extended discussions on the asymptotic solutions about turning points will be shortly published.

F-centers in LiCl Crystals

By Kuniya FUKUDA, Hiroaki MATSUMOTO
and Akizo OKUDA*

*Department of Physics, Faculty of Science,
Kyoto University*

(Received May 23, 1959)

Optical and spin resonance absorptions were measured on the LiCl crystals irradiated by X- or γ-ray at room temperature.

In Fig. 1 are shown the optical absorption curves of the colored crystals; curve I shows the absorption of the crystal irradiated by X-ray at room temperature and curve II that obtained after the colored crystal showing curve I was bleached by F-light. LiCl crystals are so much hygroscopic that the optical measurements are very difficult. In our experiments the crystal could be kept transparent throughout the period of X-ray irradiation and optical measurements by holding it in a vacuum vessel, which has two quartz windows for optical measurements and one Al-foil window for X-ray irradiation; the cloudiness on the crystal surface caused by moisture could be removed by heating slowly the crystal during evacuation of the vessel. In curve I there exists no appreciable absorption except the absorption of F-center at 395 mμ, which has the half-width of about 0.65 eV. On the other hand, Ottmer1) measured the optical absorption of the X-ray irradiated crystal by immersing it into the saturated solution of LiCl and found out two small humps on the long wavelength side of F-absorption. These very small absorption bands at 580 and 650 mμ are tentatively assigned to R_2 and M centers respectively, but further investigations are necessary for conclusive assignments.

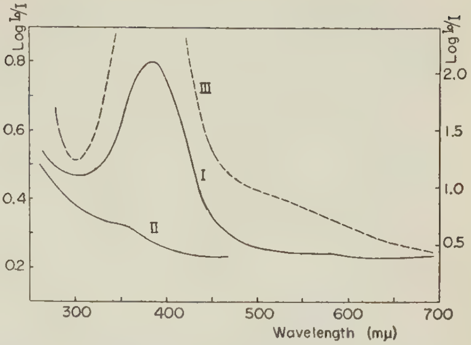

Fig. 1. The optical absorption curves of colored LiCl crystals. Curve I: after 5 hrs irradiation of X-ray (30 kV, 20 mA), curve-II: after F-light bleaching of the sample showing curve-I, curve-III: after 100 hrs irradiation of γ-ray (dosage: 2×10^5 r/hr).

Electron spin resonance measurements were carried out on the crystal irradiated by Co^{60} γ-ray at room temperature, the optical absorption of which is shown as curve III in Fig. 1. In this case the crystal shows also only F-absorption; and the absorption below 300 mμ results from the polyvinyl coating film, which protects the crystal from moisture for optical measurements. The density of F-centers is estimated as $10^{18}\mathrm{cm}^{-3}$ in the order of magnitude from Smakula's formula, provided that for LiCl the refractive index and the oscillator strength of F-center are approximated as 1.5 and unity respectively. The derivative curve of the spin resonance absorption was recorded, which centered at the external magnetic field $H=8{,}515\pm5$ gauss for the microwave frequency of 23,804 MCPS and had the peak to peak width of 50 gauss. Thus, for F-center of LiCl the g-value is 1.997 ± 0.002 and the half-width 60 gauss because of the Gaussian shape of absorption. This value of g is about the same as that of F-center in KCl2) and the half-width of 60 gauss considerably smaller than that of 90 gauss predicted by Kittel3). He calculated the widths of F-center resonance for various alkali-halides by making appropriate extrapolations from the results of KCl F-center, but it is likely that the discrepancy in the above extent, though it is smaller for LiF F-center3),4), occurs between the observed and the predicted width by his method based on the L.C.A.O. model of F-center wave function*. The half-width value of 60 gauss leads to the density of F-center electron $|\psi(\mathrm{Li})|^2=0.95\times10^{23}\mathrm{cm}^{-3}$ at the nucleus of a nearest neighbour Li ion, because the contributions from the nuclei of the next nearest neighbour Cl ions to the width may be neglected.

If the L.C.A.O. type wave function is assumed for LiCl F-center, the above value of F-electron density gives $\xi=0.36$ in $|\psi(\mathrm{Li})|^2=\frac{1}{6}\xi|\psi_{\mathrm{Li}}(0)|^2$ for LiCl in contrast to $\xi=0.6$ for KCl2), where $|\psi_{\mathrm{Li}}(0)|^2$ is the density of 2s electron at the nucleus for free atom.

Observation of a Peculiar Type of Domain Structure of Triclinic Tungsten Trioxide

By Sigetosi TANISAKI

Faculty of Literature and Science, Yamaguchi University

(Received March 23, 1959)

Triclinic tungsten trioxide has usually the domain structure whose walls are (010) twin planes as shown in the previous note[1]. In the monoclinic-triclinic phase transition, (110) domain walls observed in the monoclinic phase change itself into the irregular boundaries rather than the domain walls in the triclinic phase, and each part of the crystal divided by the boundaries has a regular (010) domain structure which is sensitive to the external stress as well as in the monoclinic phase[2].

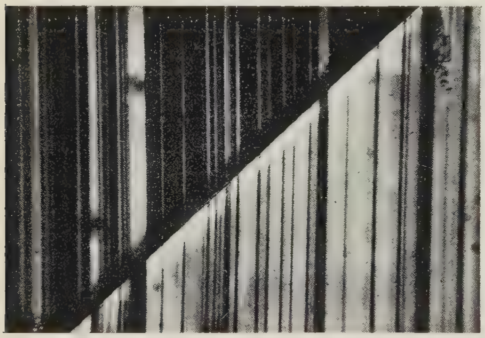

Fig. 1. Domain structure obtained by the pressure along *b*-axis.

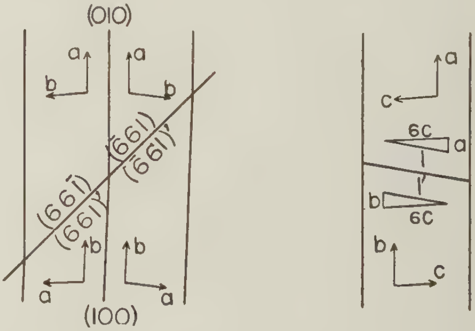
The appearance of a peculiar type of domain structure under the pressure along *b*-axis is observed between crossed nicols (Fig. 1). In Fig. 1 the left upper part is the original (010) domains and the right lower part is the new domains induced by the stress, and the angle between a domain wall of the upper part and that of the lower part is about 178°. The boundary between upper and lower parts is not vertical to *c* surface of the crystal but inclined to it. Apparently the domain structure of this type is very similar to that obtained by the pressure along *c* axis in the monoclinic phase (Photo. 4 in the previous paper[2]) except the inclination of the boundary to the crystal surface, and similarly as in the previous paper it can be explained by taking into consideration the reversal of *a* and *b* axes by the pressure on either side of the boundary and the condition of continuity that the crystal must have the least strain at the boundary. It is supposed that the orientation of the crystallographic axes of each domain is as shown in Fig. 2 and the boundary plane is very close to $(\bar{6}61)$ and $(66\bar{1})$, or $(\bar{6}61)'$ and $(661)'$ for either side, where indices with a prime are used for the planes of lower part. Then the peculiar domain pattern observed between crossed nicols which is caused by the difference of the extinction position of each domain can be easily understood from this orientation of the crystallographic axes. The angles between (010) walls of the upper domains and (100) walls of the lower domains are calculated to be 178°16′ for the boundary of $(\bar{6}61)$ and $(\bar{6}61)'$ and 178°20′ for $(66\bar{1})$ and $(661)'$ from the lattice constants of the triclinic phase ($a=7.30$Å, $b=7.52$Å, $c=7.69$Å, $\alpha=88°50'$, $\beta=90°55'$, $\gamma=90°56'$)[1]. Though there is a difference of angle 5′ between them, the coincidence of these values with the measured one is satisfactory. In the side view of the crystal, if the boundary plane is assumed to be $(\bar{6}61)$ etc. themselves, l and l' in Fig. 2 (b) are corresponding lengths at the boundary on either side of it, whose values are calculated to be 46.59_9Å and 46.59_8Å respectively, and the calculated value of the angle between *a* axis and the direction of l is 81°54′ whose measured value is about 81°. The small difference between these values shows that the boundary is not $(\bar{6}61)$ etc. themselves but very close to them. Of course the fitness at the boundary is not perfect and there must be a strain in the crystal. The supposition for the orientation of the crystallographic axes of each domain is ascertained by taking X-ray rotational photographs of either side of the boundary.



(a) (b)

Fig. 2. (a) top and (b) side views of supposed domain structure.

The (100) domain structure induced by the stress does not seem to be stable in the triclinic phase and the change to the (010) domain structure followed by a gradual displacement of the boundary takes place below the transition temperature to the monoclinic phase when heating up the crystal. In other words the orientation of the crystal axes reversed by the stress is not maintained in transforming from the triclinic phase to the monoclinic phase, but recovers the original orientation before the phase transition takes place.

The author wishes to thank Prof. K. Tanaka for his continual encouragement. This work was supported in part by the Grant in Aid for the Fundamental Scientific Research from the Ministry of Education.

Dielectric Property of Triglycine Sulfate Single Crystal at 9000 Mc/s Region

By Atsuo NISHIOKA
Electrical Communication Laboratoyy, Musashino, Tokyo,
and Minoru TAKEUCHI
Fuji Electric Machine Manufacturing Company, Ltd., Tokyo

(Received May 28, 1959)

Ferroelectricity of triglycine sulfate was found by Matthias et al,[1] and studied in detail by Hoshino,[2] Kiyasu,[3] and Toyota,[4] but its dielectric property in the microwave region is not yet reported. Since it has been suggested that the ferroelectricity of this crystal may be contributed from the hydrogen bond, it is interesting to study how the hydorogen bond affect the dielectric property of this crystal at the microwave frequencies, and to compare with that of some other hydrogen-bonded crystals like rochelle salt, which had been studied in the microwave region by Akao et al.[5]

Firsty the dielectric constant, ε, and loss tangent, tan δ, were measured at room temperature in the ferroelectric b-axis by the standing wave method at 9600 Mc/s; $\varepsilon_b=19.7\pm0.2$ and tan $\delta=0.043\pm0.002$. This value of dielectric constant seems to be relatively high, compared with that of low frequency value, e.g., $\varepsilon_b=35$ at 10 kc/s measured by Hoshino et al,[2] and the medium value of tan δ suggest that the dielectric relaxation process is effective in the microwave region.

Then, we have measured the temperature dependence of the dielectric property of thin plate crystals by the cavity perturbation method, using H_{111} mode. A circular disk of 2.8 mm in diameter and 0.18 mm in thickns was suspended by a small Teflon rod at the center of H_{111} cavity with its ab-plane parallel to the high frequency electric field. Because the value of above quoted dielectric constant and the dimensions of the specimen were near the limit of the approximation of the cavity perturbation method, it was difficult to estimate the accurate value of the dielectric constant, and thus we show the temperature dependence of the observed frequency shift due to the insertion of crystal into the cavity above and below the Curie point, in place of the dielectric constant, in Fig. 1. The reduced frequency shift refered to 21°C which is purely contributed from the crystal, show the marked anomaly in the b-axis at 47°C, the Curie point, but no anomaly in the a-axis. These tendency is parallel to that observed at low frequency by Hoshino,[2] and therefore, we may suppose that the dielectric anomaly of triglycine sulfate crystal does not disappear in the microwave frequency, and is more sharp than that of rochelle salt at 10,000 Mc/s,[5] and so it would be necessary to cover wide frequency range extending to the shorter wave length, to clarify the mechanism of the dielectric relaxation of this crystal.

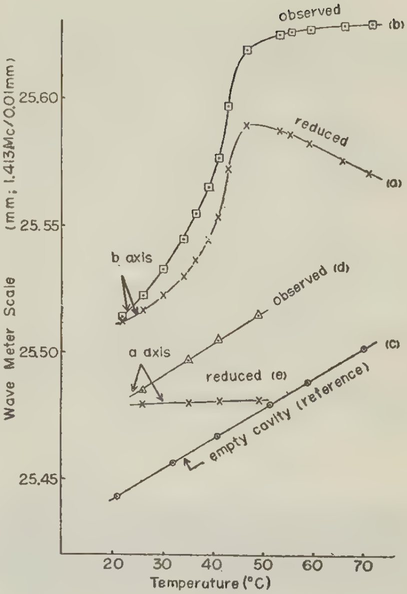

Fig. 1. Obserued frequency change of H_{111} cavity with temperature Curves (*a*) and (*e*) show values corrected for thermal expamsion of the cavity.

NMR Second Moment of a Radical under the Restricted Rotation

By Akira Miyake, Riichirô Chûjô
Faculty of Liberal Arts and Science, Shizuoka University, Shizuoka
and Hatsuko Adachi
Fujieda-Nishi High School, Shizuoka Prefecture

(Received May 25, 1959)

As we can assume the rotation of the side chain group, *e.g.* CH_3 radical, in the polymer is caused rapidly at higher temperatures under the restricting potential

$$V(\varphi)=\frac{u}{2}(1-\cos\varphi)+\frac{v}{2}(1-\cos 3\varphi)\ , \tag{1}$$

so we may have the second moment of NMR due to the group, according to Gutowsky *et al.*,1)

$$\varDelta H_2{}^2=3\hbar^2\gamma^2 I(I+1)\frac{1}{N}\sum_j\sum_k r_{jk}{}^{-6}\langle P_2(\cos\theta_{jk})^2\rangle \tag{2}$$

$$\langle P_2(\cos\theta_{jk})^2\rangle=\left\langle\left[\int_{-\pi}^{\pi}P_2(\cos\theta_{jk})\exp\{-V(\varphi)/kT\}d\varphi\Big/\int_{-\pi}^{\pi}\exp\{-V(\varphi)/kT\}d\varphi\right]^2\right\rangle_{\text{isotropic mean}}, \tag{3}$$

where

$$\begin{aligned}P_2(\cos\theta_{jk})=&P_2(\cos\theta')P_2(\cos\gamma_{jk})\\&-\frac{1}{3}P_2{}^1(\cos\theta')P_2{}^1(\cos\gamma_{jk})\cos(\varphi-\varphi_{jk}')\\&+\frac{1}{12}P_2{}^2(\cos\theta')P_2{}^2(\cos\gamma_{jk})\cos 2(\varphi-\varphi_{jk}')\ ,\end{aligned} \tag{4}$$

$P_2(z)$ and $P_2{}^m(z)$ $(m=1,\ 2)$ denote Legendre and associated Legendre polynomials of the second order respectively, γ_{jk} is the angle between the rotational axis and the internuclear vector connecting the jth nucleus with the kth, other notation is similar to that used in the previous article.2)

Eq. (3) results in3)

$$\begin{aligned}\langle P_2(\cos\theta_{jk})^2\rangle=&\frac{1}{5}\left\{P_2(\cos\gamma_{jk})\right\}^2\\&+\left\{I_0(u/2kT)I_0(v/2kT)+2\sum_{m=1}^{\infty}I_{3m}(u/2kT)I_m(v/2kT)\right\}^{-2}\\&\times\left[\frac{1}{15}\left\{P_2{}^1(\cos\gamma_{jk})\right\}^2\left\{I_1(u/2kT)I_0(v/2kT)\right.\right.\\&\left.+\sum_{m=1}^{\infty}(I_{3m-1}(u/2kT)+I_{3m+1}(u/2kT))I_m(v/2kT)\right\}^2\\&+\frac{1}{60}\left\{P_2{}^2(\cos\gamma_{jk})\right\}^2\left\{I_2(u/2kT)I_0(v/2kT)\right.\\&\left.\left.+\sum_{m=1}^{\infty}(I_{3m-2}(u/2kT)+I_{3m+2}(u/2kT))I_m(v/2kT)\right\}^2\right]\ ,\end{aligned} \tag{5}$$

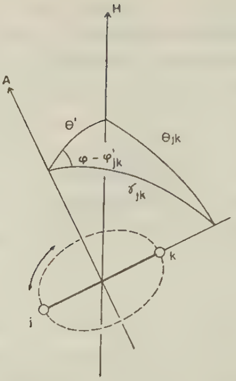

Fig. 1. Explanatory figure for angles θ_{jk}, θ', γ_{jk}, and $\varphi-\varphi_{jk}'$. H and A denote the static field and the rotational axis directions respectively.

which is reduced to

$$\frac{1}{4}f_1(T)=\frac{1}{20}+\frac{3}{20}\left\{\frac{I_2(u/2kT)}{I_0(u/2kT)}\right\}^2 \tag{6}$$

if $v=0$, and to

$$\frac{1}{4}f_3(T)=\frac{1}{20} \tag{6'}$$

if $u=0$, as shown in the previous article.2)

On the contrary, the theoretical second moment is given by Eq. (2) where in place of Eq. (3)

$$\langle P_2(\cos\theta_{jk})^2\rangle=\left\langle\int_{-\pi}^{\pi}\{P_2(\cos\theta_{jk})\}^2\exp\{-V(\varphi)/kT\}d\varphi\Big/\int_{-\pi}^{\pi}\exp\{-V(\varphi)/kT\}d\varphi\right\rangle_{\text{isotropic mean}}=\frac{1}{5} \tag{3'}$$

must be substituted. The theoretical one is constant, as already indicated.4) The case in which azimuths of one- and three-fold potential minima in Eq. (1) are distributed independently of each other is discussed by Odajima.5)

Ferroelectricity in Potassium Ferrocyanide Trihydrate

By Shigeru WAKU, Hisao HIRABAYASHI,
Hiroo TOYODA and Hiroshi IWASAKI
Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation,
and Ryoichi KIRIYAMA
Department of Chemistry, Osaka University, Osaka

(Received June 8, 1959)

One of the authors has reported a study on the dielectric anomaly in [101] and [10$\bar{1}$] directions of potassium ferrocyanide trihydrate crystals. In investigating dielectric and hysteresis properties of this substance, we have discovered ferroelectric behavior below −22°C. Potassium ferro cyanide trihydrate, K_4 [Fe (CN)$_6$]. $3H_2O$, cristallizes with monoclinic symmetry and space group C 2/c, having cell constants $a=9.32A$, $b=16.84A$, $c=9.32A$ and $\beta=90°\pm5'$ at room temperature.[2] Due to its pseudotetragonal lattice structure, large crystals show usually lamellar twinning with twin axis along with twin axis along [010]. Cleavage is perfect perpendicular to b axis.

Dielectric measurements were made on plates cut perpendicular to [010], [101] and [10$\bar{1}$] directions. Fig. 1 shows the curves of the small signal dielectric constant of these plates. In [010] direction, there is no dielectric anomaly except a small peak at −22°C. In [101] and [10$\bar{1}$] directions, five peaks are seen at about −22, −26, −33, −43 and −80°C respectively. Height of the peaks along one of these two directions is far larger than the other. Ferroelectric hysteresis loop appears in [101] and [10$\bar{1}$] directions below −22°C down to −140°C, the lowest temperature of measurement. As the coercive field increases rapidly with decreasing temperature, saturated figures of ferroelectric hysteresis loop can be observed only in a narrow temperature range. In [010] direction, ferroelectric hysteresis does not appear over a whole range of measuring temperature. Feature of the spontaneous polarization at the ferroelectric transition, corresponding to the first dielectric peak at about −22°C, suggests that this transition is of a second order. Abrupt increase of spontaneous polarization at about −33°C corresponds to the third dielectric peak seen in Fig. 1. There are no distinguished differences in hysteresis characteristics between [101] and [10$\bar{1}$] directions, in contradiction to the dielectric anisotropy. This discrepancy may be partly due to the probable change of polarization direction caused by the high electric field in hysteresis measurement. The fact that the lower curve in Fig. 1 shifted to the higher one under the application of high field, seems to support this assumption. As it is certain that the ferroelectric axis lies in the cleavage (010) plane, the space group just below the Curie point may be Cc. Therefore, two independent directions of polarization may be possible. This possibility, together with the existence of lamellar twin, makes the determination of polarization axis quite difficult.

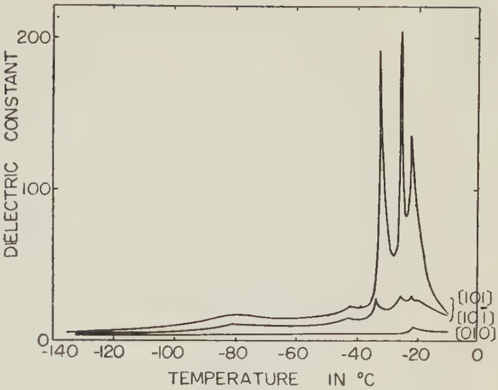

Fig. 1. Dielectric constant, measured along [010], [101] and [10$\bar{1}$] directions, as a function of temperature.

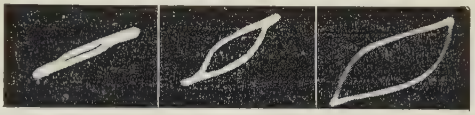

−25.0°C −31.4°C −55.6°C

Fig. 2. Hysteresis loops at three different temperetures.

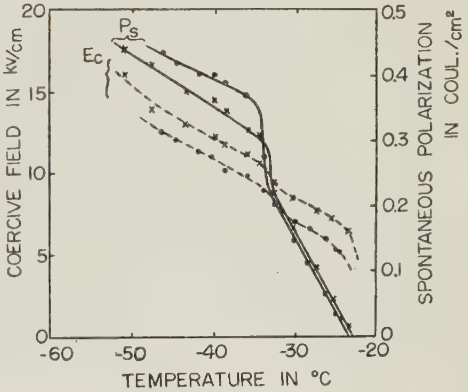

Fig. 3. Spontaneous polarization and coercive field along [101], [10$\bar{1}$] direction as a function of temperature.

We have also examined several isomorphous compounds, most of which show some anomalies above liquid nitrogen temperature. Detailed studies of these materials will be reported subsequently.

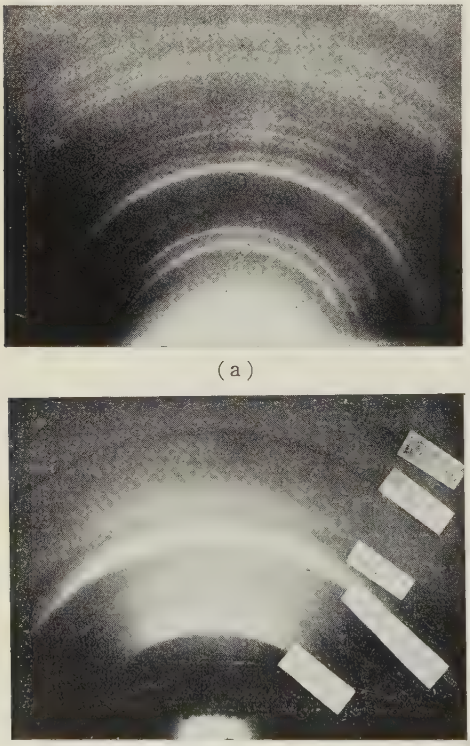
On the Structure of Green Rust of Iron

By Hide YOSHIOKA
Physical Institute, Nagoya University, Nagoya

(Received June 3, 1959)

Dasgupta and Mackay[1] proposed a structure of green rust which we previously studied by means of electron diffraction[2]. However, their analysis of our data on a rhombohedral cell seems to be unable to explain our observation that the rust sometimes produces a diffraction pattern as we denoted by S.R.S. (II) in our paper. The intensity of rings of the pattern is asymmetrically distributed as shown in Figs. 1 and 2. This fact indicates that the Intenzitätbereich in the reciprocal lattice is much elongated in one direction, namely, the crystal is nearly two-dimensional. Accordingly, we indexed rings which appear in the pattern S.R.S. (II) by ($hk0$). The hexagonal indices given by Mackay for our ($hk0$) rings do not belong to the same zone axis and conflict with the above fact.



(a)
(b)

Fig. 1. Electron diffraction pattern of green rust.
(a) normal pattern (S.R.S. (I)).
(b) S.R.S. (II).

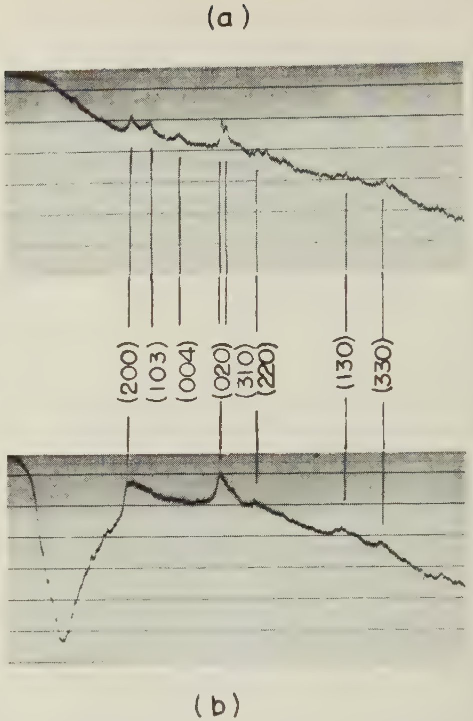


Fig. 2. Microphotometric trace of diffraction rings.
(a) normal pattern (S.R.S. (I)).
(b) S.R.S. (II).

We determined c-axis so as to index the other rings in green rust pattern as (hkl) with $l \neq 0$ on orthorhombic system. Therefore, it is not conclusive that c-axis is perpendicular to ab-plane. Thus, the monoclinic structure suggested by Dasgupta and Mackay may be possible. Their monoclinic cell gives the same index as ours when $l=0$.

Finally, it is worthwhile to note that the inner two rings which exist in X-ray data of Feitknecht and Keller[3] and are missing in our electron diffraction data can be indexed as (001) and (002) using our cell vectors. The fact that they are missing in our photograph seems to indicate that our crystals are very thin plates parallel to ab-plane. The small glancing angles to ab-plane make the reflexions (001) and (002) unfavorable in electron diffraction, as in the case of graphite where (002) ring is usually weak in electron diffraction[4].

The author wishes to express his thanks to Mr. H. Morimoto for the microphotometry of the diffraction rings.

Extraordinary Hall Effect in Silicon-Iron Single Crystals

By Eiji TATSUMOTO and Tetsuhiko OKAMOTO

Department of Physics, Faculty of Science, Hiroshima University

(Received April 27, 1959)

The extraordinary Hall effect in ferromagnetic metals is observed in company with the ordinary Hall effect until the magnetization saturates, as is suggested by the empirical formula, $e_h = R_1 M + R_0 H_{eff}$.[1]. Here, e_h is the Hall resistivity or the Hall voltage per unit current density, $R_1 M$ the extraordinary Hall resistivity, R_1 the extraordinary Hall coefficient, M, the magnetization in the direction of the applied field, $R_0 H_{eff}$. the ordinary Hall resistivity, R_0, the ordinary Hall coefficient and H_{eff}. the effective field in the ordinary effect.

Usually, the extraordinary resistivity, $R_1 M$, is much larger than the ordinary resistivity, $R_0 H_{eff}$., except in extremely low temperatures. Even in such a case, in order to obtain the extraordinary Hall coefficient, R_1, we must take into consideration the size effect of the specimens, because the definite width and thickness of the specimens result in the difference between the magnetizations near the edge and in the central part of the specimens at a given applied field, until the magnetization saturates. The magnetization in the direction of the applied field is larger near the edge than in the central part in low applied fields because magnetic poles appear at the edge, so that the demagnetizing field in the direction of the applied field becomes smaller near the edge than in the central part.

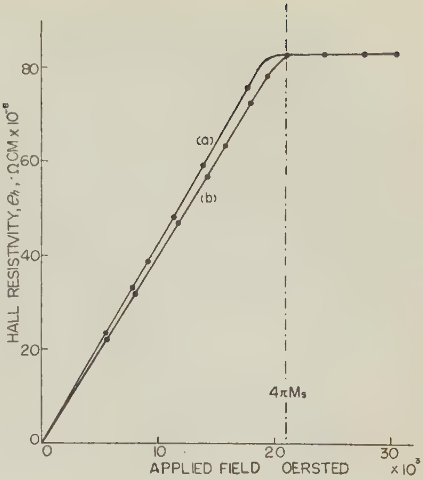

Fig. 1. Hall resistivities measured by contacting the probes, respectively, at the edges (a), and about 1.5 mm inside from the edges (b), of a 1.23% silicon-iron single crystal strip, 0.5 mm × 9 mm × 35 mm, with the (001)-[100] crystal orientation.

In Fig. 1, the two seemingly different Hall resistivities are given as an example. These are measured on the 1.23% silicon-iron single crystal strip,[2] 0.5 mm × 9 mm × 35 mm, with the (001)−[100] crystal orientation by contacting the probes, respectively, at the edges (a-curve) and about 1.5 mm inside from the edges at room temperature. This difference evidently results from the difference between the magnetizations near the edge and in the central part of the specimen, as is described above. Near the edge, magnetizing becomes suddenly hard as the magnetization reaches the saturation value as is inferred from a-curve. In a-curve, about 26,000 oersted in applied field is necessary to saturate the magnetization completely, while in b-curve it is about 23,000 oersted. The difference in amount of the field is mainly attributable to the difference in the magnetizing field that is normal to the specimen near the contacting probes, being caused by the appearance of magnetic poles at the edge. In b-curve, the applied field, H_0, is nearly proportional to the magnetization ($H_0 \simeq 4\pi M$), because the demagnetizing factor is nearly 4π in the whole magnetizing process ($H_0 \simeq B$) and the magnetizing field, H, is much smaller than $4\pi M$ ($B \simeq 4\pi M$). Here B is the magnetic induction of the specimen. Referring to the linearity of b-curve until the magnetization nearly saturates, the extraordinary Hall resistivity is regarded as proportional to the magnetization as is given by $R_1 M$ in Fig. 1. Thus we can obtain the extraordinary Hall coefficient, R_1, approximately from b-curve, not from a-curve. However, we can obtain R_1 more accurately even in the measurement in a-curve, by adopting the value at the intersection between the axis of $4\pi M_s$, 21,000 oersted, in the applied field and the backward extrapolation of the straight line in the ordinary effect in the applied fields larger than $4\pi M_s$, in Fig. 1. This is because the ordinary Hall effect is the same in a- and b-curves after the complete saturation magnetization. With this procedure, the ordinary Hall resistivity, $R_0 H_{eff}$., is eliminated, since experimentally the effective field in the ordinary effect is regarded as the magnetizing field, H. As for the effective field, it is to be published by the same authors simultaneously under the title, "Effective Field in the Ordinary Hall Effect in Ferromagnetics".

By adopting this procedure in the masurements on the $(001)-[100]$, $(001)-[110]$ and $(0\bar{1}1)-[111]$ specimens and polycrystals, the extraordinary Hall effect is confirmed to be isotropic as was ascertained by Webster[3] on iron single crystals. In this case the extraordinary Hall coefficient at room temperature is 49.2×10^{-11} volt cm/oersted amp.

Effective Field in the Ordinary Hall Effect in Ferromagnetics

By Eiji TATSUMOTO and Tetsuhiko OKAMOTO

Department of Physics, Faculty of Science, Hiroshima University

(Received April 27, 1959)

The nature of the effective field in the ordinary Hall effect in ferromagnetics has not yet been confirmed. From the empirical consideration Pugh and Rostoker[1] have suggested this to be the magnetizing field, H, while Wannier[2] has theoretically expected this to be $H+2\pi M(1+p)$, where M is the magnetization and p the relative probability of a conduction electron penetrating in the interior of a polarized electron ($p\leq 1$). On the other hand, Smit[3] has asserted this to be $B=H+4\pi M$. Now in this report the effective field is pointed out to be the magnetizing field, H, just as suggested by Pugh et al.

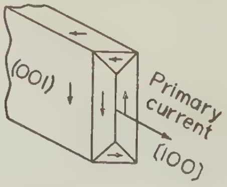

Fig. 1. Domain structure, in the iron single crystal strips with the $(001)-[100]$ crystal orientation, produced by the circular magnetic field due to the primary current.

The ordinary Hall effect has already been confirmed experimentally by the present authors to be anisotropic and to vary by the lattice deformation in the measurements on the 1.23% silicon-iron single crystal strips[4] and on the pure iron single crystal strips, though concerning the latter case it has not been published yet. However, the extraordinary Hall effect is isotropic[5,6] and hardly affected by the lattice deformation. The lattice deformation is made by applying tensions in the elestic range. In the $(001)-[100]$ specimens, the domain structure as shown in Fig. 1 is produced by the circular magnetic field due to the primary current when it is sufficiently strong.[7] Tensions applied to the direction of the primary current changes the domains perpendicular to the primary current into those parallel to the same direction. In both cases with and without tensions, the extraordinary Hall effect is almost not different. This means that the extraordinary Hall effect does not depend on the magnetizing process, but depends on the amount of the magnetization only.

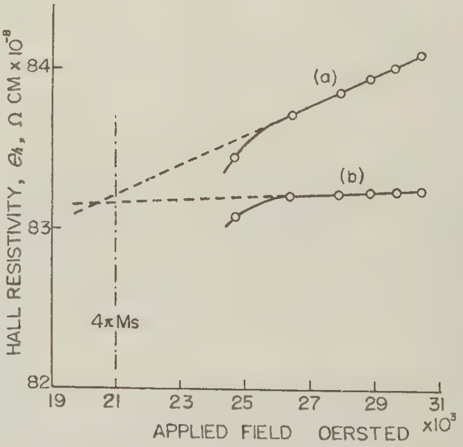

Fig. 2. Hall resistivities measured in high applied fields on the 1.23% silicon-iron single crystal strip, 0.5 mm × 9 mm × 35 mm, with the $(001)-[100]$ crystal orientation by contacting the probes at the edges: a- and b-curves stand for those measured when 0.25 kg/mm² and 1.9 kg/mm² are applied in the [100] direction, respectively.

In Fig. 2 are given the Hall resistivities measured, in high applied fields, on the 1.23% silicon-iron single crystal strip, 0.5 mm × 9 mm × 35 mm, with the $(001)-[100]$ crystal orientation, when 0.25 kg/mm² (a-curve) and 1.9 kg/mm² (b-curve) are applied in the direction of the primary current, i.e. in the [100] direction, respectively. These measurements were made by contacting the probes at the edges of the specimen. According to such a way of measurement, about 26,000 oersted in applied field is necessary to complete the extraordinary Hall effect, while about 21,000 oersted, $4\pi M_s$, is enough to saturate the magnetization technically if the demagnetizing factor is 4π. This fact is mainly due to the appearance of magnetic poles at the edge of the specimen[6]. When the linear parts in high applied fields, i.e. the ordinary Hall resistivities, are extrapolated backward, they intersect each other around $4\pi M_s$, 21,000 oersted, in the applied field. This means that the effective field is just the magnetizing field, H, and is neither $H+2\pi M(1+p)$ nor $B=H+4\pi M$, because if the effective field is $H+2\pi M(1+p)$ or $B=H+4\pi M$, the intersection point should be between zero and $2\pi M_s$, 10,500 oersted, or around zero in the applied field, respectively. Accordingly we may safely conclude that the effective field in the ordinary Hall effect is the magnetizing field.

An Extended Form of Weyl-Laue Theorem and its Application to Surface Problems

By Akira SUGIYAMA

Nagoya Technical College, Nagoya

(Received March 16, 1959)

A metal is assumed simply to consist of a uniform distribution of positive charge with density ρ_0 ($=k_F{}^3/3\pi^2$, k_F the usual Fermi momentum* volume V_0 and area of boundary surface S_0 and of a number $N_0=\rho_0 V_0$ of electrons. The electrons are free in such a potential box with an infinitely high barrier that has similar shape as the positive charge, but whose volume V is not taken necessarily to be equal to V_0.

The free electrons are specified by wave vectors $\vec{k}$, and the number $N(k)$ of energy levels of the free electrons within $|\vec{k}|\leq k$ in the potential box of any shape with volume V and the area of the boundary surface $S\sim S_0$ is expressed in the form

$$N(k)=\frac{k^3 V}{3\pi^2}-\frac{k^2 S_0}{8\pi} \tag{1}$$

where the first term represents the Weyl-Laue[1] theorem, and the second term is the correction term considering effects of the boundary surfaces. The validity of the second term is inferable from a physical insight, though a mathematical proof is given only for particular cases of outer surfaces of cubic, platelike and spherical boxes and inner surfaces of spherical and cylindrical cavities in larger boxes.

The formula (1) gives a simple method of deriving in a general way some interesting properties of surfaces of any shape as given below.

At 0°K, the maximum momentum k_m of the occupied levels is determined by

$$N(k_m)=N_0=k_F{}^2 V_0/3\pi^2 \tag{2}$$

According to Friedel[2], the interior density of the free electrons $\rho_i=k_m{}^3/3\pi^2$ should be equal to ρ_0, or

$$k_m=k_F\ . \tag{3}$$

Then, from (1), (2) and (3), we obtain the relation

$$V=V_0+b_\infty S_0\ ,\quad b_\infty k_F=3\pi/8 \tag{4}$$

1. Using (2) and (3), ρ_i is rewritten in

$$\rho_i=(N_0/V)+(k_F{}^2/8\pi)(S_0/V)$$

which shows that the surface of an infinitely high barrier expels the free electrons into the interior by an amount of $k_F{}^2/8\pi$ per unit area, since the first term N_0/V is the average density. The same has been shown by Bardeen[3] and Swiatecki[4] for a particular case of the plane surface.

2. The total energy E of the electron system is given as

$$E=\int_0^{k_m}\frac{1}{2}k^2\frac{\partial N}{\partial k}dk=\frac{k_m{}^5 V}{10\pi^2}-\frac{k_m{}^4 S_0}{32\pi^2} \tag{5}$$

or

$$=\frac{k_F{}^5 V_0}{10\pi^2}+\frac{k_F{}^4 S_0}{160\pi}$$

by using (3) and (4). Now the second term shows the surface energy

$$E_S{}^{(0)}=k_F{}^4/160\pi \tag{6}$$

per unit area of any shape, which agrees with the result given by previous authors[4,5] for a particular case of the plane surface**.

The surface energy (6) is proved to be approximately valid even for inner surface of cavities with smaller radius in spite of an assumption made in deriving (1) that the boundary surface has a larger radius of curvature.

---

* Atomic units are used.

** On rough assumption $V=V_0$, we obtain $k_m=k_F+(\pi S_0/8V_0)$ from (2), instead of (3), and then the surface energy $E_S{}^{(1)}=k_F{}^4/32\pi$ from (5), instead of (6). $E_S{}^{(1)}$ agrees with the results given by Brager et al[6]. for the plane surface, and by Brager[7] for the spherical one.

For an example, the formation of an atomic vacancy in monovalent metals is equivalent to creating the cavity of Wigner-Seitz radius r_S in the positive charge distribution, and therefore we can estimate the formation energy of vacancy ΔE_v equal to $4\pi r_S^2 \cdot \beta E_S^{(0)}$, where β is a factor representing effects of curvature. On the other hand, Seeger and Bross[8] have carried out numerical calculation of ΔE_v based on the Friedel's sum rule and the assumption of infinitely high potential barrier, from which we obtain $\beta \sim 0.93$.

For another example, the formation energy of a vacancy-pair with the distance $2C$ is estimated to be $\Delta E_{v-p} = S(C) \cdot \beta E_S^{(0)}$, where $S(C)$ denotes the surface area of the rotational ellipsoid with foci separated by $2C$ and twice volume of single vacancy. From the numerical calculations of ΔE_{v-p} by Seeger et al.[8], we obtain $\beta \sim 0.95$ for the range.

These examples agree in showing approximate validity of (6), or $\beta \sim 1$, for surfaces of larger curvature. Then the association energy of a vacancy pair is interpreted as a gain in surface energy due to decrease in the total surface area when two single vacancies make a pair.

Detailed treatments will be discussed later.

NMR Second Moment of a Radical Rotating in a Periodic Potential

By Akira MIYAKE and Riichirô CHÛJÔ

Faculty of Liberal Arts and Science, Shizuoka University, Shizuoka

(Received May 25, 1959)

The influence of the motion of a radical, *e.g.* NH_2, CH_3 or benzene ring, in a periodic potential upon the second moment of NMR was discussed by Gutowsky and Pake,[1] Andrew and Bersohn,[2] Powles and Gutowsky,[3] and Das.[4] Although the theoretical second moment is nearly unaffected by the motion, as indicated by Anderson,[5] Kubo and Tomita,[6] yet the observed one which is practically obtained through cutting off the tails of the absorption line is changed almost in parallel with the motional narrowing of the line width.[7]

The second moment due to the radical is given by

$$\Delta H_2{}^2 = \frac{3}{4}\hbar^2\gamma^2 I(I+1)\frac{1}{N}\sum_j\sum_k \langle r_{jk}{}^{-6}(3\cos^2\theta_{jk}-1)^2\rangle\,, \tag{1}$$

where γ is the gyromagnetic ratio of resonating nuclei, I their spin quantum number, N the number of resonating nuclei in the radical, r_{jk} the distance between the jth and the kth resonating nuclei, θ_{jk} the angle between the applied static field direction and the r_{jk} direction. Let the n-fold periodic potential for the rotational angle φ of the radical be

$$V_n(\varphi) = \frac{u}{2}(1-\cos n\varphi)\,. \tag{2}$$

When the n-fold symmetry axis is perpendicular to every r_{jk} direction, we can take

$$\cos\theta_{jk} = \sin\theta' \cos(\varphi - \varphi_{jk}')\,, \tag{3}$$

where θ' is the angle between the static field direction and the symmetry axis, φ_{jk}' azimuth of the r_{jk} direction.

As at high temperatures the motion is very rapid, we can consider the over-all motional average nuclear magnetic interaction, so that we may have

$$\Delta H_2{}^2 = \frac{3}{4}\hbar^2\gamma^2 I(I+1)\frac{1}{N}\sum_j\sum_k r_{jk}{}^{-6} f_n(T)\,, \tag{4}$$

$$f_n(T) = \left\langle\left[\int_{-\pi}^{\pi}(3\cos^2\theta_{jk}-1)\exp\{-V_n(\varphi)/kT\}d\varphi \Big/ \int_{-\pi}^{\pi}\exp\{-V_n(\varphi)/kT\}d\varphi\right]^2\right\rangle_{\text{isotropic mean}}, \tag{5}$$

where the isotropic mean is taken over θ' and φ_{jk}'. Eq. (5) gives

$$\left.\begin{aligned} f_1(T) &= \frac{1}{5}+\frac{3}{5}\left\{\frac{I_2(u/2kT)}{I_0(u/2kT)}\right\}^2 \simeq \frac{1}{5}+\frac{3}{320}(u/2kT)^4+\cdots, \\ f_2(T) &= \frac{1}{5}+\frac{3}{5}\left\{\frac{I_1(u/2kT)}{I_0(u/2kT)}\right\}^2 \simeq \frac{1}{5}+\frac{3}{20}(u/2kT)^2+\cdots, \\ f_n(T) &= \frac{1}{5} \qquad\qquad n \geqq 3 \qquad\qquad , \end{aligned}\right\} \tag{6}$$

where $I_n(x)$ is modified Bessel function of the nth order.

On the other hand, at low temperatures the motion is almost confined to the bottom of a potential trough, so we must have in place of $f_n(T)$

$$g_n(T) = \left\langle\left[\int_{-\pi/n}^{\pi/n}(3\cos^2\theta_{jk}-1)\exp\{-V_n(\varphi)/kT\}d\varphi\right.\right.$$

$$\Big/\int_{-\pi/n}^{\pi/n}\exp\{-V_n(\varphi)/kT\}d\varphi\Big]^2\Big\rangle_{\text{isotropic mean}}, \tag{5'}$$

provided the motion within the trough is rapid. Eq. (5′) gives

$$\left.\begin{aligned} g_1(T)&=f_1(T)\simeq\frac{4}{5}-\frac{12}{5}(2kT/u)+\cdots \qquad ,\\ g_2(T)&=f_2(T)\simeq\frac{4}{5}-\frac{3}{5}(2kT/u)+\cdots \qquad ,\\ g_n(T)&=\frac{1}{5}+\frac{3}{20}\frac{n^2}{\pi^2}\sin^2(2\pi/n)\\ &\quad\cdot\left\{1-8\sum_{r=1}^{\infty}\frac{(-1)^r}{(nr+2)(nr-2)}\frac{I_r(u/2kT)}{I_0(u/2kT)}\right\}^2\\ &\simeq\frac{4}{5}-\frac{12}{5n^2}(2kT/u)+\cdots \qquad n\geqq 3\,. \end{aligned}\right\} \tag{6'}$$

As

$$\langle V_n\rangle=\int_{-\pi/n}^{\pi/n}V_n(\varphi)\exp\{-V_n(\varphi)/kT\}d\varphi \Big/\int_{-\pi/n}^{\pi/n}\exp\{-V_n(\varphi)/kT\}d\varphi\simeq\frac{1}{2}kT+\cdots$$

at low temperatures, we can write

$$\frac{5}{4}g_n(T)\simeq 1-\frac{12}{n^2}\frac{\langle V_n\rangle}{u} \qquad n\geqq 1\,, \tag{7}$$

which is to be compared with that given by Das,[4] where factor 12 of the second term in the right side of Eq. (7) is substituted by 112/9.

The relation

$$f_n(\infty)/g_n(0)=1/4 \qquad n\geqq 1 \tag{8}$$

coincides with the conclusion already given by Gutowsky and Pake.[1] The diversity in the cases $n=1$, $n=2$ and $n\geqq 3$, as seen in Eqs. (6) and (6′), arises from the nature of symmetry in the nuclear magnetic dipolar interaction. $f_n(T)$ and $g_n(T)$ *vs.* $2kT/u$ are shown graphically in Fig. 1.

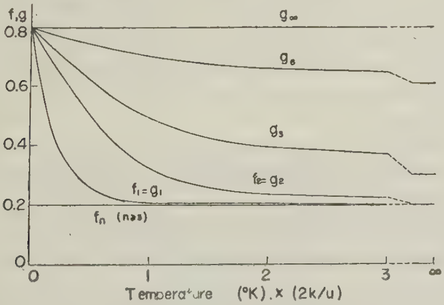

Fig. 1. $f_n(T)$ and $g_n(T)$ *vs.* $2kT/u$ for $n=1$, 2, 3, 6 and ∞.

New Cold Cathode Using Magnesium Oxide

By Tetsuji IMAI, Yoshihiko MIZUSHIMA
and Yoshitaka IGARASHI

Electrical Communication Laboratory
Nippon Telegraph
and Telehone Public Corporation,
Tokyo, Japan

(Received May 21, 1959)

It was reported by Jacobs[1),2)] that a target on which magnesium oxide was deposited emitted secondary electrons as much as one thousand times the primary ones. Although the phenomenon resembled Malter's Effect on a cathode of composition (Al)–Al_2O_3–Cs_2O, Jacobs emphasized that the phenomenon was quite different from that Effect and due to the avalanche process produced in the magnesium oxide layer. Furthermore, with proper

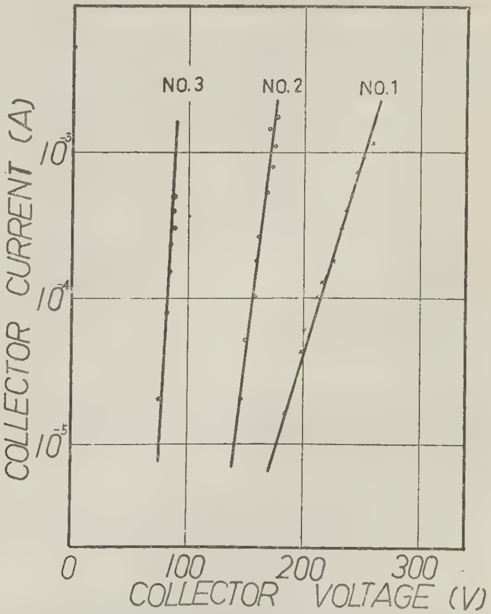

Fig. 1. Collector voltage—current characteristics of MgO cathodes. No. 1, 2 and 3 are test tubes having different electrode configurations.

disposition of the potential across the layer, the emission current could be made self-sustaining, with no primary current. This was first reported by Dobischek, Jacobs and Freely[3] and on BaO by Yoshida et al.[4]

We could prepare the magnesium oxide cathodes yielding self-sustaining emission current of the order of milliamperes in a quite simple way which will be given elswhere in detail. According to Jacobs, a rather complicated method is necessary to obtain the extremely high yield of secondary emission or self-sustaining emission, that is, both the evaporation of magnesium and the heat treatment of the deposit should be applied in an atmosphere of oxygen in order to get good results.

Some results obtained by us on the relation between the self-sustaining emission and the collector voltage are illustrated in Fig. 1, which implies the relation

$$I=I_0 \exp(NV),$$

where I is the emission current from the cathode, V collector voltage, I_0 and N constants depending on the cathode and electrode configurations. The cathode was not self-starting and required some external stimulus, such as electrons, photons or ions. Among others electron bombardment was the most effective to start the current. Illumination with light from incandescent lamp was also effective. Between the light intensity (L) and the time (t) which was required to start, we obtained a relation,

$$L\cdot t=\text{const}.$$

One of the most remarkable phenomena observed is an accumulation effect of light stimulation at the magnesium oxide cathode. Holding the distance between the cathode and the light source constant, the cathode was exposed to light of a constant flux intermittently. The integrated time of exposure until an electron emission sets in was found to be independent on the length of pause. One of these results is given in Fig. 2. The pause length between light exposures was chosen as 5 sec, 15 sec, 30 sec, 1 min, 2 min, 5 min and 10 min, but substantially constant total-exposure-time was required to start an emission. This implies that a physical phenomenon caused by light stimulation is able to maintain for a long time without appreciable decay. The light exposure will eject electrons, out of the MgO as the photo-emission, leaving the outside of the MgO layer positively charged and the positive charge on the MgO surface can not escape owing to the extreme high resistivity of the layer.

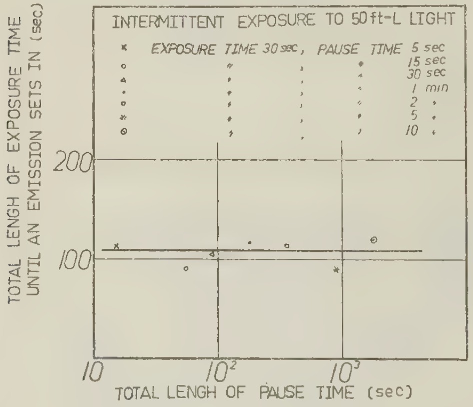

Fig. 2. The relation between the integrated time of exposure until an emission sets in and the length of pause at the intermittent exposure method.

It was found further that the photo-effect mentioned above had a cut-off-energy in the ultraviolet region. It was also found that the characteristic phosphorescent glow was violet or blue and in some cases redish violet.

Microwave Spectrum of Ethyl Iodide

By Takahiro KASUYA and Takeshi OKA
Department of Physics, Faculty of Science, University of Tokyo, Tokyo

(Received May 21, 1959)

The microwave spectrum of ethyl iodide C_2H_5I was observed in the frequency range from 5 to 30 kMc/sec. About fifty lines were assigned to the a-type transitios, and other twenty to the b-type transitions.

This molecule is a slightly asymmetric rotor with $b_p \doteqdot -0.003$, having a very large quadrupole coupling constant, and the calculated frequencies could not satisfactorily be fitted to the observed spectrum with the first order quadrupole treatment alone.

The second order quadrupole effect was calculated using the wave function expanded in the power series of b_p[1]. With the parameters listed in Table II, the discrepancies between the calculated and observed frequencies were less than 1 Mc/sec (Table I).

The hyperfine anomalies in $K=1$ lines reported by Wagner and Dailey in the case of C_2H_5Br[2]

Table I. Spectroscopic parameters of ethyl iodide.

A	29109.2±5 Mc/sec	$(eqQ)_{aa}$	−1481.9±0.5 Mc/sec
B	2979.2 ±0.5	$\eta=(\chi_{bb}-\chi_{cc})/\chi_{a}$	=0.22 (assumed)
C	2797.1 ±0.5	$\xi=\chi_{bc}/\chi_{aa}$	=0.60 (〃)

were also observed in this molecule. For example, the hyperfine component corresponding to 7/2→9/2 of $2_{12}\rightarrow3_{13}$ transition was found to show the splitting of 1.09 Mc/sec. This splitting was explained by taking into account of the internal rotation of CH_3 group (Table II).

Table II. An example of hyperfine anomaly.

$2_{12}\rightarrow3_{13}$	obs.	calc.
9/2→11/2	17096.08	17095.84
7/2→ 9/2	17034.84	17035.30 (E)
	17035.75	17034.21 (A)
3/2→ 5/2	16976.8	16976.6
1/2→ 3/2	17007.76	17007.14

The quadrupole interaction term averaged by the rigid asymmetric rotor wave function is known to be

$$eqQ=\frac{(eqQ)_{aa}}{(J+1)(2J+3)}\Big[\{3K^2-J(J+1)\}+(-1)^{\gamma}\frac{J(J+1)\eta}{2}\delta_{K,1}+\text{asymmetry correction}\Big].^{3)}$$

The second term $\pm[J(J+1)\eta]/2$ which does not vanish for $K=1$ must be multiplied by a factor ε, owing to the coupling of internal and overall rotation[4].

For A-state of internal rotation ε is one, but for E-state it is dependent sensitively on potential, which can be used to evaluate the barrier height[5]. Treating the internal rotation problem by the Hamiltonian developed by Kilb, Lin and Wilson[6], the potential value of about 2.4 kcal/mole was obtained. This should be compared with that of C_2H_5Cl and C_2H_5Br [7]*.

From the parameters listed in Table I, the structural constants were determined as follows

Table III. Microwave spectrum of ethyl iodide.

Angular Correlation of Gamma Rays from Xe^{126} and Te^{126}

By Mitsuo SAKAI, Hidetsugu IKEGAMI, Toshimitsu YAMAZAKI
Institute for Nuclear Study, University of Tokyo, Tanashimachi,
Kitatamagun, Tokyo, Japan

and Kazusuke SUGIYAMA
Department of Physics, Tohoku University, Sendai, Japan

(Received February 21, 1959)

The angular correlation of gamma rays in 2−2−0 cascade transitions in Xe^{126} and Te^{126} is measured from the decay of I^{126} in order to obtain the mixing ratio of competing E2 and M1 transitions in the 2−2 transition. The mixing ratio is found to have positive sign for both nuclei, as expected from the systematics of excited levels in even-even nuclei.

§ 1. Introduction

The systematics of excited levels in even-even nuclei revealed recently1) that the nuclei having 0−2−2 spin sequence[*] appear in three neutron-islands where the 1/2 orbit competes with the higher angular momentum orbit owing to the large pairing energy, namely $38 \leq N \leq 48$, $(2\,p_{1/2}, 1\,g_{9/2})$, $64 \leq N \leq 74$, $(3\,s_{1/2}, 1\,h_{11/2})$ and $110 \leq N \leq 120$, $(3\,p_{1/2}, 1\,i_{13/2})$[**]. Moreover it was pointed out from a rather poor statistics that the sign of mixing ratio δ of competing E2 and M1 transitions from the second 2+ to the first 2+ level alternates from one island to the other. The sign of the first and third islands is negative[***] and that of the second island is positive. This observation seems to be very important for understanding the physical meaning of the mixing ratio in even-even nuclei.

Since in the second island δ was measured only in Sn^{116} 3) and Te^{122} 4), it was considered worth while to measure the sign of δ in Xe^{126} and Te^{126} by using gamma rays from I^{126} (13 day) in order to put this interesting rule on the more solid experimental bases.

The decay scheme of I^{126} (Fig. 1) was very well established by beta and gamma spectroscopy5). Therefore the problem is now to measure the angular correlations between 0.75-MeV and 0.65-MeV gamma rays in Te^{126} and between 0.48-MeV and 0.386-MeV gamma rays in Xe^{126}.

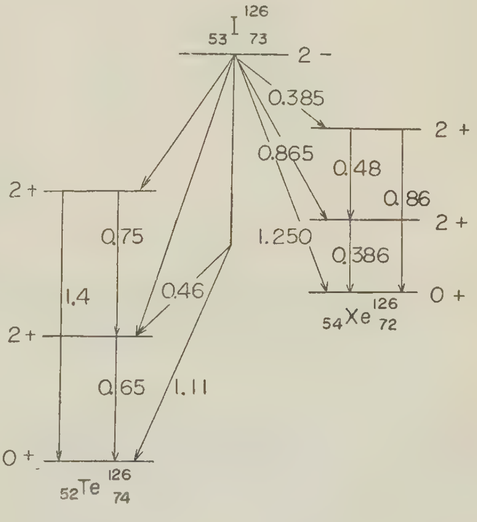

Fig. 1. Decay scheme of I^{126} proposed by Koert et al.

§ 2. Source Preparation

The I^{126} sample was prepared by bombarding a natural antimony layer with 200 microampere-hours of 30-MeV alpha particles in the 63-in. cyclotron of the Institute for Nuclear Study of University of Tokyo, leading to the reaction Sb^{123} (α, n) I^{126}. Since I^{124} (4.5 day) was produced at the same time, the measurement was started about 40 days after the bombardment. The scintillation spectrum of $\mathrm{I}^{124}+\mathrm{I}^{126}$ is presented in Fig. 2 with its time dependence. A radio active NaI solution of

---

[*] The nuclei having 4+ or 0+ level near the second 2+ level are included in this category.

[**] Notice that there exist proton islands originating from the competition of proton configurations $(2\,p_{1/2}, 1\,g_{9/2})$ and $(3\,s_{1/2}, 1\,h_{11/2})$. The last one and the third neutron island overlap each other.

[***] It was remarked recently2) that several nuclei in the third island have positive mixing ratio. However this may be explained by the fact that the second proton island overlaps just this region, so it is not inconsistent with the rule.

1 mm diameter and 4 mm long in a plastic container was served as the source for the correlation experiment for avoiding the influence of extra-nuclear fields.

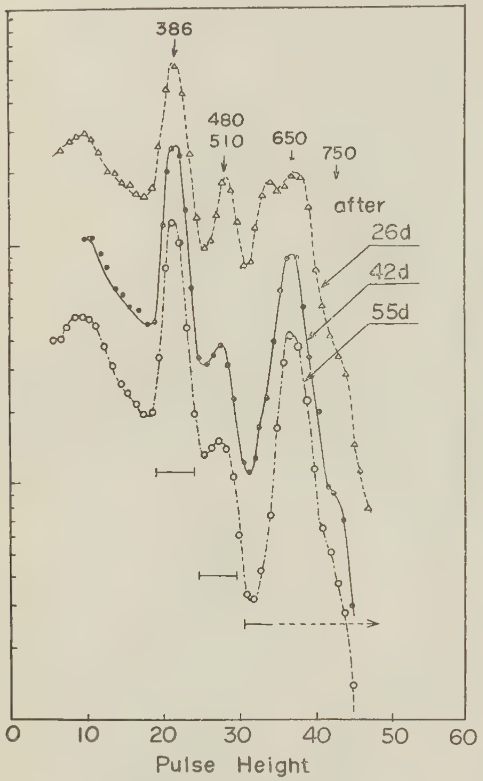

Fig. 2. Scintillation pulse height spectra of gamma rays in decay of $I^{126}+I^{124}$ taken 26 days, 42 days and 52 days after the bombardment.

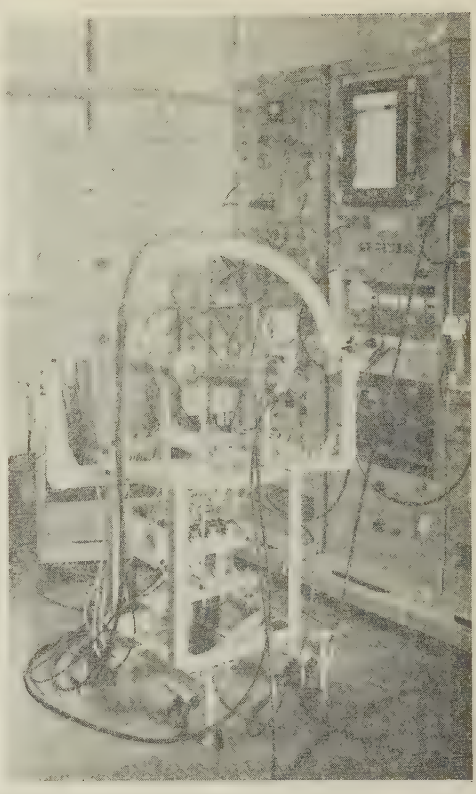

Fig. 3. The angular correlation apparatus.

§ 3. Results

The angular correlation apparatus is shown in Fig. 3, consisting of two detectors, one fixed and one movable, mounted on a table. NaI (TI) crystals, one 2-in. in diameter by 2-in. height and one 1¾-in. in diameter by 2-in. height from Harshaw Chemical Corporation, were coupled to Dumont 6292 photomultipliers. The coincidence circuit was a conventional one of which $2\tau \simeq 0.6\mu$ sec. Throughout the measurement, the accidental coincidence counts were about 10% of the total coincidence counts. The five measuring points, separated each other by 15°, were chosen from 90° to 150° for avoiding the false coincidence counts in region at 180° produced by annihilation radiation.

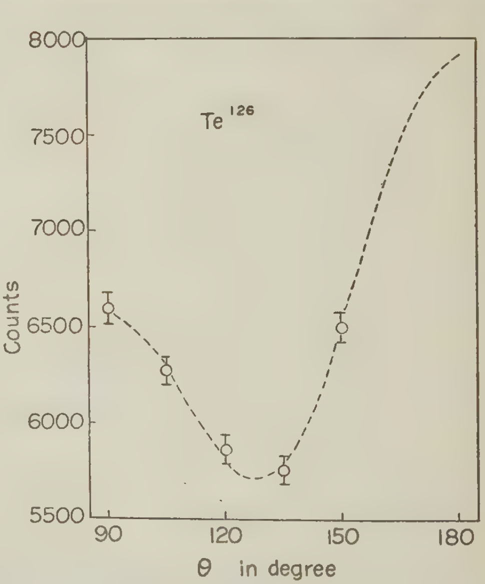

Fig. 4. Correlation curve in Te^{126}. The dashed curve is the calculated one.

1) *Angular correlation in* Te^{126}

The lower end of integral gate in each channel is set at 0.62-Mev pulse height as indicated in Fig. 2. In this gate setting, as known from the decay scheme, we can expected no other coincidences than that between 0.65-MeV and 0.75-MeV gamma rays. The result is presented in Fig. 4. Assuming the experimental correlation function $W'(\theta)$ as $1+A_2'P_2(\cos\theta)+A_4'P_4(\cos\theta)$, the least square fit has given $A_2'=0.055\pm0.008$ and $A_4'=0.214\pm0.012$. The calculated correlation curve with these A_2' and A_4' is presented also in Fig. 4. Since the energies of the gamma rays in Te^{126} and Xe^{126} are not so different from that of annihilation radiation, the correction for finite solid angle was made according to Church-Kraushaar's method⁶⁾, by measuring the angular resolution with annihilation radiation of Na^{22}. The correction coefficients Q_0/Q_2 and Q_0/Q_4 were, then, obtained to be 0.93 and 0.80, respectively. The correlation coefficients corrected for finite solid angle were the followings: $A_2=0.059\pm0.009$ and $A_4=0.268\pm0.014$.

2) *Angular correlation in* Xe^{126}

In this case the differential gates were used. The window setting in each channel, being at the photo-peaks of 0.386-MeV and 0.48-MeV respectively, was indicated in Fig. 2. The geometrical conditions were the same as that in Te^{126}. The following two points were carefully checked. The first point is the contribution of 0.51-MeV annihilation radiation to the coincidence counts because it gives excessive coincidence counts in position at 180°. Since in the present geometrical setting the overall angular resolution deduced by using annihilation radiation in Na^{22} was found to be 10.5° at half maximum, it was concluded that there was no such influence in region between 90° and 150°. The second point is the contribution of coincidence counts from the 0.65-MeV and 0.76-MeV gamma rays in Te^{126} to the correlation pattern in question. The estimation of this undesirable contribution was found to be about 10% in the present window setting, and since the observed correlation pattern was similar to that of Te^{126}, the subtraction of this contribution from the observed value could be expected to produce not so serious effect for getting the true correlation function of Xe^{126}. The corrected value is presented in Fig. 5 with the least squares curve. According to the same precedure as the preceding paragraph, the final result was obtained: $A_2'=0.066\pm0.023$, $A_4'=0.235\pm0.033$, $A_2=-0.071\pm0.025$ and $A_4=0.294\pm0.041$.

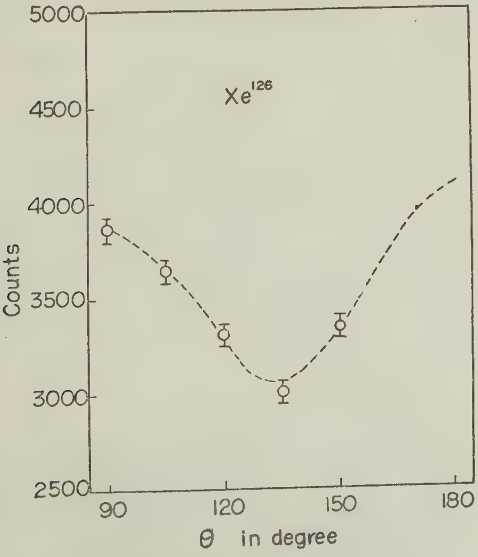

Fig. 5. Correlation curve in Xe^{126}. The dashed curve is the calculated one.

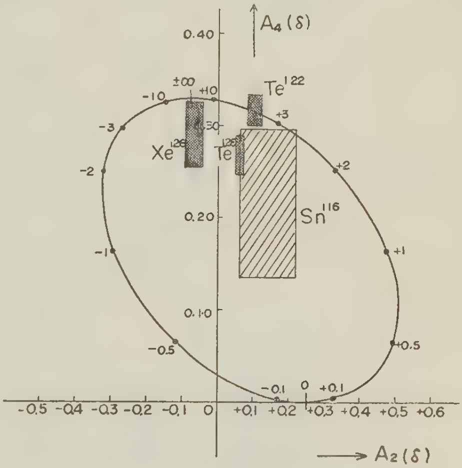

Fig. 6. Elliptical representation of A_2 and A_4 in cascade gamma transition for nuclei in 2nd S(2) island. The parameter on the ellipse indicates directly δ instead of $\delta'(=\delta(1+|\delta|)^{-1})$ used in reference 7.

§ 4. Discussion

The values of A_2 and A_4 obtained in § 3 are presented in the elliptical representation of A_2 and $A_4$⁷⁾. The A_2 and A_4 in Sn^{116} ³⁾ and Te^{122} ⁴⁾ are put also in the same figure. Parameters attached to the ellipse are mixing ratio δ in stead of $\delta'(=\delta(1+|\delta|)^{-1})$ used in reference⁷⁾. From this figure, it can be seen that the mixing ratio of these nuclei has positive sign as expected from the rule¹⁾. This rule seems to be very important for understanding the physical meaning of mixing ratio in even-even nuclei and for shedding light on the excitation mechanism of so-called vibrational levels.

Acknowledgement

We wish to thank Professor S. Kikuchi, Director of the Institute for Nuclear Study, and Professor I. Nonaka for their constant interest and encouragement. The help given by Dr. K. Saito of our Institute and Dr. H. Shimojima, Mr. H. Fukutomi and Mr. T. Nitta of the Tokyo Institute of Technology on the chemical separation of racioactive isotope is deeply appreciated.

Decay of I^{124}

By Kazusuke SUGIYAMA

Department of Physics, Tohoku University, Sendai

Hidetsugu IKEGAMI, Toshimitsu YAMAZAKI and Mitsuo SAKAI

Institute for Nuclear Study, University of Tokyo,
Kitatamagun, Tokyo

(Received May 1, 1959)

The gamma and beta rays following the decay of I^{124} which was produced by Sb (α, n) reaction have been studied with scintillation spectrometers both single and in coincidence, and with a beta-ray spectrometer. Three gamma rays at 2.74-MeV, 2.29-MeV and 1.50-MeV and probably 0.9-MeV which were not found in decay of Sb^{124} were observed. The beta-gamma coincidence experiments revealed that the first positron group decays to the ground level of Te^{124} so that the energy difference between I^{124} and Te^{124} becomes 3.22-MeV, being consistent with beta decay energy systematics. In addition this beta component was found to have an unique 1st forbidden type spectrum, showing the spin and parity of the ground state of I^{124} is $2-$. From these results we led to conclude the presence of two new levels at 2.88-MeV and 2.74-MeV which the spin value is probably 1 and the parity is negative. A doublet level at the second excited level previously reported was not confirmed in the present experiment. However a definite evidence of cross-over transition from the second level to the ground level was obtained which may indicate a presence of a $2+$ level at the second excited level. The tentative decay scheme is proposed.

§ 1. Introduction

The excited levels in Te^{124} were studied in detail by making use of the radiations from the decay of Sb^{124}.[1] Especially Dzelepov et al.[2] published very recently the level scheme of Te^{124}, showing the presence of a doublet at the second excited level. However the positron emitter I^{124} (4.5-day) decaying to the same daughter nucleus was not yet studied except the Michell's work[3] in 1949.

Since I^{124} belongs to the so-called 2nd $S(2)$ pattern[4] of which the systematic investigation of excited levels was taken as the central project of our group and since so little information on this isotope was available up to the present*, it was considered worth while to produce a sample of this isotope for studying the radiations from this isotope by scintillation counter techniques developed since the time of Michell's work.

§ 2. Source Preparation

The I^{124} sample was prepared by bombarding a natural antimony layer with 200 microampere-hours of 30–MeV alpha particles in the 63″ cyclotron of the Institute for Nuclear Study of the University of Tokyo, leading to the reaction $Sb^{121}(\alpha, n)I^{124}$. The antimony layer soft-soldered on the thin copper plate was fastened on the large copper block which was served as the head for the probe of 4″ in diameter. After the bombardment, the antimony layer was turn off from the backing copper plate, and dissolved in a mixture of sulfuric acid and potassium sulfate. The active iodine was warmed up to the temperature of about 300°C**.

Since the bombardment produces the radioactive I^{123}, I^{125} and I^{126} aside from I^{124} in question (see Table I), the measurement was started one week after the bombardment, avoiding the interference of the very strong 0.159 MeV gamma ray from I^{123}. The presence of radiations from I^{126} gave no significant disturbance in the following measurements.

Table I. Nuclear reaction in natural antimony by 30 MeV alpha particles.

§ 3. Gamma Ray Spectrum

a) *Single spectrum analysis*

The gamma ray spectrum was taken by the scintillation counter which consisted of a cylindrical NaI (Tl) crystal, 4-in. long and 4-in. in diameter coupled with a Dumont type 6364 photo-multiplier and Sunvic 100-channel pulse-height analyser. In this measurement the gamma rays were collimated by a cylin-

drical aperture of 0.8 cm and 10 cm long in the lead shield. This procedure was essentially useful for measuring higher energy gamma ray, reducing sum and escape peaks. For the purpose of comparison the spectrum of Sb ^{124} was also measured. In Fig. 1 the scintillation gamma ray spectra of these isotopes are presented and in Table II the energy of the gamma rays is tabulated with their relative intensity. The last value was obtained from the efficiency curve and photofraction curves for this detection system.

The new gamma rays at 1.50 MeV, 2.29 MeV and 2.74 MeV were observed. The last one was suspected to be a composite peak of 2.74 MeV and 2.88 MeV gamma rays but the definite conclusion was not obtained. Moreover, the comparison with the spectra of Sb^{124} indicated the presence of a gamma ray in region of energy 0.9 MeV. Both of pulse height peaks at 2.74 MeV and 2.29 MeV were observed to have the same decay time as that of 1.70 MeV gamma ray, having verified that these gamma rays belongs to I^{124}, since the 1.70 MeV gamma ray was found in the decay of Sb^{124}.

b) *Coincidence measurement*

The coincidence measurement was performed by making use of the multi-channel pulse-height analyser. Selection of a definite gamma ray from gate detector can be made with the single channel analyser and then gamma ray spectrum in coincidence with it via main detector may display on the multi-channel analyser. We have used three coincidence apparatus which had the following combination; $1\frac{1}{2}$-in. $\phi\times 1\frac{1}{2}$-in. height (gate)+4-in. $\phi\times 4$-in. height (main)+Sunvic 100 channels pulse-height analyser, $1\frac{1}{2}$-in. $\phi\times 1\frac{1}{2}$-in. height (gate)+$1\frac{1}{2}$-in. $\phi\times 1\frac{1}{2}$-in. height (main)+fast-slow coincidence circuit of which $2\tau\simeq 30$ mμs* and $1\frac{3}{4}$-in. $\phi\times 2$-in. height (gate)+2-in. $\phi\times 2$-in. height (main)+INS 10 channels pulse-height analyser** with slow gate circuit of which $2\tau\simeq 4\mu$s.

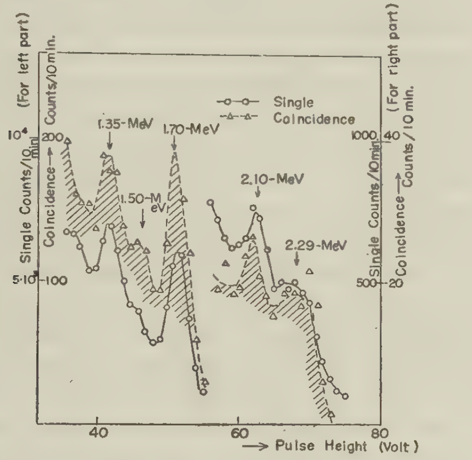

Fig. 2. Coincidence spectrum with 0-61-Mev photo-peak.

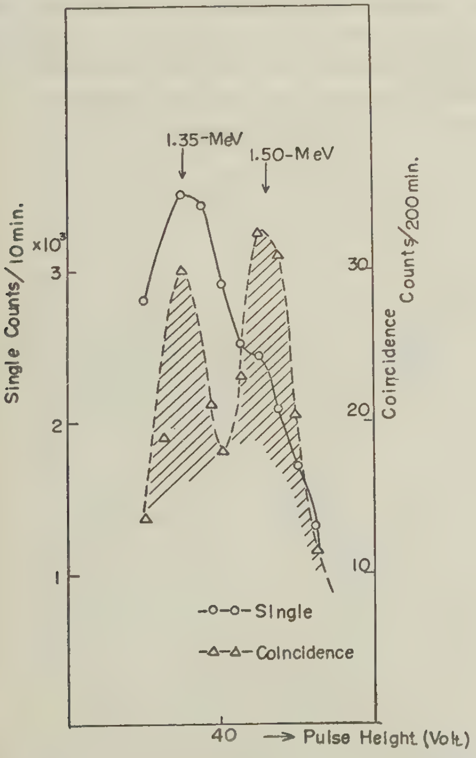

Fig. 3. Coincidence spectrum with 0.72-Mev photo-peak.

The results cross-checked by these two systems are tabulated in Table III. The typical coincidence spectra are presented in Fig. 2, Fig. 3 and Fig. 4. It should be mentioned that further careful examination of the coincidence spectrum with 1.35 MeV gamma ray in the region 0.9∼1.1 MeV indicates a presence of 0.9 MeV gamma ray. This fact is consistent with the observation in the preceding paragraph.

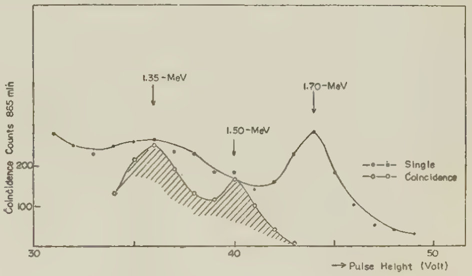

Fig. 4. Coincidence spectrum with about 1.35-Mev pulse-height region.

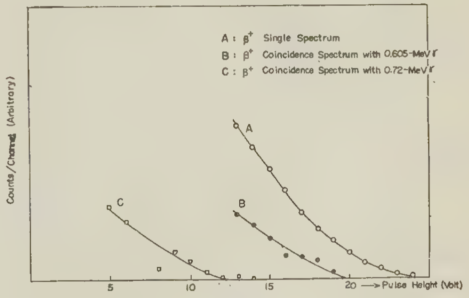

Fig. 5. $\beta^+-\gamma$ coincidence spectrum.

§ 4. Beta Ray Spectrum

a) *$\beta^+-\gamma$ coincidence spectrum*

In this case, the main detector was a beta ray detector which consisted of 1-in. $\phi\times 5$ mm thickness plastic scintillator coupled with a Dumont 6292 photomultiplier and the gate detector was a cylindrical NaI (Tl) crystal, 2-in. long. and 2-in. diameter attached to a Dumont 6292 photomultiplier. An INS 10 channels pulse-height analyser was used as the displaying apparatus for coincidence pulses. The total and coincidence spectra are presented in Fig. 5 which revealed the main beta component decays to the ground level and the 0.605 MeV gamma ray is in coincidence with the second beta component and 0.72 MeV gamma ray in coincidence with the third beta component. Since the maximum energy of the first beta component was known to be 2.20 MeV$^{3)}$, this fact indicates the energy difference between I^{124} and Te^{124} is 3.22 MeV, being consistent with the beta decay energy systematics. (see Fig. 6)

---

* M. Sugawara: to be published.

** INS 10-channels pulse-height analyser was developed by the electronics section of the Institute for Nuclear Study.

b) *Fermi plot analysis*

In order to get the Fermi plot of the first beta component, INS III beta spectrometer* (a sector type double focusing beta ray spectrometer of which $\rho=18$ cm) was used. The shape factor deduced from the Fermi plot is presented in Fig. 7, showing clearly a characteristic curve for the unique first forbidden type spectrum. Combining the result of the preceding paragraph, we concluded that the ground level of I^{124} has the spin value of 2 and negative parity.

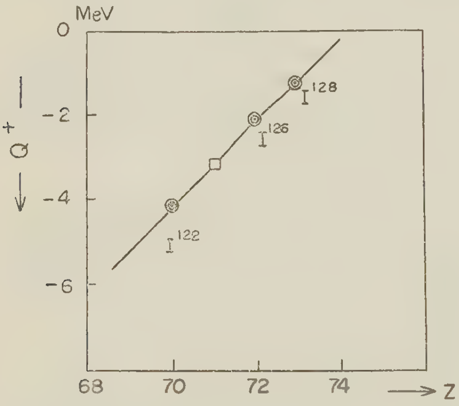

Fig. 6. Beta decay energy systematics.

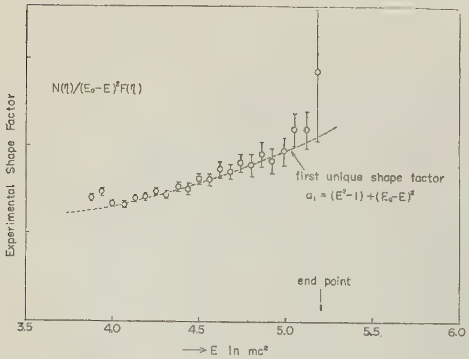

Fig. 7. Shape factor for the first positron component of I^{124}.

§ 5. Conclusion

The gamma ray spectrum showed the new photo-peaks at 2.74 MeV, 2.31 MeV, 1.50 MeV and probably at 0.9 MeV which were not observed in the decay of Sb^{124}. This fact indicates the presence of the new levels in Te^{124}. Since the 2.74 MeV gamma ray was found to decay directly to the ground level of Te^{124} and since the 2.28 MeV gamma ray was found to coincide with the 0.605 MeV gamma ray, we were led to assign the new excited level at 2.88 MeV and 2.74 MeV above the ground level.

The spin value of the ground level of I^{124} was definitely established as 2− by the shape of the 2.02 MeV first positron spectrum. Since the beta component decays to the ground level, the energy difference between I^{124} and Te^{124} should be 3.22 MeV which is consistent with the beta decay energy systematics. As the ground level of Sb^{124}, of which the spin and parity are known as 3−$^{5)}$ can not decay to the new levels by beta ray emission, we were led to conclude that the spin and parity of these levels is probably 1−.

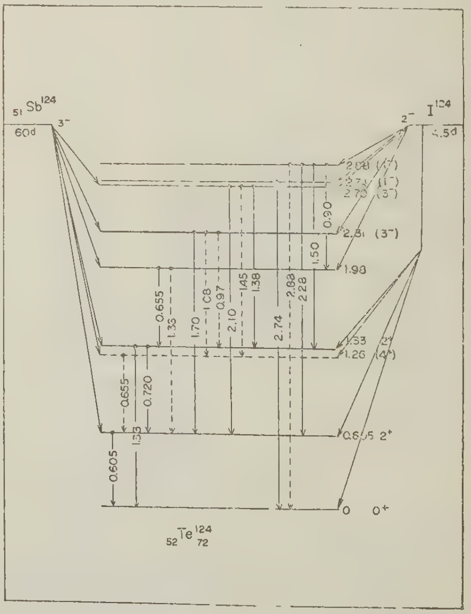

Fig. 8. Proposed decay scheme of I^{124}. The decay scheme of Sb^{124} proposed by B. S. Dzelepov et al. (ref. 2) is also shown in this figure.

---

* The details of this spectrometer will be soon published.

The 1.35 MeV gamma ray is in coincidence with the 1.50 MeV gamma ray and partially with 1.35 MeV gamma ray as shown in Fig. 4. This fact indicates; 1) the second 1.33 MeV level should be capable to de-excite to the ground level by cross-over gamma radiation and the spin and parity of this level may be 2+ as expected from the gamma ray energy relation and from the energy systematics of excited level of the S(2) pattern and 2) there must be a gamma ray of about 1.35 MeV which decays in parallel with these 1.35 MeV gamma rays and 3) the presence of a new excited level at 2.88 MeV of which the energy is the sum of 1.33 MeV and 1.50 MeV is evident, Fig. 8 shows a rather complicated decay scheme deduced from the present results and the information from the decay of Sb^{124}. Of course it is too complicated that we could not pretend it is a real one. Especially the interesting doublet at the second excited level reported by Dzelepov et al. can not be confirmed in the present experiment.

The only possibility of obtaining a negative parity for the I^{124} ground level lies in assigning on $h_{11/2}$ state to the 71st neutron which seems to be the same situation as that of I^{126}. So far as the spin of new levels are concerned, it may be understood as the following configurations from the single particle aspect

$$\{(1g_{7/2})^1(1h_{11/2})^1(3-)\}_p\{(2d_{3/2})^2(2+)\}_n(1-)$$

and

$$\{(2d_{5/2})^1(1h_{11/2})^1(3-)\}_p\{(2d_{3/2})^2(2+)\}_n(1-)$$

Therefore these two level seems to have the intimate relation to the two 3− levels just bellow these 1− levels, since the configuration of latter levels were thought as

$$\{(1g_{7/2})^1(1h_{11/2})^1(3-)\}\{(2d_{3/2})^2(0+)\}_n(3-)$$

and

$$\{(2d_{3/2})^1(1h_{11/2})^1(3-)\}_p\{(2d_{3/2})^2(0+)\}_n(3-)$$

respectively. Of course it may be possible to discuss these levels by the collective model. And in this case, the explanation as an appearance of octupole vibrational levels seems to be very attractive.

The present authors express their sincere thanks to Professor S. Kikuchi and Professor I. Nonaka for their encouragement and interest in the research. Their thanks are also due to Dr. K. Saito of the Institute for Nuclear Study and Dr. H. Shimojima, Mr. H. Fukutomi and Mr. T. Nitta of the Tokyo Institute of Technology for their skillful chemical separation of radioactive isotope and to the cyclotron crew of the Institute for Nuclear Study for their kindful cooperations. One of authors (K, S) is grateful to Prof. M. Kimura and the staff of the Laboratory of Nuclear Physics, Tohoku University, for encouragement in the experiment.

Theory of Thermoelectric Power of Ionic Crystals, II.

By Eijirō HAGA

Department of Physics, Faculty of Science, Niigata University

(Received December 25, 1958)

A theory of the thermoelectric power of the NaCl crystal doped with $CdCl_2$ is developed, when we measure it by using the chlorine gas electrode. We derive also the expressions of it by taking into account the Coulomb interaction between defects in NaCl and AgBr, and estimate the correction terms to the simple theory. Next the relation between the thermoelectric power with the metallic electrodes and that with the halogen electrodes is derived, and the theoretical result is compared with experiments in silver halides and lead halides.

§1. Introduction

There is only a qualitative theory[1] on the mechanism of thermal diffusion of ions in ionic crystals. The information about this is obtained from the thermoelectric power. The purpose of the present paper is to investigate the thermal properties of alkali halides from the knowledge of the thermoelectric power. In the previous paper (I) we have developed a theory of the thermoelectric effects in AgBr or AgCl, under the condition that the silver metal is used as electrode and defects distribute at random in it.[2] In the case of alkali halides, however, alkali metals are not available as electrode because of their low melting points. Therefore, we shall develope a theory of the thermoelectric power of NaCl with use of the chlorine gas electrode as devised by Reinhold.[3]

As is well known, the ionic conduction in alkali halides is due to the presence of the Schottky defects in contrast with silver halides. Etzel and Maurer have measured the ionic conduction in NaCl doped with $CdCl_2$, and estimated several important parameters making use of the simple theory in which the Coulomb interaction between defects is left out of consideration.[4] Their measurements show that below 400°C the intrinsic effects can be neglected in comparison with the impurity effects.

Further, the analyses of the ionic conduction have been carried out taking into account the Coulomb interaction between defects in AgBr by Teltow[5] and in NaCl at impurity range by Lidiard[6]. The values of parameters thus obtained are considerably different from those based on the simple theory. Therefore, it seems interesting to study the effect of the Coulomb interaction on the thermoelectric power. This effect will be considered in the Debye-Huckel approximation[7] for NaCl and AgBr.

§2. Thermoelectric Power of NaCl

Let us consider the following arrangement devised by Reinhold:

$$M\,|\,C,\ Cl_2\,|\,NaCl\,|\,Cl_2,\ C\,|\,M\,. \qquad (1)$$

Here, C is the graphite rod inserted ("eingeschmolzen") into a sample of NaCl, and M is the lead wire. We shall calculate the difference of the Fermi levels per degree, eQ, between the topps of two graphite rods in NaCl, which is equal to the thermoelectric power measured in the arrangement (1) times the magnitude of electronic charge if the thermoelectric powers of M and C are left out of consideration.

The chlorine atom in NaCl near the contact with C and that in the chlorine gas at the same temperature, are in thermal equilibrium through the process of generation of V-centers in NaCl, so that we have

$$\mu_{Cl}^{NaCl}=\mu_{Cl_2}^{Cl_2}/2\,, \qquad (2)$$

where μ_{Cl}^{NaCl} and $\mu_{Cl_2}^{Cl_2}$ are the chemical potential of a chlorine atom in NaCl and that of a chlorine molecule in the chlorine gas, respectively. Further, the following reaction takes place at the constact between NaCl and C:

$$Cl \leftrightarrows Cl^- - e^-\,. \qquad (3)$$

The above equilibrium will be established through the process in which electrons from C recombine with trapped holes in V-centers and the double layer is formed at the contact between NaCl and C, or through the inverse process. We have, from the reaction (3),

$$\mu_{\mathrm{Cl}}^{\mathrm{NaCl}}=\mu_{\mathrm{Cl}^-}^{\mathrm{NaCl}}-\zeta_{e^-}^{C}\,, \tag{4}$$

where $\zeta_{\mathrm{Cl}^-}^{\mathrm{NaCl}}$ and $\zeta_{e^-}^{C}$ are the electrochemical potential of a chlorine ion in NaCl and that of an electron in C, respectively. From Eqs. (2) and (4), we find the following fundamental equation for Q:

$$eQ=eQ_{\mathrm{Cl}^-}^{\mathrm{NaCl}}-s_{\mathrm{Cl}_2}^{\mathrm{Cl}_2}/2\,, \tag{5}$$

where $eQ_{\mathrm{Cl}^-}^{\mathrm{NaCl}}$ is the value obtained by subtracting the electrochemical potential of a chlorine ion in NaCl at a certain point from that at other point at lower temperature by 1°C, and $s_{\mathrm{Cl}_2}^{\mathrm{Cl}_2}$ is the entropy of a chlorine molecule in the chlorine gas. Now the problem is merely to calculate $eQ_{\mathrm{Cl}^-}^{\mathrm{NaCl}}$.

Let us now assume that positive and negative ion vacancies are distributed at random. The chemical potential of an Na^+ vacancy, μ_+, and that of a Cl^- vacancy, μ_-, which are defined as the Gibbs free energy of taking out a sodium ion and a chlorine ion in a normal site into the vacuum, respectively, are then given by

$$\left.\begin{aligned}\mu_+&=\mu_+{}^0+kT\ln c_+\\ \mu_-&=\mu_-{}^0+kT\ln c_-\end{aligned}\right\} \tag{6}$$

where $\mu_+{}^0$ and $\mu_-{}^0$ are the Gibbs free energies of taking out a sodium ion and a chlorine ion in a normal site in a perfect crystal of NaCl into the vacuum, respectively, c_+ and c_- are the mol fractions of sodium- and chlorine-ion vacancies, respectively. From Eqs. (5) and (6), we can derive an expression for the thermoelectric power:

$$eQ=-\frac{t_-}{T}(h_s+Q_+{}^*+Q_-{}^*)+\frac{Q_+{}^*}{T}-k\ln c_+ +\left(s_{\mathrm{Cl}^-}^{P}-\frac{1}{2}s_{\mathrm{Cl}_2}^{\mathrm{Cl}_2}\right)+k\Sigma\ln\frac{\nu_P}{\nu_+}\,. \tag{7}$$

Here t_- is the transport number of the chlorine ion, h_s is the enthalpy of formation of a pair of Schottky defects, $Q_+{}^*$ and $Q_-{}^*$ are the heat of transport of an Na^+- and a Cl^--vacancy, and $s_{\mathrm{Cl}^-}^{P}$ is the entropy of a sodium ion in a perfect crystal of NaCl. Further, ν_P and ν_+ are the frequency of a normal mode of lattice oscillations in a perfect crystal and that in a crystal including only an Na^+ vacancy as defect, and $\sum$ means the summation over all normal modes. The entropy of a pair of Schottky defects, s_s, is written as

$$s_s=k\Sigma\ln(\nu_P/\nu_+)+k\Sigma\ln(\nu_P/\nu_-)\,, \tag{8}$$

of which both terms are expected to be positive.[8] If we assume that they are equal, we have $k\ln\nu_P/\nu_+\sim 150\ \mu v$/degree according to Etzel and Maurer.[4] Further, the analysis of Etzel and Maurer gives $h_s\sim 2.02\ ev$. It may be assumed that $s_{\mathrm{Cl}^-}^{P}$ is equal to a half of the entropy of a pair of ions in a perfect crystal of NaCl which is obtained from the experiment on the specific heat. Then, we can find the values of $Q_+{}^*$ by comparing the theoretical expression (7) with the experiment on the thermoelectric power of NaCl at the impurity range ($t_-\sim 0$). It is to be noted that the diffusion of pairs of Cd^{++} and Na^+ vacancies, and of those of Na^+- and Cl^--vacancies, have no effect on Eq. (7), since they have no charge.

So far, we have neglected the Coulomb interaction between defects. We shall now consider this effect in the impurity range making use of the Debye-Hückel approximation. The chemical potential of an Na^+ vacancy, μ_+, is now written as[7]

$$\mu_+=\mu_+{}^0+kT\ln(c_+f_+)\,. \tag{9}$$

If the charge neutrality is assumed, the activity coefficient, f_+, is given by[7]

$$\ln f_+=-\frac{e^2}{2\varepsilon kT}\frac{\kappa}{1+\kappa R}\,,\qquad \kappa^2=\frac{8\pi e^2c_+}{v\varepsilon kT}\,, \tag{10}$$

where R is the effective shortest distance of approach of a Cd^{++} and an Na^+ vacancy without forming a complex, ε is the dielectric constant, and v is the volume per pair of ions of pure salt. Lidiard[6] has put $R\equiv\sqrt{2}\,a$ and $e^2/\sqrt{2}\,k\varepsilon a\equiv T_0$, where a is the normal anion-cation separation, and obtained $T_0=3900$°K from comparison with the experiment of Etzel and Maurer.[4] Further, he has obtained the expression of the degree of association of a Cd^{++} and an Na^+ vacancy, p, as

Table I. The value of Q_c in μv/°C in NaCl

°C	$c_0=10^{-4}$	$c_0=10^{-8}$	$c_0=10^{-2}$
200	+26	+59	+63
300	+ 4	+22	+25
400	− 4	+ 5	+ 9
500	− 7	− 3	+ 1
600	− 7	− 6	− 2
700	− 7	− 8	− 4

$$\frac{p}{(1-p)^2}=\exp\left[\frac{T_0}{T}+\ln(12c_0)-\frac{2(2\sqrt{2}\,\pi)^{1/2}(T_0/T)^{3/2}[c_0(1-p)]^{1/2}}{1+4(\sqrt{2}\,\pi)^{1/2}[(1-p)c_0T_0/T]^{1/2}}\right], \tag{11}$$

where c_0 is the mol fraction of doped cadmium. From Eqs. (10) and (11), $\ln f_+$ is written as

$$-kT\ln f_+=\frac{kT_0}{2}\left[1+\frac{T}{T_0}\ln(12c_0)-\frac{T}{T_0}\ln\frac{p}{(1-p)^2}\right]. \tag{12}$$

The electric field is obtainable from the condition that the current density due to Na^+ vacancies :[11]

$$j_+=\frac{\sigma_+}{e}\left(eE+\frac{\partial\mu_+}{\partial c_+}\frac{dc_+}{dx}+\frac{Q_+}{T}\frac{dT}{dx}\right) \tag{13}$$

vanishes. Here σ_+ is the partial conductivity due to Na^+ vacancies. From Eqs. (9), (11), (12) and (13), we find

$$eQ=\frac{Q_+{}^*}{T}-k\ln[c_0(1-p)]+\left(s^P_{Cl^-}-\frac{1}{2}s^{Cl_2}_{Cl_2}\right)+k\Sigma\ln\frac{\nu_P}{\nu_+}+eQ_c\,, \tag{14}$$

where eQ_c is obtained by differentiating Eq. (12) with respect to T as

$$eQ_c=\frac{k}{2}\,\frac{[1+p+p\ln\{12c_0(1-p)^2/p\}]\cdot[T_0/T+\ln\{12c_0(1-p)^2/p\}]}{p[T_0/T+\ln\{12c_0(1-p)^2/p\}]-2(1+p)[1+4(\sqrt{2}\,\pi)^{1/2}\{(1-p)c_0T_0/T\}^{1/2}]} \tag{15}$$

and represents the deviation from the simple theory. Table I. shows the values of Q_c in μv/degree at several temperatures and with several mol fractions of doped cadmium, where p has been obtained from Eq. (11). It is seen from Table I. that the correction term, Q_c, is so small that it need not to be taken into account in the analysis of the thermoelectric power of NaCl, at least, in the impurity range.

Nikitinskaya and Murin have measured the thermoelectric power of NaCl by making use of Pt etc. as the electrodes.[9] It is difficult to interprete their results, since we do not know what is the equilibrium condition at the junction between Pt and NaCl. The experiment with use of the chlorine electrode is desirable.

§ 3. The Effect of the Coulomb Interaction on the Thermoelectric Power of AgBr, and the Relations between Q_M and Q_H

Let us consider the effect of the Coulomb interaction also in the case of AgBr in the Debye-Hückel approximation, The ionic conduction in AgBr is due to both Ag^+ interstitial ions and vacancies. The chemical potential of an Ag^+ vacancy, μ_v, is given by Eqs. (9) and (10), where R means the effective shortest of approach of three kinds of ions (i.e. a Cd^{++} dissociated, an Ag^+ interstitial ion and an Ag^+ vacancy) without forming a complex, and the suffix v is used in place of $+$, in this section. The chemical potential of an Ag^+ interstitial ion, μ_i, is given by

$$\mu_i=\mu_i{}^0+kT\ln(c_if_i/2)\,, \tag{16}$$

where c_i and f_i are the mol fraction and the activity coefficient of an Ag^+ interstitial ion, respectively. The neutrality condition gives $f_i=f_v$. The current density due to Ag^+ vacancies, j_v, is given by Eq. (14). On the other hand, the current density due to Ag^+ interstitial ions, j_i, is given by[11]

$$j_i=\frac{\sigma_i}{e}\left(eE-\frac{\partial\mu_i}{\partial c_i}\frac{dc_i}{dx}-\frac{\partial\mu_i}{\partial c_v}\frac{dc_v}{dx}-\frac{Q_i{}^*}{T}\frac{dT}{dx}\right), \tag{17}$$

where σ_i is the partial conductivity due to Ag^+ interstitial ions. As f_i and accordingly μ_i depend on c_v, the third term in Eq. (17) represents the diffusion of Ag^+ interstitial ions in the presence of the concentration gradient of Ag^+ vacancies. From Eqs. (3) and (7) in (I), we find the thermoelectric power Q :

$$eQ=-\frac{t_i}{T}(h_F+Q_i{}^*+Q_v{}^*)-k\ln c_v+\frac{Q_v{}^*}{T}+\alpha+eQ_c\,. \tag{18}$$

Here t_i is the transport number of Ag^+ interstitial ions, α is the notation used in (I). Further, Q_c represents the deviation from the simple theory and is given by

$$eQ_c=-\frac{\partial}{\partial T}[kT\ln f_v]+2kTt_i\frac{\partial}{\partial T}\ln f_v\,, \tag{19}$$

$$\frac{\partial}{\partial T}[kT\ln f_v]=\frac{e^2\kappa}{4\varepsilon(1+\kappa R)^2}\left[\frac{1}{T}+(3+2\kappa R)\frac{1}{\varepsilon}\frac{d\varepsilon}{dT}+\frac{1}{v}\frac{dv}{dT}+2\kappa\frac{dR}{dT}-\frac{1}{c_v}\frac{dc_v}{dT}\right], \tag{20}$$

$$2kT\frac{\partial}{\partial T}\ln f_v=\frac{e^2}{\varepsilon T}\frac{\kappa}{1+\kappa R}+2\frac{\partial}{\partial T}[kT\ln f_v]\,. \tag{21}$$

Now, we roughly estimate the values of Q_c making use of the values of parameters obtained from the simple theory by Teltow.5) Table II shows the values of Q_c in μv/degre for AgBr+0.25%−CdBr$_2$ and pure AgBr. For comparison, the experimental values of Patrick and Lawson are also shown. Here, the value of ε is obtained from the extrapolation of the experimental values of Eucken and Büchner.10) It is seen from Table II that the correction due to the Coulomb interaction is small compared with the experimental values.

Reinhold3) has measured the thermoelectric powers of silver halides and lead halides in two different ways, one is with use of the metallic electrodes and the other with use of the halogen electrodes. We shall find the relations between the thermoelectric powers with the metallic electrodes, Q_M, and those with the halogen electrodes, Q_H. The assumption of local equilibrium in silver halides, AgX, leads to

$$\zeta_{\mathrm{Ag}^+}+\zeta_{\mathrm{X}^-}=\mu_L^P \tag{22}$$

where μ_L^P is the chemical potential of a pair of ions in a perfect crystal of AgX. From Eq. (5) and Eq. (3) in (I), we obtain

$$Q_H=Q_M+S \tag{23}$$

$$eS=s_L^P-s_{\mathrm{Ag}}^{\mathrm{Ag}}-s_{\mathrm{X}_2}^{\mathrm{X}_2}/2\,, \tag{24}$$

where s_L^P is the entropy of a pair of ions in a perfect crystal of AgX. Similarly we have, in the case of lead halides,

$$eS=(s_L^P-s_{\mathrm{Pb}}^{\mathrm{Pb}}-s_{\mathrm{X}_2}^{\mathrm{X}_2})/2\,, \tag{25}$$

where s_L^P is the entropy per molecule of PbX$_2$ in a perfect crystal of PbX$_2$. Table III shows the values of Q_H-Q_M in μv/degree obtained by Reinhold and those of S in μv/degree found from the experiment on the specific heat.

Ionic Conduction in β-Ag_2Te and β-Ag_2Se

By Shin-ya MIYATANI

Department of Physics, Faculty of Science,
Niigata University

(Received March 17, 1959)

The ionic conductivity, σ_i, of β-Ag_2Te and β-Ag_2Se is estimated from the time constant of the ionic polarization with the help of the galvanic cell Ag|AgI|specimen|Pt, showing that σ_i depends on the composition (deviation from the stoichiometric ratio) in contrast with the composition-independent σ_i in their α phase. The chemical potential of Ag ion, ζ_i, known from the e.m.f., E, of the cell is also dependent on the composition in the β phase, and accordingly E does not represent the relative position of the Fermi level as in the α phase. This composition dependence of ζ_i and σ_i is accounted for by a simple theory. In addition, the electronic properties measured as functions of E are also compared with the theory with a correction to E by ζ_i.

§ 1. Introduction

As known from the measurements of the transport numbers by Tubandt, Wagner et al.[1], Ag ions are mobile in Ag_2S, Ag_2Se and Ag_2Te. The ionic conductivity, σ_i is fairly large in their α phases, while it is so small in their β phases that the measurement of the transport number becomes difficult except β-Ag_2S in which the electronic conductivity, σ_e, is also small as shown in Fig. 1. We have already reported about "polarization method" for measuring σ_i, which is available even in such a case of small transport number[2],[3]. The results for β-Ag_2Te and β-Ag_2Se obtained by this method will be reported in the present paper. Fig. 1 shows a somewhat schematic diagram of σ_e and σ_i thus obtained vs temperature[3].

Now, as used already in Tubandt-Wagner method, the galvanic cell Ag|AgI| Ag_2 VIb specimen Pt is very convenient, since Ag can be freely supplied to or removed from the specimen and e.m.f., E, of the cell gives us the information of the chemical potential of Ag, ζ_i, in the specimen[4],[5]. That is,

$$eE=\zeta_a{}^0-\zeta_a=\zeta_e{}^0+\zeta_i{}^0-(\zeta_e+\zeta_i)\ , \qquad (1)$$

where ζ_a, ζ_i and ζ_e are the chemical potentials of an Ag atom, Ag ion and electron in the specimen respectively, and the superscript 0 represents those in Ag-saturated state. In the α phase, $\zeta_i=\zeta_i{}^0$, namely ζ_i is composition-independent, since there are more than two available sites for each Ag ion (average crystal)[6], giving $eE=\zeta_e{}^0-\zeta_e$, that is, E representing the relative position of the Fermi level. In the β phase, on the contrary, $\zeta_i\neq\zeta_i{}^0$, namely composition-dependent, as seen later, which means that the character of average crystal becomes lost. Correspondingly, the ionic conductivity, σ_i, is composition-independent in the α phase, while it will be, in general, composition-dependent in the β phase as AgCl, AgBr etc. In fact, σ_i depends on the composition in β-Ag_2Se as seen later. Thus, the β phases of Ag_2Te and Ag_2Se are of interest in the sense that they are located in a transient region from the average type to non-average.

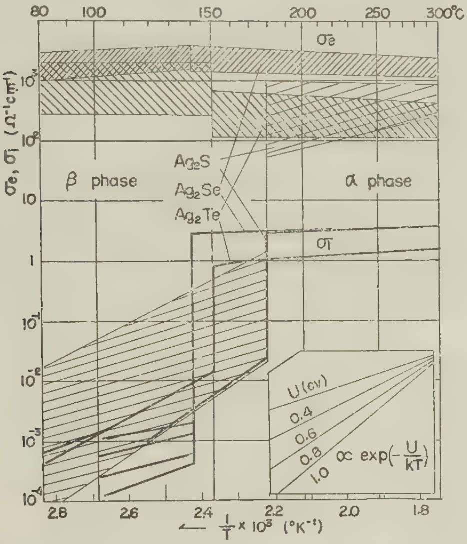

Fig. 1. σ_e and σ_i vs $1/T$ (somewhat schematic). The σ_e's are in the range shown by hatching, depending on the composition. $\exp(-U/kT)$ is also drawn for reference.

§ 2. Experimental and Comparison with Theory

(a) *The chemical potential of Ag ion*

Fig. 2 shows E and σ_e vs temperature for various x values where x represents the deviation from the stoichiometric ratio as $Ag_{2(1+x)}Te$ (or Se) and is equal to the concentration of excess Ag, D, divided by the concentration of Ag ion, N, ($eN=4.77\times10^3 C\ cm^{-3}$ for Ag_2Te and 5.25×10^3 for Ag_2Se). First, let us consider Ag_2Te. The E vs temperature curves (Fig. 2(a)) show that they become to separate from each other with decreasing temperature. Such a separation is not observed in the α phase and can not be attributed to the chemical potential of electron, ζ_e since the electrical properties such as thermoelectric power, Nernst coefficient etc. do not indicate the increase of degeneracy large enough to account for such a separation. It should be, therefore, attributed to the chemical potential of Ag ion, ζ_i, that is, ζ_i should be composition-dependent.

In order to obtain the theoretical expression for ζ_i, let us assume there are two available sites, a and b, of different occupation energies, E_a and E_b ($E_a>E_b$) for each Ag ion. In the limit of perfect average crystal ($E_a=E_b$) the two sites are equivalent, and in the other limit of $E_a\gg E_b$ the a-site corresponds to interstitial and the b-site to normal site.

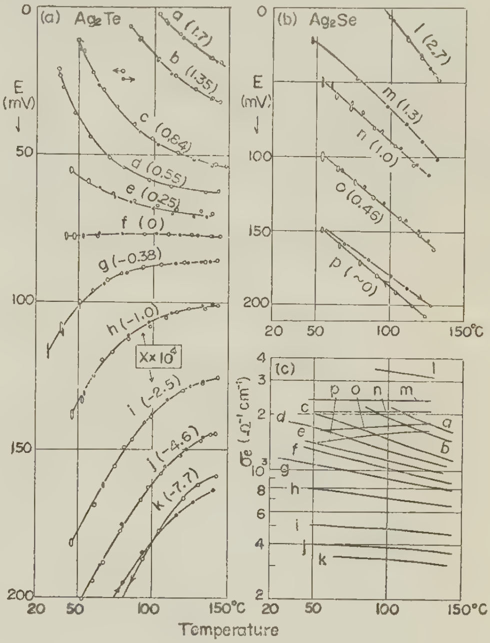

Fig. 2. (a) E vs temperature for Ag_2Te with various x values where the x values are known relative to a certain composition from the amount of Ag removed or supplied across AgI, and $x=0$ is determined by the analysis in the α phase. (b) The similar plots for Ag_2Se where $x=0$ is determined by the analysis of σ_i as seen later. (c) σ_e vs temperature corresponding to (a) and (b).

Then ζ_i is given, as seen in the next paragraph, by

$$\left.\begin{aligned}\zeta_i&=\frac{E_a+E_b}{2}-\frac{kT}{2}\log j+kT\log(\sqrt{1+z^2}+z)\,,\\ z&\equiv\frac{n-N}{2\sqrt{j}\,AN}=\frac{x}{2\sqrt{j}\,A}\,,\\ A&\equiv\exp\left(-\frac{E_a-E_b}{2kT}\right),\end{aligned}\right\}\qquad(2)$$

where n is the concentration of Ag ion, N is that in the stoichiometric composition which is equal to the concentration of the b-site, N_b, and j is the ratio of the number of a-site to b-site, N_a/N_b. Eq. (2) is reduced, if $|z|\gg 1$, to

$$\left.\begin{aligned}\zeta_i&=E_a+kT\log\frac{n-N}{N_a} &&(n>N)\,,\\ \zeta_v&=-\zeta_i=-E_b+kT\log\frac{N-n}{N} &&(n<N)\,,\end{aligned}\right\}\qquad(3)$$

which are the familiar expressions for single defect; interstitial only and vacancy only respectively. Fig. 3(a) shows $\log(\sqrt{1+z^2}+z)$ (the last term of Eq. (2) divided by kT) vs $\log A$, taking $x/\sqrt{j}$ as parameter. The abscissa can be regarded as $1/T$ in a certain scale because of $-\log A=(E_a-E_b)/(2kT)$. This function tends to $\log(x/\sqrt{j})-\log A$ for $z\gg 1$ as shown by broken lines, corresponding to Eq. (3). Further, since $\log(\sqrt{1+z^2}+z)$ is an odd function of z or x, the curves for negative x become same, exclusive of sign. For negative x, however, the curves in the figure may be regarded as $|-\log\sqrt{j}+\log(\sqrt{1+z^2}+z)|$ vs $\log A$ taking x itself as parameter if $|z|$ is large, since the latter function tends to $\log(x/A)$. Fig. 3(a) is rewritten as 3(b); $-(1/2)\log j+\log(\sqrt{1+z^2}+z)$ vs x, taking A and j as parameters, which represents how ζ_i changes with x at a fixed temperature.

Now, returning to the experimental, the change of E with varying temperature in Fig. 2(a) is constituted of three factors; the change of $\zeta_a{}^0$, of ζ_e, and of ζ_i. The first corresponds to the change of the saturation limit for Ag, and the second is due to the change of carrier densities and the energy

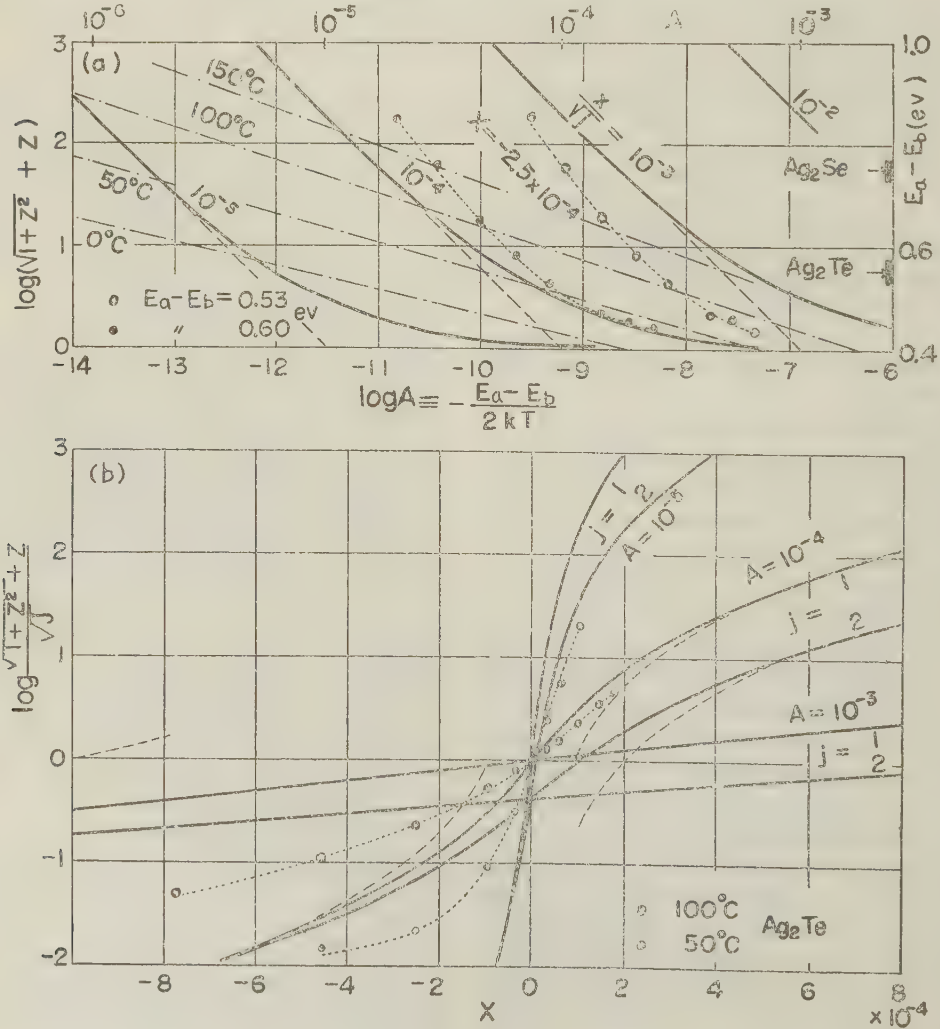

Fig. 3.

gap which may be taken as constant (composition-independent) in the present rough discussion, and the last will be due to the temperature dependent term in Eq. (2). One will see in Fig. 2(a) that the inclinations of E-curves decrease with increasing temperature and become almost zero at the neighborhood of the transition point, which may mean that the composition-dependent term of ζ_i tends to zero at such a temperature. Further the E curve for $x=0$ is almost horizontal and so we may take the curves in Fig. 2 (a) as representing the last term of Eq. (2), exclusive of the respective additive constants coming from the difference of ζ_e which will be nearly equal to the difference of E at a higher temperature e.g. 140°C. Thus, comparing Fig. 2(a) with 3(a), one will see that it may be possible to account for the experimental by Eq. (2). The value of E_a-E_b is accordingly obtainable, e.g. from the inclination of E curves for large z. Some of the experimental values are shown in Fig. 3(a) and (b); assuming two values of E_a-E_b for (a) and assuming the curve passes the origin for (b). From these plots, one will see that the experimental and theory show at least a qualitative agreement. The value of E_a-E_b thus estimated is shown on the ordinate axis at right. For convenience, E_a-E_b vs $\log A$ lines are also drawn as the chain lines, making use of which it is easy to know the A value from the E_a-E_b value.

Next, let us consider Ag_2Se (Fig. 2(b)). In

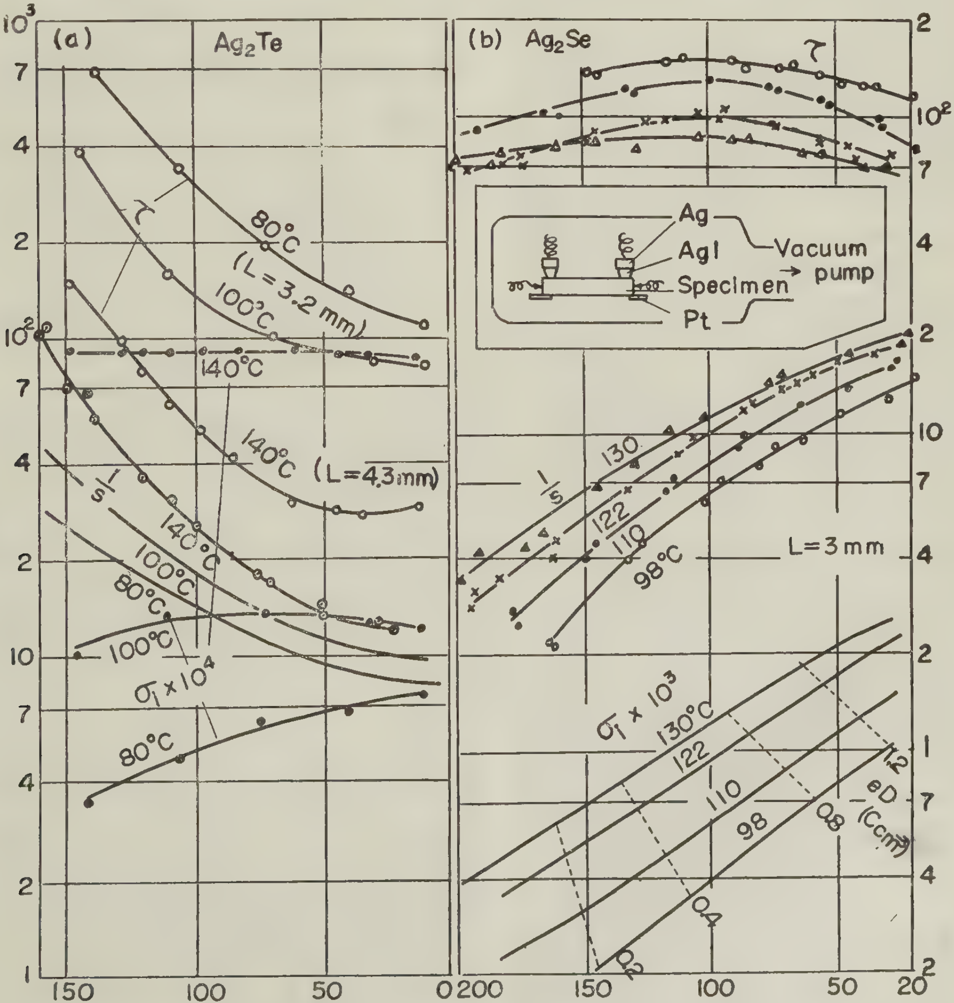

Fig. 4. τ (sec), $1/s$ (C v^{-1} cm^{-3}), and σ_i (Ω^{-1} cm^{-1}) vs E.

this case, the negative x is not realized owing to the evaporation (or precipitation) of Se, and so the separation as appears in Ag_2Te is not remarkable. However, the rapid increase of E with increasing temperature suggests also that it is due to ζ_i. The value of A will be estimated in the next section.

(b) *Ionic conductivity*

As mentioned in Introduction, the ionic conductivity, σ_i, is obtainable from the polarization as follows[2]: When a constant direct current is sent to the specimen through platinum electrodes, the polarization of Ag ions occurs along the specimen. The time constant, τ, for the polarization to build up or decay out is given by

$$\frac{1}{\tau}=\left(\frac{\pi}{L}\right)^2\frac{\sigma_i\sigma_e}{\sigma_i+\sigma_e}\frac{\partial(\zeta_e+\zeta_i)/e}{\partial(eD)}\approx\left(\frac{\pi}{L}\right)^2\sigma_i\left|\frac{\partial E}{\partial(eD)}\right|, \tag{4}$$

where L is the length of the specimen (see also the next paragraph (b)), The value of $|\partial E/\partial(eD)|\equiv s$ is known if one measures the change of E at the change of eD which is equal to the amount of electricity sent across AgI divided by the volume of the specimen. The time constant, τ, is also obtainable from the time rate of change of E at the polarization building up and decaying out (see the schematic diagram in Fig. 4). Thus σ_i is estimated with use of Eq. (4). When σ_i is as small as the present case, L should be chosen properly small so that τ is not too large. Besides, AgI–5%AgCl is used in place of pure AgI, since σ_i in the γ phase of pure AgI is very small.

Fig. 4 shows τ, $1/s$ and σ_i obtained from them vs E for different temperatures. As seen in the figure, σ_i of β-Ag_2Te is almost composition independent at least at higher temperatures, while σ_i of β-Ag_2Se depends remarkably on the composition. Then, let us consider such a composition dependence with the help of the simple model assumed in the preceding section. From a simple calculation (see § 3 (c)), σ_i is expected as

$$\sigma_i=eN\sqrt{j}\,A\{(a+b)\sqrt{1+z^2}+(a-b)z\}\,, \tag{5}$$

where a and b are the mobilities of Ag ion in the a-site and b-site respectively. If z is large, Eq. (5) is reduced to $\sigma_i=2eN\sqrt{j}\,Az=eaD$. In order to compare Eq. (5) with the experimental, σ_i of Ag_2Se is plotted against eD (relative) as Fig. 5, which shows that σ_i is, in fact, proportional to eD for large z only if the origin of eD is properly chosen as shown in the figure. From the inclination of the straight lines representing $\sigma_i=eaD$, the value of a is determined for each temperature as 0.9×10^{-3} cm² sec⁻¹ volt⁻¹ at 98°C, 1.1×10^{-3} at 110°C, 1.4×10^{-3} at 122°C and 1.6×10^{-3} at 130°C. Further, the deviation from this line is

$$\sigma_i-aeD=eN\sqrt{j}\,A(a+b)(\sqrt{1+z^2}-z)\,, \tag{6}$$

which is $eN\sqrt{j}\,A(a+b)\equiv\sigma_{i0}$ at $z=0$ $(D=0)$.

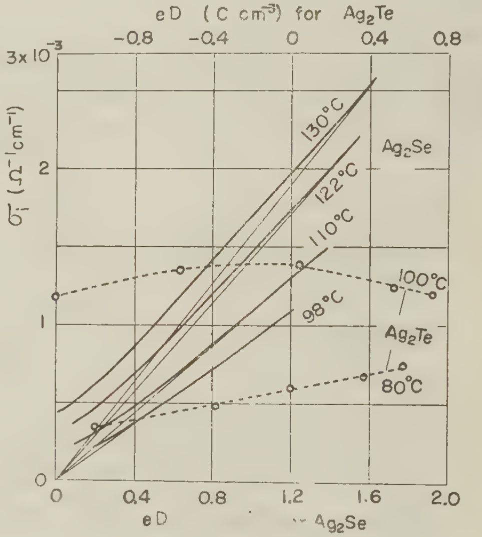

Fig. 5. σ_i vs eD.

The value of σ_{i0} is estimated by extrapolation to $D=0$, and hence we have $jA(1+b/a)$ as 3.2×10^{-5} (110°C), 4.0×10^{-5} (122°C) and 5.1×10^{-5} (130°C). Thus we see that A is order of 10^{-5} at these temperatures. On the other hand, the value of A is required to be $1\sim2\times10^{-5}$ at 124°C from the analysis of the electronic properties (see § 3 (d)). The value of E_a-E_b thus estimated is also shown in Fig. 3(a).

Next, let us consider σ_i of Ag_2Te. At temperatures higher than 140°C, where ζ_i is almost composition independent as mentioned in (a), σ_i is expected to be also composition independent just as in the α phase. This is in fact the case as mentioned already (Fig. 4). Regarding the composition dependence at lower temperatures (Fig. 5), we can not say anything sure since the measurement of τ is not too reliable.

In conclusion, one will see, from the description so far, that what determines the composition dependence of ζ_i and σ_i is A (or the reduced energy difference between two sites, $(E_a-E_b)/(kT)$) and x (or the amount of excess or deficit mobile ions). The α-phase of Ag_2Te, Ag_2Se and Ag_2S and the β phase of Ag_2S are average type, and β-Ag_2Se is almost non-average, and β-Ag_2Te is just intermediate.

§ 3. Theoretical and Electronic Properties

(a) *The chemical potential of an Ag ion*

If there are two available sites, a and b, of different occupation energies, E_a and E_b ($E_a>E_b$) for an Ag ion, then Ag ions will be distributed in these two kinds of sites with different concentration, n_a and n_b. From the condition of thermal equilibrium we have

$$\zeta_i=E_a+kT\log\frac{n_a}{N_a-n_a}\,, \tag{7}$$

$$\frac{n_a(N_b-n_b)}{n_b(N_a-n_a)}=\exp\left(-\frac{E_a-E_b}{kT}\right)\equiv A^2\,, \tag{8}$$

where N_a and N_b are the concentration of the a-sites and b-sites respectively. From Eqs. (7), (8) and $n=n_a+n_b$, ζ_i is, putting $N_b=N$, $N_a=jN$, expressed as

$$\left.\begin{aligned}\zeta_i&=\frac{E_a+E_b}{2}+kT\log\frac{\sqrt{1+z^2}+z-\sqrt{j}\,A}{\sqrt{j}-A(z+\sqrt{1+z^2})}\,,\\ z&\equiv\frac{1-A^2}{2\sqrt{j}\,A}\left(\frac{n}{N}-\frac{1-jA^2}{1-A^2}\right).\end{aligned}\right\} \tag{9}$$

Also, n_a and n_b are given by

$$n_a=\frac{\sqrt{j}\,NA}{1-A^2}(z+\sqrt{1+z^2}-\sqrt{j}\,A)\,, \tag{10}$$

$$n_b=\frac{N}{1-A^2}\{1-\sqrt{j}\,A(\sqrt{1+z^2}-z)\} \tag{11}$$

respectively. If $A\ll 1$, i.e. $(E_a-E_b)\gg kT$, then Eq. (9) is reduced to

$$\left.\begin{aligned}\zeta_i&=\frac{E_a+E_b}{2}-\frac{kT}{2}\log j+kT\log(\sqrt{1+z^2}+z)\,,\\ z&=\frac{1}{2\sqrt{j}\,A}\left(\frac{n}{N}-1\right).\end{aligned}\right\} \tag{12}$$

(b) *Polarization*

When a constant direct current is sent to the specimen through the platinum electrodes at the ends of the specimen, the current densities carried by electrons and ions, i_e and i_i, are given by

$$i_e=\sigma_e\frac{d}{dx}\left(\frac{\zeta_e}{e}-\Phi\right), \tag{13}$$

$$i_i=-\sigma_i\frac{d}{dx}\left(\frac{\zeta_i}{e}+\Phi\right), \tag{14}$$

where Φ is the electrostatic potential. Under the boundary condition that there is neither supply nor removal of Ag at the electrodes, these differential equations can be solved²⁾, resulting in the expression for the time constant, τ, as given by Eq. (4).

(c) *Ionic conductivity*

The ionic conductivity, σ_i, may be expressed as

$$\sigma_i=en_a\mu_a+en_b\mu_b\,, \tag{15}$$

where μ_a and μ_b are the mobilities of Ag ions in the a-site and b-site respectively. In particular, if $E_a=E_b$ (perfect average), then $\mu_a=\mu_b=\mu$ and hence $\sigma_i=en\mu\approx eN\mu$, that is, composition-independent σ_i. On the contrary, if $E_a-E_b\gg kT$, and $|x|$ is so large that Eq. (3) is valid, then Eq. (15) is reduced to $\sigma_i=en_a\mu_a$ for positive x and $\sigma_i=en_b\mu_b\equiv e(N-n_b)\mu_v$ for negative x. As seen by the latter equation, μ_a, μ_b, and so μ_v will be dependent of n_a and n_b as given by $\mu_a=a(N_a-n_a)/N_a$, $\mu_b=b(N-n_b)/N$, and so $\mu_v=bn_b/N$. Then σ_i may be given by

$$\sigma_i=ean_a\frac{N_a-n_a}{N_a}+ebn_b\frac{N-n_b}{N}\,, \tag{16}$$

which is rewritten, making use of Eqs. (10) and (11), as

$$\sigma_i=\frac{eN\sqrt{j}A}{(1-A^2)^2}\left(a+\frac{b}{y^2}\right)(y-\sqrt{j}\,A)\left(1-\frac{A}{\sqrt{j}}y\right), \tag{17}$$

where $y=\sqrt{1+z^2}+z$. If $A\ll 1$, it is reduced to

$$\begin{aligned}\sigma_i&=eN\sqrt{j}\,A\left(ay+\frac{b}{y}\right)\\ &=eN\sqrt{j}\,A\{(a+b)\sqrt{1+z^2}+(a-b)z\}\,,\end{aligned} \tag{18}$$

which is again reduced to $eN\sqrt{j}\,A2az=ea(n-N)$ for $n<N$, and $eb(N-n)$ for $N>n$, if $|z|\gg 1$. Here, it becomes meaningless to give a and b seperately according as A increases and approaches to unity where the a- and b-sites are equivalent.

(d) *Electronic properties*

Fig. 6(a) shows σ_e and $R\sigma_e$ vs eE/kT for Ag_2Se, where R is the Hall coefficient. As emphasized so far, E contains ζ_i beside ζ_e, and so the above plot is rewritten as the plot against $eE/kT+\log(\sqrt{1+z^2}+z)=$ const. $-\eta_1$ as (b), where $A=10^{-5}$ and $j=1$ are assumed and η_1 is the reduced Fermi energy. (c) is the similar plot for $\theta\equiv e\Theta/k$ (reduced thermoelectric power). The theoretical curves are drawn so as to fit with the experimental points as shown in (b) and (c), where the relaxation time is assumed constant, i.e. the mean free path $l=l_0(\mathcal{E}/kT)^{1/2}$ since $R\sigma_e$ is almost constant. We obtain, under such assumptions, the electron mobility $\mu=el_0/\sqrt{2m_1kT}$ as 1500 cm^2 s^{-1} v^{-1} and effective electron mass, m_1, as 0.11m at 124°C. Next, Fig. 7(a) and (b) are the similar plots against eE/kT corrected by $\log(\sqrt{1+z^2}+z)$ for Ag$_2$Te, where $A=2.7\times10^{-4}$ ($E_a-E_b=0.53$ eV) and $j=1$ are assumed; (a) is σ_e and $R\sigma_e$ vs η_1+const. and (b) is θ, q, $\sqrt{b}$, and w vs η_1+const., where $q\equiv eQ(kR\sigma_e)^{-1}$ is the reduced Nernst coefficient, $b\equiv(-\Delta\sigma)\sigma^{-1}(HR\sigma_e)^{-2}$ is the reduced magnetoresistance, and $w\equiv\Delta\Theta\Theta^{-1}(HR\sigma_e)^{-2}$ is the reduced magnetothermoelectric power. The theoretical expressions are as follows; $q=\eta-\theta-\gamma/\alpha$, $b=\varphi/(t\alpha^2)-1$, and $w=(\eta-\theta)b+\gamma/\alpha-\psi/(t\alpha^2)$, where $\eta=\eta_1$, $t=\sigma_1/(\sigma_1+\sigma_2)$ (σ_1; electron conductivity, σ_2: hole conductivity and α, γ, φ and ψ are the Fermi-Dirac integrals as defined in the reference 7). The theoretical curves are drawn as shown in the figure where the constant mean free path $l=l_0$ and the effective mass of hole $m_2=m$ are assumed. They agree with the experimental points fairly well except w, indicating the validity of our various assumptions. Thus we obtain the electron mobility $\mu_1=el_{01}/\sqrt{2m_1kT}$ as 5430 cm^2 s^{-1} v^{-1}, hole mobility μ_2 as 80 〃, m_1 as 0.06m, and the energy gap E_G as 1.5kT at 100°C. For both Ag$_2$Se and Ag$_2$Te, the agreement between experiment and theory as shown in Figs. 6 and 7 will be never obtained without the correction to E.

Structures of Ferroelectric Domains in Triglycine Sulfate

By Hiroo TOYODA, Shigeru WAKU and Hisao HIRABAYASHI
Nippon Telegraph and Telephone Public Corporation, Tokyo, Japan

(Received March 19, 1959)

Domain structures in ferroelectric glycine sulfate are studied by etching in various alcohols. Methyl alcohol etches the head of polarization more readily than the tail end, and gives, in a relatively short time, clear domain patterns. Moreover, this etchant etches the (001) surface very slowly and after a long time delineates the arranging manner of domains along the polarization axis. Domain boundaries have cylindrical surfaces parallel to b axis, but the sections perpendicular to the axis are quite indefinite in dimensition and direction. Domain terminated with a rounded tip in the antiparallell domain was observed. Crystal imperfection seems to have a considsrable effect on the domain structure of this crystal. Some preliminary studies of domain wall motion under the application of electric field are also reported.

§ 1. Introduction

since the discovery of ferroelectric glycine sulfate[1] many workers have had interests on this material. Crystal structure and optical properties[2], phase transition[3], dielectric and thermal properties[4], coercive field and spontaneous polarization[5],[6], switching properties[7]-[10], secondary electron emission[11], piezo-electric constants[12], conditions of crystal growth[13,14] have been studied. One of the authors has investigated the etch pits on the crystal by various liquids and discovered the difference of the etch pits between the tail and head of the polarization[15].

In order to visualize the domains, there are three principal techniques. The first one, the etching technique, is usually applied to barium titanate[16]-[20]. Phosphoric, nitric, chroric and fluoric acids etch the head of polarization of this material more easily than the tail end. The second one uses the polarized light and can reveal the domain structures by the displacement of optic planes. This is widely used for barium titanate[21]-[24] and other perovskite families[25]-[27], for rochelle salt[28]-[31], and potassium dihydrogen phosphate[32]. The third one takes advantage of the pyroelectric property of rochelle salt[33],[34]. Fine powder of sulphur, lycopodium and carmine, blown over a charged crystal, adheres to the surface and covers it with patches of red and yellow, indicating the polarity. The authors, in progress of the study, were informed that recently G. L. Pearson improved this technique and developed a colloical process applicable to all the ferroelectrics*.

Studies on the domain structure in triglycine sulfate (hereafter abbreviated as TGS) have not yet been reported. The reason exists, for one thing, in the fact that there are only 180° domain walls and that polarization reversal does not bring about any rotation of optic planes. Though Wood and Holden[2] noted the unsymmetrical etch pits to determine the crystal symmetry, precise description was omitted. The authors have investigated the domain structures of this material, using the etching technique and electron-microscope[35].

The crystal symmetry of TGS, $(NH_2CH_2COOH)_3H_2SO_4$, below its Curie point at 47°C, belongs to monoclinic space group, C_2^2 or $P2_1$. Wood and Holden[2] have presented two possible choices of axes. In this paper the authors adopt the one with β more close to 90°. Lattice parameters are

$$a_0=9.15\text{Å},\ b_0=12.69\text{Å},\ c_0=5.73\text{Å},\ \beta=105°40'.$$

An optic plane is inclined to (100) at an angle of 93° and approximately parallel to $(10\bar{2})$, Fig. 1 shows these relations.

§ 2. Experiments

Etch patterns on (010) surfaces

Etchants examined are water, acetic acid, acetone, ethyl ether, methyl alcohol, ethyl alcohol, n-buthyl alcohl, ethylene glycol, glycerine, ethylene glycol mono-methyl ether, and methyl alcohol containing various salts. All of these chemicals are of chemically pure grade.

---

* The authors are grateful to Dr. T. Nakamura for his kindness to show them a private communication from G. L. Pearson.

At first, etching results of naturally cleaved b face will be summarized. Water and acetic acid solve the surface very rapidly over the whole area, and no definite etch pattern can be found, while acetone, ethyl ether and glycerine do not etch the surface even after more than 24 hours at 30°C.

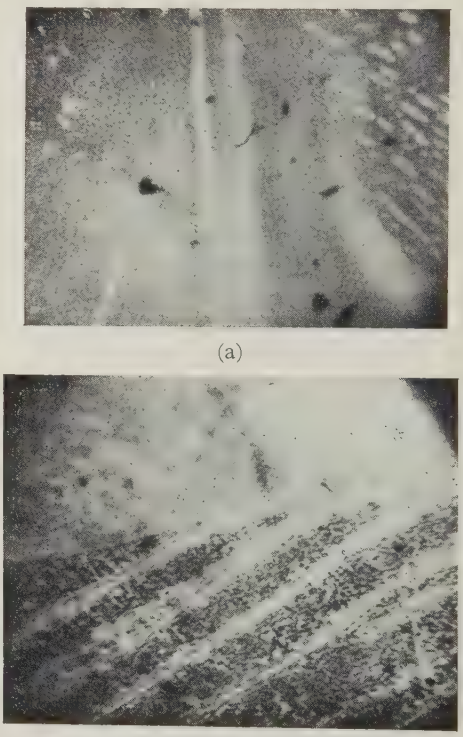
(×80)

Fig. 2. Etch pattern on (010) surface produced by methyl alcohol at 10°C for two days. Dark (uneven) area corresponds to the head of polarization, while light (flat) area corresponds to the tail.

Alcohols mentioned above, except glycerine, etch the surface in somewhat different manners. Monovalent alcohols examined all give similar etch pits, though the etching rate decreases with the increase of molecular weight. Etch pits due to methyl alcohol at 10°C for two days are shown in Fig. 2. Uneven part is found to correspond to the positive pole end of ferroelectric polarization, and the flat part to correspond to the negative pole. Etching rate increases with etching temperature. The pits at lower temperature are of the pyramidal shape, while those at higher temperature are long and of wave form. The results obtained at 27°C for two hours are shown in Fig. 3.



(a)

(b)

Fig. 3. Etch patterns on (010) surfaces produced by methyl alcohol at 27°C for two hours. (a) ×20, (b) ×70.

Fig. 4 shows the fine structure, revealed by electron microscope, of an etched surface. $(0\bar{1}0)$ faces overwhelm the negative pole end, while at positive end, considerable appearance of surfaces inclined to b axis, such as $\{1\bar{1}\bar{1}\}$ and $\{1\bar{1}0\}$, is characteristic.

Ethylene glycol etches the surface in a

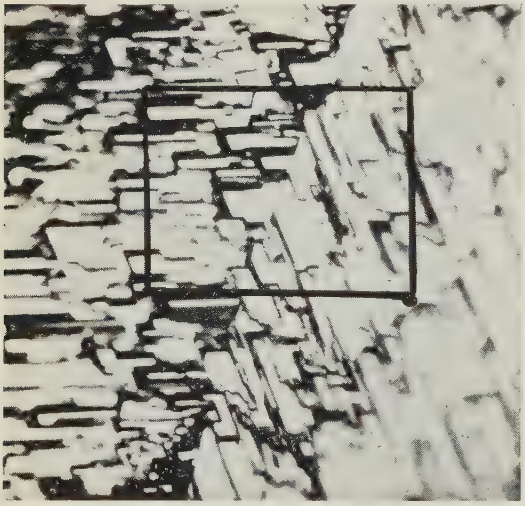
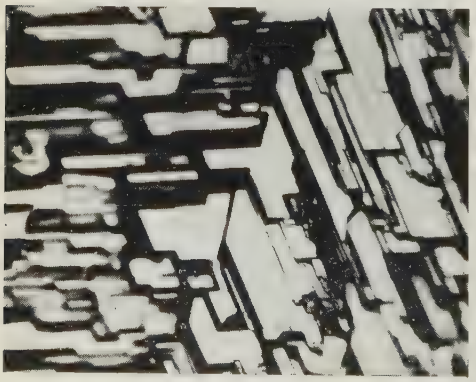
stream-line pattern, which is nearly rectilinear. Ethylene glycol mono-methyl ether, the socalled methyl cellosolve, is one of the most interesting ethcants. At higher temperature, the etch pits are not very different from the ones by ethylene glycol. Fig. 5 shows the picture of the etched surface at 27°C for 30 hours. Though presence of domains of both polarities is evidenced by the boundaries seen in the figure, the difference of the appearance between the head and the tail of polarization is not readily recognized. Etching rate becomes, however, very slow at lower temperature. Etching at 10°C for more than two weeks produces a remarkably regular etch pattern. Fig. 6 and 7 are pictures of typical parts of etched surfaces. Most of the edges, as seen in the pictures, correspond to $\langle 10\bar{1} \rangle$ and $\langle 100 \rangle$. The part, which displays the long strip-shaped patterns in Fig. 6, corresponds to the tail of polarization, while the short figures represent the head. Fig. 6 and 8 contain some domain boundaries. Patterns on both sides of the boundary differs each other, but the directions of edge lines are common to both regions.



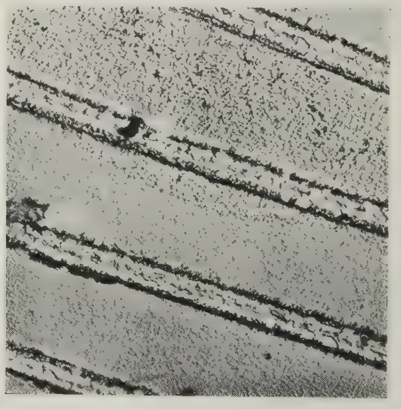
(a)



(b)

Fig. 8. Domain boundary reverled by methyl cellosolve on (010) surface. (a) ×180; (b) framed area in (a) enlarge; ×300.

Methyl alcohol containing some inorganic salts acts in a somewhat different manner, compared with pure alcohol. Methyl alcohol solves, to some degree, nitrates, hydroxides and halogenates, but it does not solve the sulfates to the same degree except in a few cases. When a crystal is immersed in methyl alcohol containing the salts other than sulfates, its whole surface is soon covered by numerous, small needlelike crystallites. No structural difference was found that might correspond to the difference of the polarization. In the methyl alcohol saturated with potassium hydroxide, a sharp striped pattern appears in addition to these crystallites. The stripes are completely linear and parallel to each other and shown in Fig. 9.



(×1000)

Fig. 9. Electronmicrospic eicture of the figure produced by methyl alcohol saturated with KOH on (010) surface.

Sulfates have completely different effect on etching. Methyl alcohol saturated with cupric sulfate did not gave any appreciable etch pits in 24 hours, while the saturated solution of ammonium sulfate gave a characteristic etch pattern, as shown in Fig. 10, with a marked difference for polarization. Etching advances more easily at the head of polarization and $\{0\bar{1}1\}$ and $\{1\bar{1}\bar{1}\}$ faces are observed distinctly in the picture.

The difference of the salts in the effect on etching may be accounted for by the fact that the salts other than sulfates can react with the sulfuric ion in TGS, and the resultant sulfate, which is less soluble in methyl alcohol, crystallizes on the surface. The significance of the characteristic etch pits given by methyl alcohol containing potassium hydroxide is not yet understood. (When the etched crystal was immersed in water, the surface dissolved, liberating some gas bubbles).

Etch patterns on the other surfaces

The effect of methyl alcohol and methyl cellosolve on the various surfaces of single crystal were investigated. Etching occurs more or less readily on all the surfaces. The etching proceeds very slowly on (001) surface, but it reveals the existence of domains. Herring-bones-shaped patterns obtained by etching in methyl alcohol for one month at room temperature are shown in Fig. 11. Characteristic [110] edges turn over to their mirror images across the domain boundaries. These boundaries are nearly parallel to b axis or direction of polarization, as is usual in 180° domain walls, but some domains have been found to terminate within the crystal with rounded end. An example is shown in Fig. 11 (b). Fig. 12 shows typical picture of several other surfaces etched in methyl alcohol for one month.

Fig. 11. Etch patterns on (001) surface produced by methyl alcohol at 10°C for one month. ×100. (b) shows a round-headed domain embeded in antiparallel domain. b-axis passes horizontally in the paper.

Shape of domains

The domain boundaries are cylindrical surfaces which are parallel to b axis, while their intersections with (010) face are rather indefinite. Spindle-shaped and rectilinear sections are most frequently observed, but their directions are not definite concerned with the crystal axes. There exist rarely domain side boundaries inclined to b axis. The angle of

inclination is not yet determined. Dimensions of domains also vary remarkably, ranging from few tenth of a millimeter to several millimeters.

Application of electric field

Cooling past the Curie point with application of D. C. electric field turns a crystal into a single domain, and the boundaries of various shapes, which have had existed before poling, completely disappear, as is found when re-etched in methyl alcohol. Also the domain patterns given by etching, after this single domain crystal is again heated over the transition without electric field, are quite different from the original domain patterns. Fig. 13 shows an etched crystal after poling by the field with opposite sign applied to two sets of diagonal quadrants respectively.

Some preliminary studies have been made on the dynamics of polarization reversal using etch technique, together with the supersonic method developed by K. Husimi[36] to measure the average polarization. Fig. 14 shows an etch pattern of a crystal with approximately vanishing average polarization, brought about by a pulse of 1.5 kv/cm and 100μ sec. at 10°C. It was assured by etch patterns that the domain penetrated completely through the crystal along b axis. Fig. 15 is also an example of a crystal with null polarization, reached by a lower field, 50 v/cm at 20°C. It was hard to say, in this case, that the domain penetration was complete. Though the electrode shape and temperature examined are not the same, this difference of penetration might be attributed to the field strength.

There are some exceptional crystals that display distinct unsymmetry in polarization reversal. In such a crystal, a low positive field E_1 brings about readily a 100 per cent polarization and the polarization does not decay after the removal of field. But in the negative direction, $-E_1$ brings about the polarization only to -50 per cent and thereafter, the polarization grows with successively growing negative field and arrives at -100 per cent by a quite higher field than E_1. When the negative field is lowered, the polarization falls off rapidly to -50 per cent at $-E_2$, the magnitude of which is far below E_1. Accordingly, a reversible pseudo-double hysteresis buckled at $-E_1$ and $-E_2$ is observed. This example may be understood as an extreme case of the phenomenon known as "lock-in". When this crystal was etched after application of high negative field, it was revealed that about one quarter of electroded area was polarized in positive direction (Fig. 16). Domain penetration was found to be complete. More detailed study on the effect of applied field are now in progress.

§ 3. Discussion

When one observes the plates of TGS along the b axis by polarized microscope, he can not find any displacement of extinction position across the domain boundaries. The fact is understood as follows. At the Curie point, crystal symmetry changes from $P2_1/m$ to $P2_1$ and two crystals with positive and negative polarization should be in the relation of mirror image against the mirror plane, which the crystal has had above Curie point. Alternatively said, two crystals are in the relation of inversion concerned with the center of symmetry of paraelectric phase. a and c axes are common to both crystals, while b axes are antiparallel to each other. Polarization reversal changes the crystal from a right handed one to a left handed one and does not displace the optic plane.

Above the Curie point, the glycine molecules have nearly flat sheetlike structures and one of them lies on the mirror plane, together with the inorganic anion, while two other glycines are situated symmetrically with re-

heavy full line; glycine molecule.

spect to the plane[4],[37]. Breakdown of the coplanarity of glycine molecule is believed to act as a trigger on the transition[1],[88]. Fig. 17 is a schematic picture of polarization reversal.

The absence of change of axial direction with polarization reversal explains the irregular shape of domain boundaries. Spindle-shaped sections may be favored since it lessens the wall energy. Imperfections may be playing the principal role to determine the various forms of boundaries. This assumption is supported by the anomaly observed under the application of electric field. Imperfections of some kinds seem to exist causing a strong crystalline field that aligns the polarization in one direction over a certain region of the crystal. Boundaries of domain terminated within the crystal as seen in Fig. 11 (b) and boundaries inclined to b axis should have higher energy because of the head-to-head coupling and they would be hard to be realized in a perfect crystal. The cause of existence may be also due to crystal imperfection.

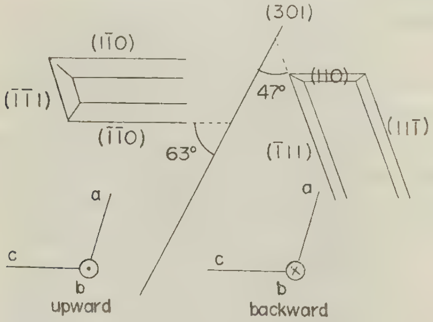

Fig. 18. A schematic picture of etch pits produced by methyl cellosolve.

Etched patterns produced by methyl cellosolve (Fig. 6 to 8) are explained in Fig. 18 on the basis of above-metinoned model. The boundary plane is taken as (301) according to an example in Fig. 8. b axis, which is perpendicular to the paper, points backwards in the right side of the boundary and upwards in the left side. Planes which appear readily by etching are shown on both sides. Difference in the etching rates for the planes with opposite indices results in different appearance of etch patterns, while the direction of intersecting lines of b faces with these planes is the same on both sides of the boundary.

Attempts have been made to reveal the twin structures in TGS by X-ray, but no result has been reached that differed in any way from the crystal of single domain. X-ray experiment showed that the change of β at the transition point was very little.

The results are summarized as follows;

1). Methyl alcohol and its solution saturated with ammonium sulfate etch more easily the head of polarization than the tail.

2). Methyl cellosolve gives a regular etch pattern closely related to the crystal axis.

3). Methyl alcohol etches other surfaces more or less readily and the etch pattern on (001) surface deilneates the domain structure.

4). Domains have cylindrical surfaces parallel to the polarization axis, while the sections normal to the axis are indefinite.

5). Crystal imperfections seem to have a large effect on the domain structure.

The authors are grateful to Mr. Y. Tanaka in preparation of the crystals of triglycine sulfate and to Mr. S. Hirota for electron microscopy. The authors wishes to express their sincere thanks to Mr. N. Niizeki for X-ray analysis and helpful discussions.

On the Electronic Structure of the U_2-center in KCl Crystals, I.

By Hiroshi MIMURA* and Yasutada UEMURA**

** Department of Applied Physics, University of Tokyo*

*** Department of Physics, University of Tokyo*

(Received May 2, 1959)

The electronic structure of the U_2 center is studied by using the so called "point ion lattice model".

The wave function which is obtained for the ground state of the U_2 center by considering the effects of various kinds of interactions, is applied to analyze the observed data of E.S.R.[1]

The 1s wave function of the free hydrogen orthogonalized to the core orbitals of the surrounding ions gives us the interpretation of E.S.R. in the order of magnitude, however, there still remain some discrepancies between the calculated and the observed values. The physical origins of these discrepancies are considered. The large zero point vibration of the U_2 center suggests to us that the width of the absorption curve of E.S.R. is broadened about 20% by the vibration. Discussions on the effect of polarization, of crystalline field and on the optical absorption are made briefly by assuming the point ion and dipole approximation.

§ 1. Introduction

In the course of the study on the electronic structure of hydrogen in alkali halide crystals, the U_2 center, which is supposed to be an interstitial hydrogen atom, is studied theoretically in this paper.

The experiments of E. S. R. and the optical absorption by Delbecq, Smaller and Yuster have given us much interesting information on the electronic states of hydrogen in alkali halides. From their experiments in U_2 center of KCl crystals we learn the following. The separation $(\Delta H)_s$ between the two peaks in the absorption pattern of E. S. R. is 500±10 gauss which corresponds to the doublet structure owing to the hyperfine interaction of the electron spin in the U_2 center with the nuclear spin of the proton. The width of each branch of the absorption pattern is measured as 68±5 gauss in the peak to peak value of the differential curve of the absorption. This value gives the half width $(\Delta H)_w$ of 81 gauss if the absorption curve is assumed to be Gaussian. It has been suggested that the width $(\Delta H)_w$ comes from the Fermi-interaction between the electron in the U_2 center and the nuclei of the surrounding ions.

Apparently it is not clearly understood why the observed width $(\Delta H)_w$ is so broad as to be comparable with those of the F center, even though the separation $(\Delta H)_s$ shows a slight change from the value of the free hydrogen.

Therefore the main purpose of this paper is to find the wave function of the U_2 center by which we are able to explain both the separation $(\Delta H)_s$ and the width $(\Delta H)_w$ quantitatively.

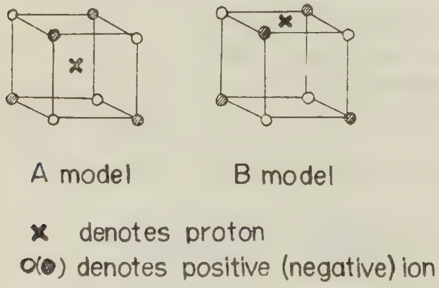

Fig. 1. Model of U_2 center.

As to the model of the U_2 center we assume that it is a hydrogen atom in the interstitial point A shown in Fig. 1. Strictly speaking it is not yet definitely established by the experiments that the hydrogen atom really exists at position A as in Fig. 1, however, it is highly probable because of the geometrically high symmetry of the point. Another possibility of the position of hydrogen, for example, is the position B as in Fig. 1, which is discussed briefly in Appendix I. The second assumption is made by confining our calculation to the range of the so called "point-ion-lattice approximation". Gourary and Adrain[(2)] have developed their theory of "point-ion-lattice approximation" and succeeded in explaining the experimental data of the optical absorption and E. S. R. which are observed in the F and M centers in alkali halides.

The results of their theoretical calculation seem to agree with the observed data, however, there remain some ambiguities in the treatment because it is difficult for this simple method of approximation to consider the effects of the displacement and polarization of the ions perfectly. In the case of the U_2 center these ambiguities are supposed to be smaller than in the cases of the F and M centers, for the crystal field arround the U_2 center has the high symmetry and there is no vacant lattice site, further more, the effect of the polarization is very small because of the localization of the trapped electron in the neighbourhood of the proton. Therefore we are able to clearly examine the applicability of this approximation. It is also believed that it will be easy to estimate the magnitudes of the complicated effects which are not included in this simple approximation.

In Chapter 1 we have tried to analyze the data of E. S. R. and to find the wave function for the ground state of U_2 center. It is shown in §4 that the wave function of the hydrogen orthogonalized to the orbitals of the core-electrons in the surrounding ions gives the correct order of magnitudes in $(\Delta H)_s$ and $(\Delta H)_w$. However, there still remain some discrepancies between the calculated and experimental values. In order to investigate the origins of the discrepancies, it is investigated in §6 to what extent the wave function is changed by the effects of the crystalline field, the polarization and the resonance to the outer orbitals in the alkali atoms. The limit of the applicability of the "point-ion-lattice approximation" is also discussed from the qualitative point of view. One of the characteristic features of U_2 center is the large amplitude of zero-point vibration of the proton in the interstitial point. The influence of this vibration on the absorption pattern of E.S.R. is estimated semi-empirically in §5 of Chapter 1.

In Chapter 2, the wave function and the

energy level for the first excited state of the U_2 center are studied by the same method as those in Chapter 1. We try to examine the three possible interpretations for the optical absorption of the U_2 center. The first, is that it corresponds to the transition between the ground and excited levels of hydrogen modified by the crystalline field, secondly that it corresponds to the exciton absorption disturbed by the U_2 center and thirdly that it corresponds to the electron transfer to the U_2 center from the four neighbouring halogen ions. In the actual crystal the latter two processes may not be clearly distinguished from each other and the observed excitation may be the mixture or in other words the resonance of the two processes. If we confine ourselves to the standpoint of the "point-ion-lattice approximation" it is not perfectly determined which of the three processes is really predominant in the crystal, and the agreement of the calculated values of the optical absorption with the observed ones seems worse than in the case of E. S. R. The reasons of the discrepancy are discussed qualitatively. As the result of whole discussions we can conclude that the hydrogen atom in alkali halides is a good tracer by which we are able to investigate the relation between the electronic structure of color centers and the many kinds of interactions which appear in the neighbourhood of centers.

I. Analysis of E. S. R.

—The electronic structure of the ground state—

§ 2. Expressions for the Separation and the Width

The absorbed microwave frequency ν corresponding to the transition between the Zeeman levels is given as follows:

$$h\nu = g\mu_B H + a_0 I_{0z} + \sum_i (a_i + b_i) I_{iz} \tag{1}$$

where H means the external magnetic field along the z axis, μ_B is the Bohr magneton, a_0 is the coupling constant of the hyperfine interaction between electron and proton, (a_i+b_i) is those between electron and i-th nucleous, and I_{0z} and I_{iz} means the nuclear spins of proton and i-th nucleus respectively. These coupling constants are expressed as follows

$$\left.\begin{array}{ll} a_0 = -\dfrac{16\pi}{3}\dfrac{\mu_B \mu_0}{I_0}|\Psi(0)|^2 & \text{Fermi interaction with proton} \\ a_i = -\dfrac{16\pi}{3}\dfrac{\mu_B \mu_i}{I_i}|\Psi(R_i)|^2 & \text{Fermi interaction with } i\text{-th nucleus} \\ b_i = 2\dfrac{\mu_B \mu_i}{I_i}\left\langle \dfrac{3\cos^2\theta - 1}{|\boldsymbol{r}-\boldsymbol{R}|^3} \right\rangle & \text{dipole-dipole interaction with } i\text{-th nucleus} \end{array}\right. \tag{2}$$

The values of μ_0, I_0 and μ_i, I_i which we use in the calculation are shown in Table I.(3)

Table I.3)

proton	$\mu_0=2.79$ (μ_N)	$I_0=1/2$
deuteron	$\mu_0=0.86$	$I_0=1$
K	$\langle\mu_K\rangle=0.38$	$I_K=3/2$
Cl	$\langle\mu_{Cl}\rangle=0.79$	$I_{Cl}=3/2$

$\mu_N = e\hbar/2MC = 5.05\times10^{-24}$ erg/gauß.

The separation $(\varDelta H)_s$ is estimated as

$$(\varDelta H)_s = \frac{a_0}{g\mu_B} \tag{3}$$

and the half width $(\varDelta H)_w$ is estimated by using the following relation.

$$(\varDelta H)_w = 2.35 \times \frac{1}{g\mu_B} \times \left[\sum_i (a_i^2 + b_i^2)\frac{1}{3}I_i(I_i+1)\right]^{\frac{1}{2}} \tag{4}$$

The g factor of U_2 center has been observed to be same as those of the free hydrogen. Therefore we assume in this paper that $g \doteqdot 2$ and avoid discussing the minor effect of spin-orbit coupling in the U_2 center. If we have the wave function $\Psi(\boldsymbol{r})$ for the ground state of U_2 center, we can estimate $(\varDelta H)_s$ and $(\varDelta H)_w$ by using (2) (3) and (4). The value of $|\Psi(0)|^2$ which is the electron density at the proton, concerns the separation $(\varDelta H)_s$ and the value of $|\Psi(\boldsymbol{R}_i)|^2$ which is the electron density at i-th nucleus is related to the width $(\varDelta H)_w$.

§ 3. The Most Primitive Model

—free hydrogen—

The fact that the doublet separation (500±10 gauss) is nearly equal to free hydrogen (506 gauss) suggests to us the estimated width, $(\varDelta H)_w$ by employing the 1s wave function of the free hydrogen $\psi_H(\boldsymbol{r})$ as the first approximation of $\Psi(\boldsymbol{r})$.

$$\Psi(\boldsymbol{r}) = \psi_H(\boldsymbol{r}) = \frac{1}{\sqrt{\pi}}e^{-r} \quad \text{(in a.u.)} \tag{5}$$

When the magnetic field H has the [1,0,0] direction, b_i vanishes and only the Fermi term a_i contributes to the width if we take into account the interaction of the trapped electron with only the eight nearest ions. The width $(\varDelta H)_w$ is estimated as about 0.01 gauss. When the direction of H is [1, 1, 1], $\sum_i b_i^2$ takes its maximum value and the width $(\varDelta H)_w$ is predicted as about 1 gauss. These values are far smaller than the experimental ones. Therefore, we have to modify $\Psi(\boldsymbol{r})$ of (5).

§ 4. Orthogonalization to the Core States

Gourary and Adrain have proposed a new method to treat the electron excess color center. They have evaluated the Zeeman energy with the trapped electron wave function orthogonalized to the core orbitals of the surrounding ions. The trapped electron wave function is obtained by the variation principle, assuming that the trial wave function is slowly varying near these ions, so that the charge distribution of ions can be replaced by that of point charge.

Applying this method to the U_2 center and taking the 1s like wave function $\psi_H(\mu r)$ in (5) as the trial function, we can easily see

$$(\psi_H|V_{cry}^0|\psi_H)=0$$

where V_{cry}^0 means the crystalline field caused by the point ion lattice. Therefore we directly orthogonalize the function $\psi_H(r)$ to the core orbitals and get the following $\Psi(\boldsymbol{r})$

$$\begin{aligned}\Psi(\boldsymbol{r})&=N[\psi_H-\sum_{ik}S_{ik}\phi_{ik}]\\ N&=[1-\sum_{ik}S_{ik}^2]^{-\frac{1}{2}}\qquad(6)\\ S_{ik}&=(\psi_H|\phi_{ik})\end{aligned}$$

where ϕ_{ik} means k-th orbital in i-th ion. In order to estimate the overlap integral S_{ik}, we use the Slater's type ϕ_{ik}, and to estimate $\phi_{ik}(0)$ we use the Hartree's function⁽⁴⁾ for ϕ_{ik}. These orbitals are as follows

$$\begin{aligned}&\phi_{ce^-,np}(\boldsymbol{r})=N_1r^{n-1}\,e^{-\nu_n r}\cos\theta\\ &\phi_{ce^-,ns}(\boldsymbol{r})=N_2r^{n-1}\,e^{-\nu_n r}\\ &\phi_{k^+,np}(\boldsymbol{r})=N_3r^{n-1}\,e^{-\mu_n r}\cos\theta\\ &\phi_{k^+,ns}(\boldsymbol{r})=N_4r^{n-1}\,e^{-\mu_n r}\qquad\text{(See Table II)}\end{aligned}$$

The estimated values of $(\varDelta H)_s$ and $(\varDelta H)_w$ by using these functions, are given as

$$\begin{aligned}&(\varDelta H)_s=550\ \text{gauss (obs. }500\pm10\text{ gauss)}\\ &(\varDelta H)_w=46\ \text{gauss (obs. 81 gauss)}\end{aligned}\qquad(7)$$

The main contribution to the width is due to the Fermi term of the trapped electron with the four Cl⁻ nuclei. The magnitude of the Fermi interaction with the K^+ nucleus is about 1/4 of that with the Cl⁻ nucleus. The magnitude of dipole-dipole interaction is estimated to be less than 1/15 of the Fermi term even though the direction of H is chosen as the most favourable one.

Table II.⁴⁾

n	μ_n (K⁺)	ν_n (Cl⁻)	$\sqrt{4\pi}\phi_{ns}^{\mathrm{K}^+}(0)$	$\sqrt{4\pi}\phi_{ns}^{\mathrm{Cl}^-}(0)$
1	18.7	16.7	161.7	136.5
2	$\frac{1}{2}$(14.85)	$\frac{1}{2}$(12.85)	46.41	38.24
3	$\frac{1}{3}$(7.75)	$\frac{1}{3}$(5.75)	15.29_5	11.31

ν, μ and ϕ in *a.u.*

The results obtained in (7) seem to be satisfactory in the order of magnitudes, but it should be remarked that the orthogonalization procedure necessarily accompanies the larger value of separation $(\varDelta H)_s$ than those of the free hydrogen whereas the observed $(\varDelta H)_s$ is nearly equal or slightly smaller than those of the free hydrogen. We have also to notice that the calculated value of $(\varDelta H)_w$ is smaller than the observed one, whereas the predicted value for the width of E. S. R. in the F and M centers by this method is always larger than the experimental one.

This tendency of discrepancy in the F and M centers is interpreted as to be plausible by the fact that the value of S_{ik} will decrease if we strictly carry out the variation of $\Psi(\boldsymbol{r})$ by including the exchange energy which is neglected in the simple treatment.

Considering the above mentioned circumstances we shall try in § 6 to discuss some possible effects which may cause the change of $\Psi(\boldsymbol{r})$ in (6).

§ 5. The Effect of the Vibration of the Hydrogen on E. S. R.

Before entering into the more detailed discussions of $\Psi(\boldsymbol{r})$, we shall consider in this section the effect of the vibration of the proton on E. S. R. Because of the light mass of the proton, it may have a considerably large amplitude of zero point vibration in the crystal and may be supposed to show some appreciable effects on E. S. R.

If the condition $h\nu_0\gg kT\gg\hbar\omega$ is satisfied, that is, the frequency ω of the fluctuation of the local magnetic field due to the hyperfine interaction is far smaller than the frequency ν_0 of the vibration, and the observed temperature T is sufficiently low to suppose that only the zero point vibration is predominant, we obtain the following equation

$$\bar{A}_i \doteqdot \int A_i(\boldsymbol{x})\chi_0^2(\boldsymbol{x})d\boldsymbol{x} \Big/ \int \chi_0^2(\boldsymbol{x})\,d\boldsymbol{x} \tag{8}$$

where $A_i(\boldsymbol{x})$ is the coupling constant of the hyperfine interaction with i-th ion when the proton is displaced by the distance $\boldsymbol{x}$ from the equilibrium point and $\chi_0(\boldsymbol{x})$ means the wave function of zeroth vibrational state of the proton or deuteron. If we assume that the adiabatic potential of the proton is given by $(\kappa/2)x^2$, the $\chi_0(\boldsymbol{x})$ is given as follows

$$\chi_0(\boldsymbol{x}) = N\exp\left(-\frac{\alpha}{2}x^2\right) : \quad \alpha = \frac{\sqrt{M\kappa}}{\hbar} \tag{9}$$

where M means the mass of the proton or deuteron.

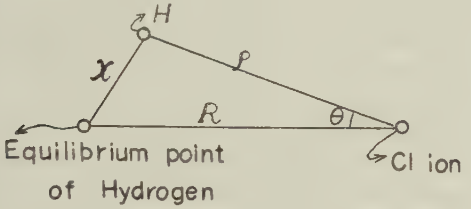

Fig. 2. Schematic representation of coordinates of proton.

By considering the fact that the width comes mainly from the Fermi interaction with four nearest Cl^- ions and it is proportional to $|\Psi(R_{Cl^-})|^2$, we further assume that $A_i(\boldsymbol{x})$ is proportional to the square of the overlap integral S between the ls orbital of hydrogen and the 3s orbital which belongs to one of the nearest Cl^- ion. As shown in Appendix II, S is well reproduced by the function $S_0 e^{-\beta\rho}$, $\beta=0.8$ in a. u. so that we have $A(\boldsymbol{x}) = A_0 e^{-2\beta\rho}$ and $A(0) = A_0 e^{-2\beta R}$, where we denote by ρ and R the distance between the chlorine nucleus and the proton and that between the chlorine nucleus and the equilibrium position of the proton respectively, as shown in Fig. 2. Using these relations we can estimate $\bar{A}$ to be as follows.

$$\begin{aligned}
\bar{A} &= A_0 \iint e^{-\alpha x^2 - 2\beta\rho}\,\rho^2 d\rho d(\cos\theta) \Big/ \iint e^{-\alpha x^2}\rho^2 d\rho d\,(\cos\theta) \\
&= A_0 e^{-2\beta R}\left[\left(1-\frac{\beta}{R\alpha}\right)e^{\frac{\beta^2}{\alpha}}\frac{1}{2}\left\{1+Erf\left[\sqrt{\alpha}\left(R-\frac{\beta}{\alpha}\right)\right]\right\}\right. \\
&\quad \left. +\left(1+\frac{\beta}{R\alpha}\right)e^{\frac{\beta^2}{\alpha}}e^{4\beta R}\frac{1}{2}\left\{1-Erf\left[\sqrt{\alpha}\left(R+\frac{\beta}{\alpha}\right)\right]\right\}\right] \\
&\doteqdot A(0)\left(1-\frac{\beta}{R\alpha}\right)e^{\frac{\beta^2}{\alpha}}
\end{aligned} \tag{10}$$

where $\quad Erf(x) = \frac{2}{\sqrt{\pi}}\int_0^x e^{-x^2}\,dx$

Therefore the width $(\Delta H)_w$ should be multiplied by the factor $\left(1-\frac{\beta}{R\alpha}\right)e^{\beta^2/\alpha}$ as the effect of the vibration. This correction factor is shown in Fig. 3 as the function of β^2/α.

In order to apply this relation to the U_2 center we have to know the value of α and to verify the assumption which was introduced to obtain the relation (10). This is a difficult problem and we have to content ourselves with a crude approximation only. We estimate semi-empirically the order of magnitude of α by using the data of thermal annihilation of the U_2-center. It has been suggested that a hydrogen atom which forms U_2-center migrates through the crystal to form a hydrogen molecule H_2 by the collision process $H+H \rightarrow H_2$. We assume that a hydrogen atom migrates in the potential field $V(x) = (1/2)V_0 \cos\left(\frac{\pi}{a}x\right)$ as shown in Fig. 5 with jumping frequency ν which is given as follows

$$\nu = \nu_j e^{-\frac{V_0}{kT}} \tag{11}$$

and we further assume that the force constant κ of the vibration can be related to this potential $V(x)$ in the following manner,

$$\kappa = \frac{1}{2}V_0\left(\frac{\pi}{a}\right)^2 \tag{12}$$

where 2a is the lattice distance and its numerical value is 5.93 (a. u.) for KCl crystal. Strictly speaking the relation (12) does not hold exactly but it may be applicable in estimating the order of magnitude. By employing (12) we can get the following relations,

$$\alpha=\frac{\sqrt{M\kappa}}{\hbar}=\frac{\pi}{\hbar a}\sqrt{\frac{MV_0}{2}} \tag{13}$$

$$h\nu_0=\frac{h}{2\pi}\sqrt{\frac{\kappa}{M}}=\frac{h}{2a}\sqrt{\frac{V_0}{M}} \tag{14}$$

On the other hand, the thermal bleaching process of the U_2-center is governed by the following kinetic equation of the *bi*-molecular reaction,

$$-\frac{dn}{dt}=\frac{\nu}{N_L}n^2 \tag{15}$$

where n is the number of U_2 centers, N_L is the number of the equilibrium points for the U_2 center and ν means the jumping frequency given by (11)*. By denoting n at $t=0$ as n_0 and integrating the equation (15), we get

$$\left(\frac{n_0}{n}-1\right)=\frac{n_0}{N_L}(t\nu_j)e^{-\frac{V_0}{kT}} \tag{16}$$

Delbecq, Smaller and Yuster mearured the decreasing of U_2 centers by the pulse annealing of $t=2$ minuits as the function of annealing temperature.(1) The initial concentration n_0 of the U_2 center is suggested as $n_0 \doteqdot 1/5\times 2\times 10^{18}$/c.c. by their experiment. In Fig. 5, we try to fit the curve (16) with their observed data. Unfortunately their experimental values are scattered, so that we can not decide the value of V_0 exactly, however, it seems to be in the range of 0.15~0.25 eV. If we assume that $V_0=0.19$ eV we obtain $\nu_0 \doteqdot 10^{13}$ sec^{-1} by using (14) and $\alpha=2.6$ by using (13). We can see that the condition $\hbar\omega \gg kT \gg \hbar\nu_0$ is satisfied. On the other hand we are able to decide ν_j as 10^{13} sec^{-1} by using Fig. 5. Of course ν_0 is not the same as ν_j, however, ν_0 and ν_j should be in the same order of magnitude. As shown in the above considerations, this condition is satisfied if we assume $V_0=0.19$ eV., on the other hand, it is not satisfied if we assume $V_0=0.25$ eV, because in this case we obtain $\nu_0 \doteqdot 10^{13}$ sec^{-1} from (14) and $\nu_j \doteqdot 10^{16}$ sec^{-1} from Fig. V.

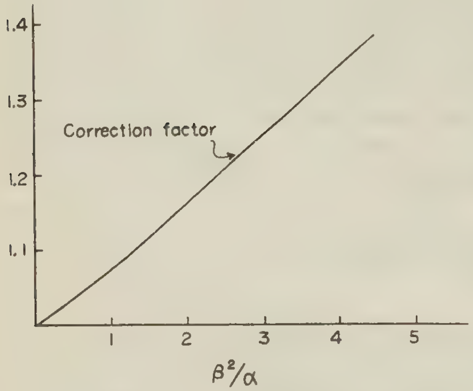

Fig. 3. Correction factor.

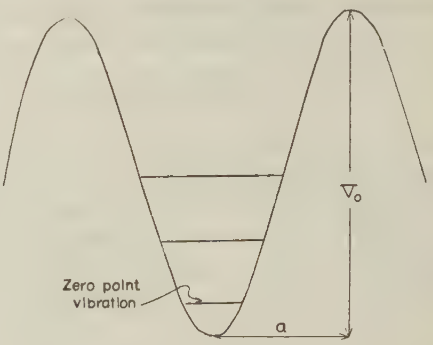

Fig. 4. Adiabatic potential for proton (schematic).

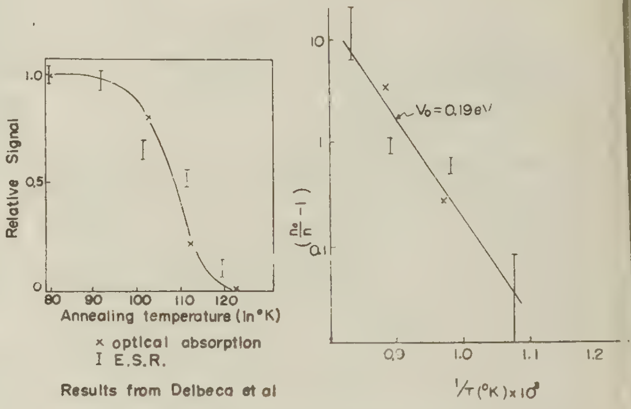

Fig. 5. Thermal bleaching behavior of U_2 center.

The experiment further shows that the maximum rate of decay of the U_2 center occurs near $n_0/n=2$ and at 108°K in the case of proton and at 113°K in the case of deuteron. This difference in the temperature is analized in Appendix III.

By considering these discussions, it is suggested that the approximate value of β^2/α is about $0.64/2.6=0.25$ in the case of proton and $0.25/\sqrt{2}=0.18$ in the case of deuteron. Therefore the correction factor is obtained as 1.21 in the case of the proton, the width $(\Delta H)_w$ of E. S. R. which is calculated in (7) by assuming the fixed center model should be multiplied by the factor of 1.21. By considering that the overlap integral is far smaller than 1, we can expand the normalization factor N in (6) as follows

---

* Strictly speaking, frequency ν may not be exactly the same as the jumping frequency (11). It may be multiplied by some numerical factor of the order 10^{-1}~10. However it has not the important meaning in the following discussions.

$$N^2=(1-\sum_{ik} S_{ik}^2)^{-1}\doteqdot 1+\sum_{ik} S_{ik}^2+\cdots$$

so that the deviation of the doublet separation from these of free hydrogen should also be multiplied by 1.21. As the correction factor is 1.15 in the case of deuteron, we may expect that the difference of $(\Delta H)_w$ in both cases is about 1/20 of $(\Delta H)_w$ itself. Unfortunately it is not clear whether the observed width $(\Delta H)_w$ is different in this order of magnitude between both cases or not, because the experiment by Delbecq, Smaller and Yuster is not sufficiently accurate to detect this small difference.

Finally it should be noticed that such an appreciable effect of the vibration on the absorption pattern of E. S. R. is the characteristic feature of the hydrogen because of its large amplitude of zero point vibration.

§ 6. Some Possible Effects Modifying $\Psi(r)$

6–A. In section 4, we considered the effect of the Pauli's exclusion principle by the orthogonalization which causes the decreasing of the electron density in the neighbourhood of ions (not at the nuclei of ions) accompanying the increasing of the electron density near the proton.

To remove the discrepancy in $(\Delta H)_s$ in (7) we have to investigate the possible effects which decrease the electron density near the proton. In order to explain the fact that $(\Delta H)_s$ is nearly equal to the value of the free hydrogen, $\psi_H=\frac{1}{\sqrt{\pi}}e^{-r}$ should be replaced by $\psi_H=\sqrt{\frac{\mu^3}{\pi}}e^{-\mu r}$ ($\mu=0.97$ in a. u.) if we take the hydrogen like ls wave function for ψ_H.

Contrary to the effect of Pauli's principle, the polarization and the crystalline field of the surrounding ion will be supposed to extend the electron distribution to the outer region of the proton. Therefore we will examine to what extent the decay constant μ of the hydrogen like wave function is decreased by these effects.

6–B. *Effect of the polarization*

We put the decay constant μ as $\mu=1+\varepsilon$ and assume that $\varepsilon\ll 1$. The total energy including polarization is as follows

$$H=H_0+H_{e.p}+H_p \tag{17}$$

where H_0 is the electronic energy and is given by $\frac{1}{2}\{-1+\varepsilon^2\}$. H_p is the self energy of polarization and $H_{e.p}$ is the interaction energy between the U_2 center and the induced polarization of the neighbouring ions. If we replace the approximate polarization by the induced point dipoles on the ions, we get the following equation

$$\begin{aligned} H_{e.p}&=-n\alpha q^2/R_i^4 \\ q&=1-4\pi\int_0^{R=R_i}\psi_H^2(r.\varepsilon)r^2dr \\ \psi_H&=Ne^{-(1+\varepsilon)r} \end{aligned} \tag{18}$$

where R_i is the distance between the proton and nearest neighbouring ions, α is the mean value of polarizabilities of the nearest ions, n is the number of the nearest ions, and q means the effective charge which induces the polarization of the nearest ions. H_p is given by $-\frac{1}{2}H_{e.p}$.⁽⁹⁾ We expand $H_p+H_{e.p}$ to the lst order in ε and minimize the value of H. The obtained value of ε is about $-\frac{1}{2}\alpha$(in a. u.)$\times 10^{-6}\doteqdot 7\times 10^{-6}$ and it is far smaller than 1.

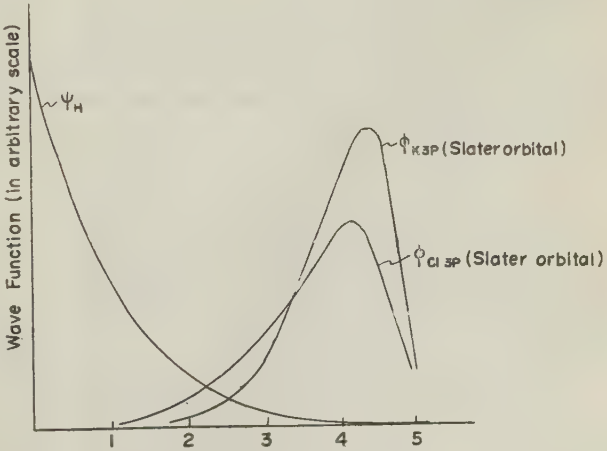

Fig. 6. Extention of wave functions.

Hence, the effect of ε on E. S. R. is quite small, so long as we confine ourselves to the point dipole approximation. However, it should be remarked that the point dipole approximation is not adequate to the U_2 center, because the effective charge q is not slowly varying near the lattice points of the neighbour ions. For example as calculated from Fig. 6, q is 50 times larger in value $R=\frac{1}{2}R_i$ than $R=R_i$, and the charge distribution of core electrons is still appreciable in this range of R. If we want to treat the polarization more in detail we have to discuss the many electron systems in which the orbitals of core electrons have variable freedom in precisely representing the polarization. Detailed discussions along these lines are not in the range of the present paper in which we assume the point ion lattice model. This problem will be discussed in a forthcoming paper.

6–C. *Effect of the mixing of f-type function owing to the crystalline field*

As shown in § 4, the expectation value of V^0_{cry} is zero so long as we confine ourselves to the use of ls like wavefunction as ψ_H, however the crystalline field V^0_{cry} causes the mixing of the $4f$ like wave function. We put ψ_H as follows

$$\begin{aligned}\psi_H&=\alpha\psi_{H1S}+\beta\psi_{H4}\\ \psi_{H1S}&=N(\varepsilon)e^{-(1+\varepsilon)r} \qquad (19)\\ \psi_{H4f}&=N(\nu)e^{-\nu r}x.y.z\ .\end{aligned}$$

and determine the variational parameters α, β, ε and ν to minimize the electronic energy of the U_2 center in the point ion lattice. The results are as follows

$$\alpha=1 \quad \beta=0.058 \quad \varepsilon=0.012 \quad \nu=1.0 \qquad (20)$$

By substituting the wave function (19) into (6) we recalculate the width and the separation. The results are as follows

$$\begin{aligned}(\varDelta H)_s&\doteqdot 525 \text{ gauss}\\ (\varDelta H)_w&\doteqdot 58 \text{ gauss}\end{aligned} \qquad (21)$$

Owing to the negative charge of Cl⁻ ion, the charge distribution of the trapped electron is reduced in the range of Cl⁻ so that it is natural that we have the smaller value of $(\varDelta H)_w$ than those obtained in (7).

Considering the limit of the point ion model it is not clear whether the values obtained in (21) are plausible or not because the degree of mixing of the f type function may depend on the detailed interactions with the core orbitals. Therefore it is necessary to treat the problem as many electrons system and the situation is similar to the case of 6–B.

6–D. *The effect of electron transfer*

So far we have considered that the trapped electron is localized in the neighbourhood of the proton. However the electron may transfer onto K⁺ ions or the electron which belongs to the Cl⁻ closed shell may transfer onto the hydrogen atom. The former process is interpreted in terms of the resonance between 4s orbitals of the nearest K atoms, and the latter is interpreted as a kind of configurational interactions. The problem to examine precisely those effects is not possible if we assume the point ion lattice, but by the following simple considerations it is suggested that these effects may not be significant.

In order to examine the resonance of the 4s orbitals of the nearest K⁺ ions, we take the L. C. A. O. procedure. In this procedure the most essential quantity is the non-diagonal matrix element of the following type $\left(\psi_{HIS}|V_{cry}|\sum_{K_i=1}^{4}\phi_{K_i 4S}\right)$. If we replace V_{cry} by $\sum_i \frac{\pm 1}{|\boldsymbol{r}-\boldsymbol{R}_i|}$ and $\sum\phi_{K_i 4s}$ by the slowly varying function, for example the Slater's one, this nondiagonal element is nearly equal to $\left(\psi_H\middle|\sum_i\frac{\pm 1}{|\boldsymbol{r}-\boldsymbol{R}_i|}\middle|\psi_f\right)$, in which ψ_f means the f symmetrical component of $\sum_{K_i}\phi_{K_i 4s}$ expanded around the proton. The effect of this term is the same as the one which has already been discussed in 6–C. The other essential point of L. C. A. O. method is that we use the A. O. of ϕ_{K4s} localizing near the ion potential field, $V_{K,\text{ion}}$, to gain the additional potential energy to those calculated by the point ion model. To estimate this effect we will compare the following two energies

$$\begin{aligned}E_A&\equiv\left(\psi_H\middle|-\frac{\varDelta}{2}-\frac{1}{r_H}-\frac{1}{r_K}\middle|\phi_{K4s}\right)\\ &=E_H(\psi_H|\phi_{K4s})+\left(\psi_H\middle|\frac{-1}{r_K}\middle|\phi_{K4s}\right)\\ E_B&\equiv\left(\psi_H\middle|-\frac{\varDelta}{2}-\frac{1}{r_H}+V_{K,\text{ion}}\middle|\phi_{K4s}\right)\\ &=E_K(\psi_H|\phi_{K4s})+\left(\psi_H\middle|\frac{-1}{r_H}\middle|\phi_{K4s}\right)\end{aligned}$$

where E_H or E_K represents the ionization energy of hydrogen (1s) or potassium (4s) electron respectively :

$$-E_K=0.1595$$
$$-E_H=0.5$$

E_A-E_B will give the energy gain of this kind. If we use the Slater's type function(5) as $\phi_{K4s}=Nr^2e^{-0.549r}$ we obtain $E_A=-0.1911$ a. u. and $E_B=-0.1912$ a. u. and the difference is very small. Thus it seems that the 4s orbital of K ion can hardly resonate with 1s orbital of hydrogen. As to the configuration interaction, the degree of mixing of the state in which a hole exists in a core orbital of Cl^- ion, can be examined by calculating the energy $E_g-\chi-I$ in the energy cycle principle. E_g means the band gap of KCl crystals, χ is the electron affinity of KCl crystals, and I is the electron affinity of the hydrogen. If we assume approximately $\chi\doteqdot0.5$ eV. and take the known values of $E_g=9.44$ eV and $I=0.71$ eV, $E_g-\chi-I$ becomes nearly equal to 9.2 eV. This energy seems too large to cause the appreciable effect of the electron transfer to the hydrogen from the Cl^- ion.

II. Brief discussions on the optical absorption

§ 7. The Wave Length of the Optical Absorption

The optical absorption peak of the U_2 band in KCl crystals appears at the wave length of 236 mμ i. e. about 5.2 eV. At present it is not clear what kind of electronic transition corresponds to this optical absorption. In this section we classify three typical types of the transition and estimate the absorption wave length or photon energy by means of the simple point ion lattice model.

7–A. *Transition of the trapped electron*

We take the wave function of 1s and 2p like state as follows

$$\Psi_{gr}=Ne^{-\nu r} \qquad \Psi_{ex}=Nxe^{-\mu r}$$

If we assume the point ion lattice model we can easily get the following relations,

$$(\Psi_{gr}|V^0_{cry}|\Psi_{gr})=(\Psi_{ex}|V^0_{cry}|\Psi_{ex})$$
$$=(\Psi_{gr}|V^0_{cry}|\Psi_{ex})=0$$

so that the absorbed energy of the photon is 10.2 eV which is the same as the energy gap between the 1s and 2p states of the free hydrogen.

In order to consider the effect of the crystalline field on the excited state, we take the following wave function,

$$\Psi_{ex}=N_1xe^{-\mu_1r}+N_2yze^{-\mu_2r}$$

where μ_1, μ_2, N_1, and N_2 are the variational parameters. If we minimize the energy of the excited state, this level appears to be about 0.18 (a. u.) lower than those of the continuum state and the corresponding absorption energy is 8.7 eV. It seems too large to be compared with the observed value of 5.2 eV. If we include the effect of exchange interaction between the trapped electron and those of the surrounding ions, the energy gap may be larger than the values obtained above. On the other hand the effect of polarization may contribute to decrease the energy gap.

In any case we can conclude that the transition of the trapped electron in the U_2 center may not take place near the energy of 5.2 eV if we confine ourselves to use the point ion lattice model.

7–B. *Exciton near the U_2 center*

There are other interpretations on the optical absorption in the U_2 center, the electron transfer model from the Cl^- ions near the U_2 center. The one is to interprete the exciton absorption near the U_2 center and the other is electron transfer to the U_2 center from the Cl^- ions. As has been already mentioned, these two processes may not be clearly distinguished from each other in the actual process.

To calculate the absorbed energy of the first process, we utilize the treatment by Bassani and Inchauspé(6) who succeeded in explaining the absorbed energies of α and β excitons. Their method is the semiclassical one, based on the electron transfer model of exciton, in which the charge distribution of the excited electron is ignored. The Coulomb field and the polarization are expressed approximately by the interaction between the point dipoles and the point charges and the complicated interaction caused by the exchange effect is neglected. A similar picture was used in this paper. According to the discussions by Bassani and Inchauspé, the difference between the excitation energy of free exciton and U_2 center is given by the difference of the following three kinds of energies Q, W, and P.

Q: Coulomb interaction energy between the charges of the point ion lattice

W: Repulsive interaction energy between

the ion cores*

P: Energy of polarization

Because of the neutrality of H atom, difference ΔQ vanishes. The difference ΔP is due to the polarization of the interstitial hydrogen and is given as follows (See Fig. 7)

$$\Delta P=\left[\frac{1}{r^4_{13}}+\frac{1}{r^4_{32}}-\frac{2\cos(r_{13}r_{23})}{r^2_{13}r^2_{32}}\right]\frac{\alpha_H}{2}\doteqdot 0.12\,\text{eV}$$

where α_H means the polarizability of the hydrogen atom and is 4.6 a. u. In this simple evaluation of ΔP, we neglect the shielding effect caused by the polarization of the other ions, and it leads us to overestimate the value of ΔP. In order to estimate ΔW, we assume approximtely that the repulsive energy W is given by⁽¹⁰⁾

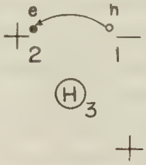

Fig. 7. Exciton model of U_2 band.

$$W\doteqdot C\frac{S^2}{R}$$

We further assume that the hydrogen migrates in the potential field given by W so that we are able to determine the constant factor C by using the known value of the height of this potential field (=0.19 eV as shown in § 5) and the estimated value of the overlap integral S.

The difference ΔW is estimated as 0.04 eV. The total energy difference $\Delta(h\nu)$ is

$$\Delta h\nu=(h\nu)_{free}-(h\nu)_{U_2}=\Delta W+\Delta P+\Delta Q\doteqdot 0.16\,\text{eV}$$

This value is far smaller than the value required, for the exciton peak appears at 7.6 eV in KCl which requires the difference $\Delta(h\nu)$ of 2.4 eV. The discrepancy seems to come from the simplified picture of the point ion and dipole model. We may have to study the effect of the polarization and the exchange interaction more precisely. As stated in §6–D. the required energy for another process is estimated to be 9.2 eV by energy cycle principle.

§ 8. Conclusions and Summary

(1) The 1s wave function of the free hydrogen which is orthogonalized to the core orbitals of the nearest ions, gives the separation $(\Delta H)_s$ and the width $(\Delta H)_w$ of E.S.R. as

$(\Delta H)_s=550$ gauss (obs. 500 gauss)

$(\Delta H)_w=46$ gauss (obs. 81 gauss)

(2) Owing to the large amplitude of zero point vibration of the interstitial hydrogen, the width $(\Delta H)_w$ spreads about 20% larger than those estimated by assuming the fixed model of hydrogen at the body diagonal interstitial point.

(3) The effects of the polarization and the crystlline field are considered by using the simple point ion lattice and the point dipole model. If we confine ourselves to this simple model, these effects on the wave function of U_2 center are very small.

(4) Brief discussions on the optical absorption are developed from the same standpoint. The estimated energy of the absorbed photon is considerably larger than the observed one. If we assume that the absorption corresponds to the transition between the ground and excited levels of hydrogen modified by the crystalline field, we get

$(h\nu)_{U_2}=8.7$ eV (obs. 5.2 eV)

If we assume that the absorption is the exciton absorption near the U_2 center, we get $(h\nu)_{U_2}=7.4$ eV (obs. 5.2 eV) and if we assume that it corresponds to the electron transfer to the U_2 center from the surrounding Cl^- ions we get

$(h\nu)_{U_2}=9.2$ eV (obs. 5.2 eV)

(5) In order to understand origin of the discrepancies between the calculated and observed values we have to take account of the core electrons more accurately, to esitimate the energy of the exchange interaction, to consider the effect of polarization more precisely and to notice further the effect of spin polarization of the core electrons,⁽⁷⁾ because the velocity of the electron in the U_2 center is nearly the same with those of the core electrons.

---

* Bassani and Inchauspé have neglected the energy difference in the process to bring back the neutral atoms into crystal.

If we take account of the difference in this process, it should be expected that the difference in the repulsive energy has only smaller effect on the absorption energy. Thus, the following estimation of ΔW should correspond to overestimation.

(6) Through all the discussions in this paper we conclude that the U_2 center is one of the best tracers which shows the physical characteristics of various kinds of interactions involved in the problem of colour centers.

Acknowledgement

The authors wish to express their hearty thanks to Professors T. Inui and R. Kubo for their encouragement. This work was supported by a grant in Aid for Fundamental Scientific Research from the Ministry of Education.

Appendix I. On the model *B* of U_2 center

Considering the geometrical symmetry only, the site *B* in Fig. 1 is possible as well as site *A*. However, the site *B* seems tentatively to be unacceptable because of the large repulsive energy. Further, the model *A* of the U_2 center is more favourable than the model *B* to interprete the observed data of E. S. R. If we assume the model *B* we may expect that the separation $(\Delta H)_s$ shows a larger deviation from the one of free hydrogen because the overlap integral S_{tk} shows the larger value than in the model *A*.

The line shape of each branch is suggested as to be a triangle if we take the primitive treatment of § 4.

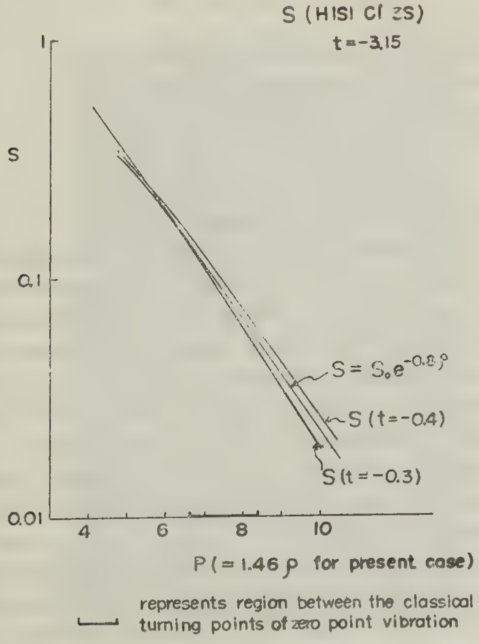

Fig. 8. Approximation for overlap integral.

The calculated results for the model *B* are as follows

$(\Delta H)_s \fallingdotseq 610$ gauss obtained by the same
$(\Delta H)_w \fallingdotseq 155$ gauss approximation in § 4
$(\Delta H)_s \fallingdotseq 560$ gauss obtained by the same
$(\Delta H)_w \fallingdotseq 127$ gauss approximation in § 6–C

Appendix II. Approximate formula for the overlap integral

We assume approximately the analytic form for the overlap integral $S(Cl\,3s|H\,1s)$ in $E_q(10)$ as follows.

$$S=S_0\,e^{-\beta\rho} \qquad \beta=0.8\text{ a. u.}$$

The value of β is determined as a tangent near the internuclear distance in Fig. 8, where the value of *S* is obtained from the Mulliken's table.⁽⁸⁾ $S(Cl\,3p\,\sigma|H\,1s)$ is also approximately given by nearly the same function as $S(Cl\,3s|H\,1s)$ in the required region of *r*.

Appendix III. On the difference of bleaching temperature between *D* and *H*

The experiments by Delbecq, Smaller and Yuster shows that the maximum rate of the decay caused by pulse annealing of 2 min. occurs at 108°K, $n/n_0=\frac{1}{2}$ in the case of proton U_2 center and at 113°K, $n/n_0=\frac{1}{2}$ in the case of deuteron U_2 center.

Using the equation (16) and the above data we can obtain the height of potential barrier for each case where ν_j is replaced approximately by ν_0 which is proportional to $M^{-1/2}$. We find that the height of potential barrier is different from each other by the value of 0.006 eV. The difference seems to come from the difference of the zero point energies in each cases.

If we estimate these energies by (14) and by assuming $V_0=0.19$ eV we obtain the following results.

$$\frac{1}{2}h\nu_0=0.02\text{ eV.} \qquad \text{for } H$$

$$\frac{1}{2}h\nu_0=\frac{0.02}{\sqrt{2}}\text{eV.} \qquad \text{for } D$$

Therefore the difference between above two values is to be 0.006 eV which is in agreement with the difference obtained from the barrier height.

Etch Pits Corresponding to Dislocations in Ferroelectric Guanidinium Aluminum Sulfate Hexahydrate

By Terutaro NAKAMURA

Department of Physics, Ochanomizu University,
Otsuka, Tokyo.

(Received May 2, 1959)

Cleavage surface of ferroelectric G.A.S.H. crystal was etched with a mixture of water and ethyl alcohol, followed by rinsing in benzene. Identical etch pits were observed on matching cleavage faces. Density of the pits is $10^4/cm^2$ in the order of magnitude. Mechanical shock produces etch pits. Successive etching causes growth of pits at the unchanged locations. These facts lead us to conclude that the pits must correspond to dislocations. Patterns of etch pits on the upper and the lower cleaved faces of the crystal indicated that dislocation penetrates the crystal several hundred micron thick. Pair arrangements and linear arrays of etch pits were observed. Etch pits, of which the deepest points differ from the centers of triangles, correspond to dislocations not perpendicular to cleavage surface.

§ 1. Introduction

The polarization reversal of ferroelectric crystals is attained through the movement of the ferroelectric domain walls, and it is very plausible that the domain wall movement has interesting interactions with crystal imperfections especially with dislocations, as pointed out by a few authors.1) It will be much interesting to inquire the behavior of polarization reversal or domain switching in connection with the dislocation. However, the information on dislocations in ferroelectric crystals has been lacking, and even the observation of a dislocation itself has not yet been reported, except the observation of growth spirals on crystals of WO_3.2)

The present article describes the observation of etch pits on {0001} cleavage surfaces of guanidinium aluminum sulfate hexahydrate, $C(NH_2)_3\ Al(SO_4)_2\cdot 6H_2O$ (usually abbreviated as G.A.S.H.) which was first reported to be ferroelectric by Holden et al in 1955,3) and has been investigated by several authors.4)–6)

Holden et al4) reported that great many triangular pits were observed on {0001} surfaces of G.A.S.H. by etching with water, without questioning whether these pits had anything to do with crystal imperfections. Our present study has revealed several important characteristics of etch pits, leading us to the conclusion that the etch pits having pyramidal form correspond almost certainly to dislocations, existing in G. A. S. H. crystals.

Crystallographic description of G.A.S.H. was made by Wood,[5)] reporting that the space group is P-31 m, while she found by optical and X-ray examination that the etch pits differently "cocked" in different parts of crystals reported by Holden et al[6)] do not result from the deviation from the parallelism of crystal structure in these different part. Crystal structure of guanadinium gallium sulfate hexahydrate, isomorph to G.A.S.H., was recently determined by S. Geller et al.[6)]

§ 2. Preparation of the Crystals

Since the solubility curve of G.A.S.H. into water makes low angle with temperature axis, and the activation energy of the diffusion depends greatly upon temperature, it is not adequate to cultivate the crystals by cooling method but evaporation method is well applicable. Equimolar mixture of $(CH_5N_3)_2H_2SO_4$ and $Al_2(SO_4)_3$ were poured into water and stirred well at about 40°C, 30% solution of $(CH_5N_3)\ H_2SO_4 \cdot Al_2(SO_4)_3$ being obtained. This solution was kept in a thermostat at 30°C, water being evaporated quite gradually there. G.A.S.H. crystals of hexagonal prismatic form, every edge of the hexagon being a few cm, hight being from a few to a fraction of cm were obtained. Some crystals were obtained from aqueous solution of crystallized G.A.S.H., by a recrystallization process. Crystals obtained from aqueous solution of $(CH_5N_3)_2H_2SO_4$ and $Al_2(SO_4)_3$ were not free from flaws, but crystals obtained by recrystallization were quite transparent.

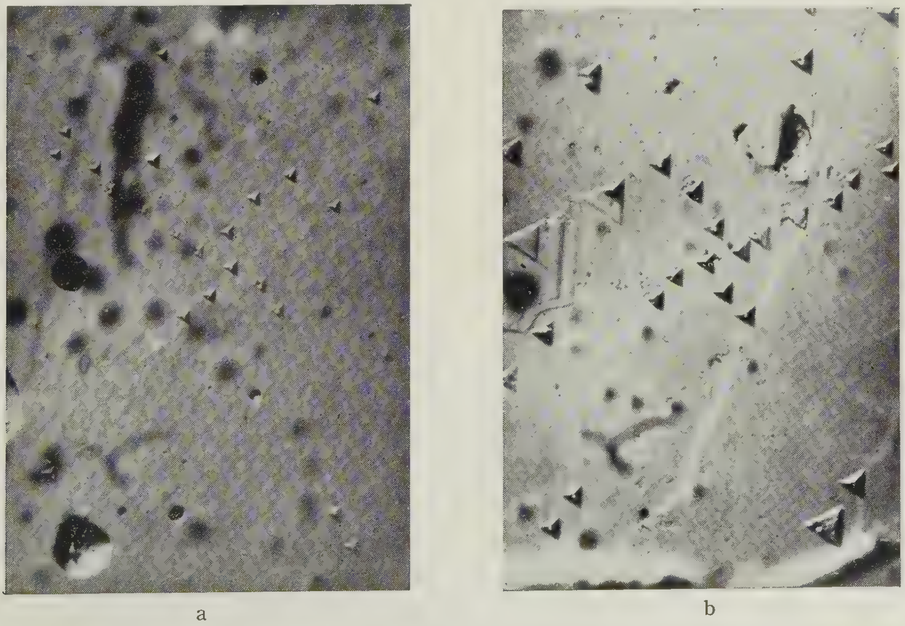
Specimens were made by cleavage along {0001} plane. Very good cleavages were obtained with a razor blade tapped sharply but lightly by a small hammer.

Etching, of which method is described in the following paragraph, revealed that the as grown crystals show different densities of etch pits piece by piece, ranging from less than 10^4 up to 10^5/cm^2.

Dielectric measurement revealed that the crystals show different P-E hysteresis loops place to place, some are biased, some are doubled, some are symmetrical, some are round-shouldered, and some are not ferroelectric without displaying any hysteresis loop.

§ 3. Etching Technique

G.A.S.H. crystal has a perfect cleavage parallel to {0001} face. Cleavage faces were etched by a mixture of ethyl alcohol and distilled water in the volume ratio 7:1, the duration of etching ranging from a few to several seconds. Immediately after etching



a b

Fig. 1. Mirror images on matched faces. (×125)

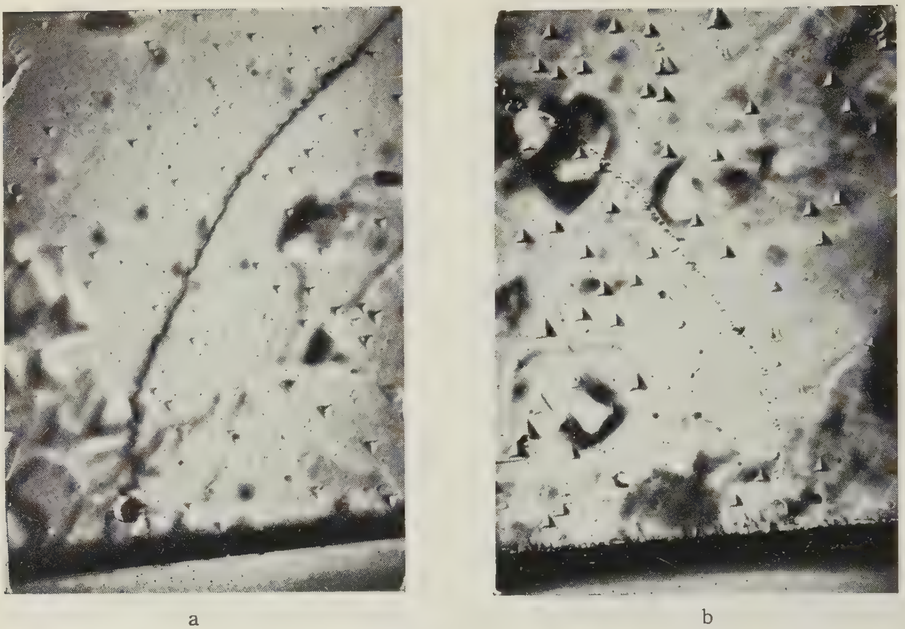


Fig. 2. Mirror images on matched faces. (×125)

in the solution, the crystal was rinsed in benzene, followed by drying the crystal, whose surface to be examined being in contact with a certain kind of blotting paper.

This method enabled us to observe triangular etch pits on uncontaminated faces, the cleavage steps remaining essentially unchanged before and after the etching. On the other hand, water as etchant, that was used by Holden et al, shows too much high speed of etchting, resulting in disappearance of cleavage steps and contamination of the surface, hence it was quite impossible to distinguish even the locality of etch pits.

§ 4. Experimental Results

(a) *Matching faces*

A piece of G.A.S.H. crystal, that had been cleaved from the crystal as grown, was cleaved into two halves. The matching cleavage faces of the crystal were etched and observed under a microscope. Some examples of couples of photomicrographs of etching surfaces are displayed in Figs. 1a, 1b, 2a, 2b, 10a and 10b. Reader will recognize that the patterns are mirror images apart from small detail.

These photographs clearly show that a certain crystal imperfection that causes preferential etching goes from one piece to another through the matching face as shown in Figs. 11 a and b. This imperfection is conceivably a dislocation, together with other experimental results reported below.

(b) *Density of etch pits*

Etch pits photographed were counted over 23 photomicrographs and distribution curve as shown in Fig. 3 was obtained. Counting of etch pits, of which density is less than $10^3/\text{cm}^2$ was not attempted, because of the limit of the visual field of microscope. The geometrical mean was calculated to be $0.7\times 10^4/\text{cm}^2$. This value $\sim 10^4/\text{cm}^2$ is reasonable, if we take these pits to correspond to dislo-

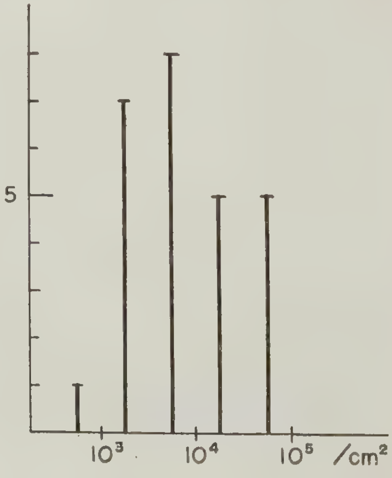

Fig. 3. Distribution of dislocation density.

cations, because the densities of etch pits corresponding to dislocations in LiF[7], KCl[8], NaCl[9] etc. have similar orders of magnitude.

(c) *Production of etch pits by mechanical shock*

If it is provided that the etch pits observed on the {0001} faces of G.A.S.H. correspond to dislocations, it will be expected that some etch pits should be observed after mechanical shock.

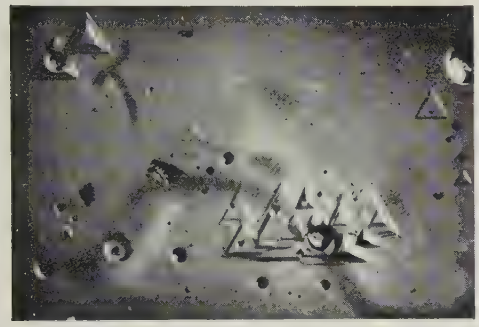

Fig. 4. Dislocation etch pits produced by dropping a steel bar onto the cleavage face. (×100)

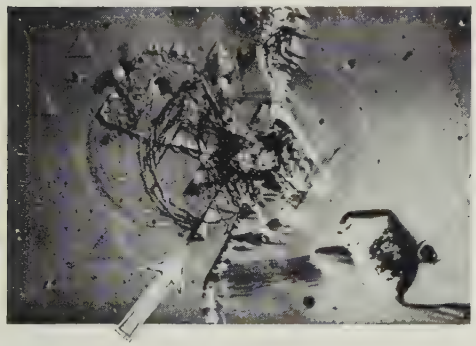

Fig. 5. Photomicrograph of needle contacted face, after a second etching. (×100)

It was easy to find a certain region of crystal, where etch pits were very few. This region was mechanically shocked by dropping a steel bar onto the surface, or by contact of point of a needle. The mechanillay shocked region underwent a second etching. The examples of results are illustrated in Figs. 4 and 5. The photomicrographs seem to indicate that dislocations were created by mechanical contacts. Flat bottomed pits observed in the photographs will be discussed in the next paragraph.

(d) *Successive etching*

The cleavage surface was successively etched. A piece of crystal was picked up, which showed a few etch pits. This crystal was etched successively. The very small pits, that were observed in the first etching, became larger and a little deeper at the unchanged locations, without producing new pyramidal pits, as shown in Figs. 6a∼d.

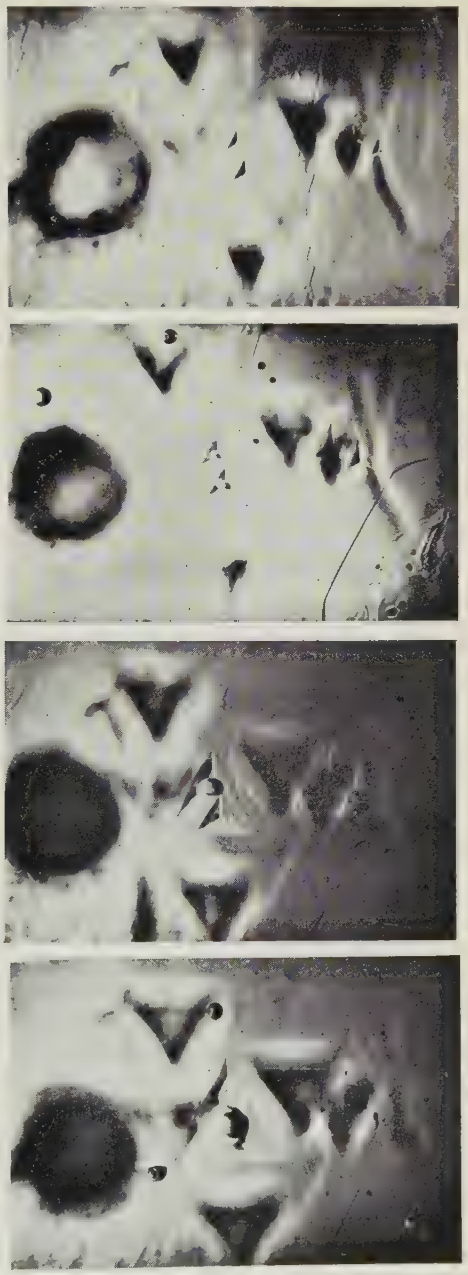

Fig. 6. Effect of successive etching. (×100)

When the state of Fig. 6d was reached, where couples of pyramidal pits became indistiguishable, pyramidal pits had deepness of several microns, indicating that the pits observed represent dislocations, of which length is at least about ten microns.

In the course of successive etching in Figs. 6 it was observable that flat-bottomed pits appeared or disappeared. These pits may correspond to emergence points of dislocation half loop, which is located or has been located extremely close to the surface. This situation is shown in Fig. 11c and discussed in § 5.

(e) *Regularity of etch pattern*

Inquiring a number of photomicrographs it is easily recognized that the distribution of etch pits are not quite at random, but pits have tendency to be arranged in a regular manner.

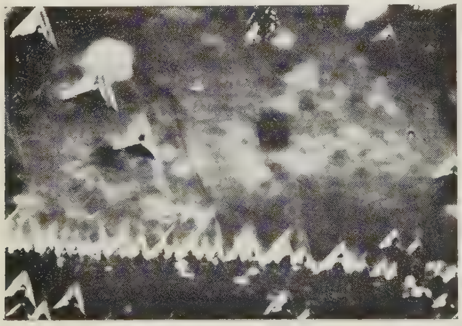

Fig. 7. Dislocation array forming grain boundary.
(×100)

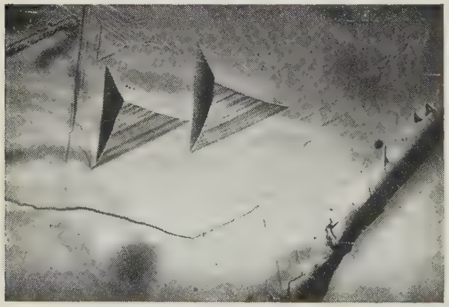

Fig. 8. Pair dislocations.
(×100)

Firstly, pairs of etch pits are very frequently observed, as shown in Figs. 1, 6 and 8. It will be very likely that a pair of pits correspond to a pair of emergence points of dislocations. This pair of points are probably both ends of dislocation half loop.

Secondly, etch pits have a tendency that they make a linear array, as seen for example in Figs. 1 and 9. Linear arrays of closely located pits as shown in the lower part of Fig. 7 is sometimes observed. It was confirmed that an array of pits were found on the grain boundary, which was observable by an optical mean.

(f) *Penetrating dislocation*

A piece of G.A.S.H. crystal, cleaved from a crystal as grown, was cleaved again into two halves. After the etching and the rinsing, both sides of every piece was dried in contact with the blotting paper simultaneously. Figs. 9 show patterns of etch pits on four faces. Patterns on matched faces are in the relation of mirror images, as seen from Figs. 9b and c. Patterns on the upper and the lower faces of piece (I), as shown in Figs. 9a and b, show that threee dislocation lines penetrate through the crystal. Since the thickness of the piece (I) was about 370μ, the dislocations corresponding to the etch pits will have a length of a few hundred microns.

Patterns on the upper and the lower faces of piece (II), as shown in Figs. 9c and d, show that one dislocation penetrate this piece, and the other two make a half loop.

Geometrical arrangement of the dislocation lines in this crystal is as shown in Fig. 9e.

§ 5. Discussion

G.A.S.H. crystal has an advantage that uncontaminated surface is easily obtained by cleavage. In these circumstances a suitable etchant is able to attack immediately the stressed region around the emergence point of the dislocation and produce an etch pit, without necessitating the presence of some concentration of impurities around it.

In the previous paragraph six experimental facts were shown, providing very strong supports of the view that the etch pit observed indicates the emergence point of a dislocation.

The density of etch pits in a good region of the crystal is as low as $10^4/\text{cm}^2$, while the density is large where linear array of dislocations that corresponds to grain boundary is observed (Fig. 7). The low value of the density, suggests that the pits do not correspond to impurities but dislocations.

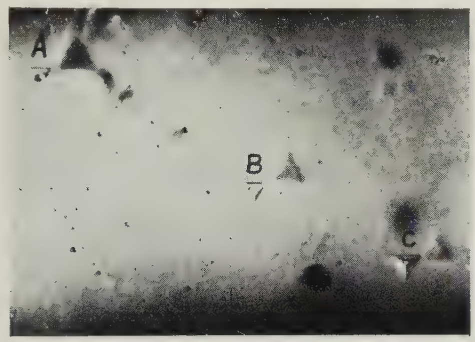
As reported by Holden et al[4), some etch pits are "cocked", namely the deepest points of the pits are displaced with respect to the centers of triangular peripheries.

The angle that a dislocation makes with the {0001} cleaved surface can be estimated by the asymmetry of the etch pits. Fig. 10c indicates the relation between cocked pits on the matching faces, of which photomicrographs are shown in Figs. 10a and 10b. The identity of the etch pits on both matched faces does not necessarily mean the coincidence of the deepest point of pits, but, if we superpose every corresponding pit so as to make the total overlapping area maximum as in Fig. 10c, the deepest points of the matching etch pits displace almost the same amount with respect to the centers of the peripheries and in the opppsite directions. This is a strong support that some dislocations make certain angles with {0001} face going from one side to another through the cleavage surface as shown in Fig. 11b.

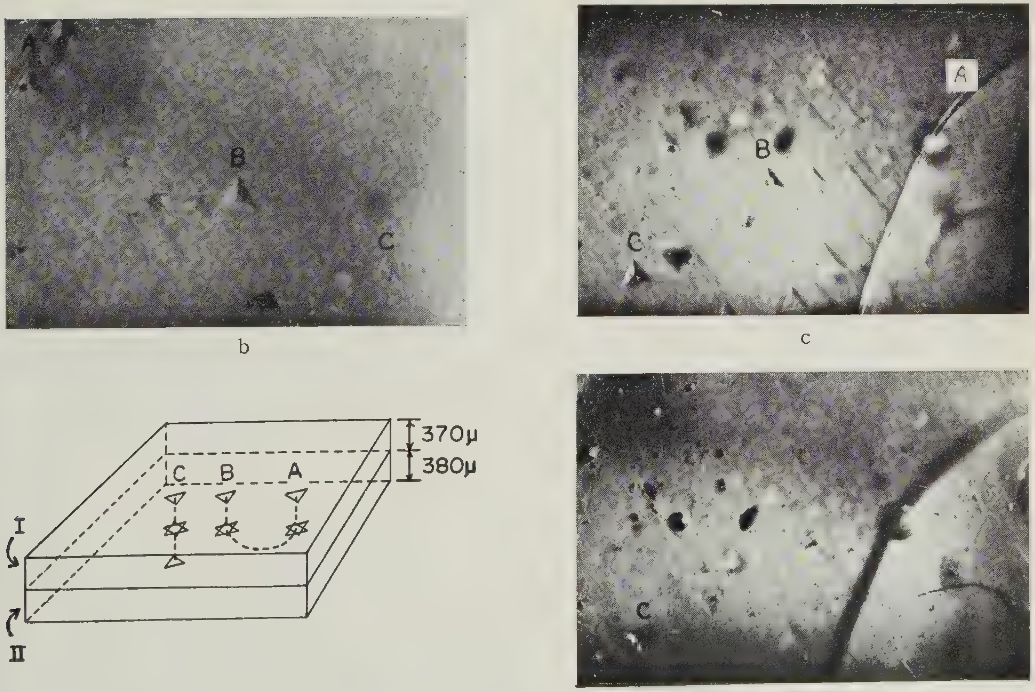
Shape of pyramical etch pits is rather shallow. Etch pits, of which edges are of the order of 1/10 mm, has a deepness of only a few microns, showing that the pyramidal faces are not crystallographic $\{11\bar{2}1\}$ plane, but form stepped walls.

In the case of "cocked" pits accordingly, small amount of displacement of the deepest point with respect to the center of triangle means rather remarkable inclination of dislocation line, some measured values of angle that the dislocations make with the {0001} basal plane amounted 15°~30° approximately.

It must be noted here that there observed are a few etch pits of triangular form, of which bottom is not pointed but very flat. Some examples of these pits are found in Figs. 1b, 4 and 12. Some of flat pits do not compose mirror images between matching faces, but they showed no positive evidence to be identified as dislocations existing there.



a



b

c

e

d

Fig. 9. Dislocation lines penetrating through a crystal.
(×100)

Neverthless some of the flat-bottomed pits are conceivable to correspond to emergence points of dislocations. If a dislocation line enters the crystal making very low angle with the cleavage face, and it lies extremely close to the surface, it is expected that the flat-bottomed pits are obtained as shown in Fig. 11c.

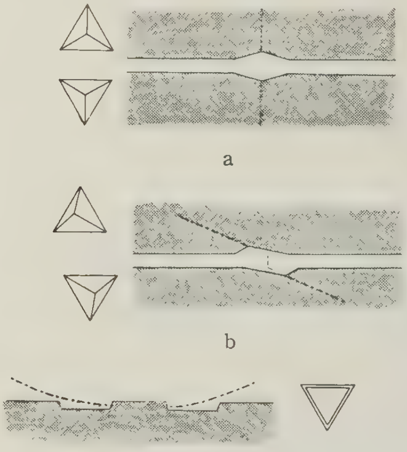
c: Superposition of cocked pits on matched faces.

Fig. 10.

An array of closely connected pits, as shown by an arrow in Fig. 5, is observed in the photomicrograph of etch figure produced by etching after mechanical shock. This figure may be accounted as a trace of moving dislocation.

Observations of etch pits on the upper and the lower cleavage faces indicated that the dislocations were existent penetrating through the crystal, a few or several hundred micron thick, as shown in Figs. 9. This experiment is expected to indicate a possible slip plane. Dislocation lines A, B, and C were perpendicular to the {0001} cleavage faces within the limits of experimental error. Slip plane seemed to be near {11$\bar{2}$0}, although precise measurement was not made.



a

b

c

a: Dislocation perpendicular to matched faces.

b: Dislocation not perpendicular to matched faces causes etch pits of which deepest points differ from the center of the triangles.

c: Dislocation that causes a flat pit.

Fig. 11.

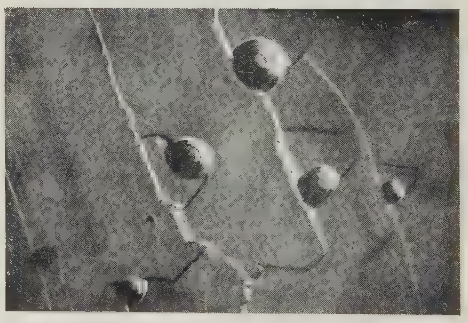


Fig. 12. Etch pits at contaminated cleavage step. (×100)

The etch pits are, however, sensitive not only to dislocations but also such crystal imperfections as contaminated points at cleavage steps and others. The etch pits produced at these defects are usually flat-bottomed as shown in Fig. 12., and easily distinguished from the dislocation pits, which are characteristic pointed ones.

Circular pits are sometimes observed, as in for example Figs. 4, 6, and 12. They are dislocation insensitive. These round pits may be due to unskilfulness of etching technique.

By the etching experiment it is found that the slip bands are difficult to produce, by compressing the specimen in the direction of $\langle 11\bar{2}0\rangle$. This seems at first glance disadvantageous to conclude for the etch pits to correspond to dislocations.

This phenomenon, however, is plausibly explained in taking into account that this substance is ferroelectric. If the compression along $\langle 11\bar{2}0\rangle$ is applied, polarization parallel to $\langle 0001\rangle$ occur by the piezoelectric effect because the space group is $P\text{–}31m$. Therefore ferroelectric domain boundary may move, resulting in the consumption of energy applied by the compression. Energy given by the compression is not used for the production of slip bands, but used for the displacement of the domain wall. This is a possible explanation that the slip bands are difficult to observe.

§ 6. Conclusion

Cleavage surface of G.A.S.H. was studied by etching technique. Identical etch pits were observed on matching faces. Density of the pits is $10^4/\text{cm}^2$ in the order of magnitude. This value supports the view that the etch pits do not correspond to impurities but emergence points of dislocations.

Mechanical shock produces etch pits. These pits show that dislocations were produced and probably moved during the etching process.

Etch pits of which deepest points displace with respect to the centers of the triangles correspond to dislocations inclined to the cleavage face.

Pairs of pits or linear arrays of pits are frequently observed.

Array of pits corresponding to grain boundary is observed.

Successive etching causes growth of pits at the unchanged locations.

Patterns of etch pits on the upper and the lower cleaved faces of the crystal indicated that dislocation penetrates the crystal, several hundred micron thick.

These experimental results lead us to the conclusion that the etch pits observed are emergence points of dislocation.

The author is much indebted to Prof. M. Sakamoto of Tokyo College of Science, for his illuminative discussions and valuable suggestions. He is also grateful to Prof. H. Takahasi of University of Tokyo, for interest and encouragement. The author is thankful to Miss M. Yamazaki, Miss Y. Nakao, Mr. K. Oi and Miss H. Kubota for their deligent and skilful assistance in the course of this work. This study was finantially supported in part by a Grant in Aid for Scientific Research from the Ministry of Education.

Nuclear Quadrupole Resonances of Nitrogen in Amino and Amido Compounds*

By Midori MINEMATSU

Department of Physics, Tokyo University of Education, Otsuka, Tokyo

(Received March 6, 1959)

Pure quadrupole spectra of N^{14} in para-bromoaniline, para-chloroaniline, para-phenylenediamine, and urea were obtained. From the spectra quadrupole coupling constants and asymmetry parameters were determined. The apparent intensity of the high frequency line was always greater than that of the low frequency line when the method of Zeeman modulation was applied. This fact was interpreted from the second-order perturbation theory of Zeeman effect. By using the method of frequency modulation, the intensity difference between two lines became so small as it was interpreted with the population-difference between each state. The principal axis system of nitrogen in para-bromoaniline was determined with Zeeman studies. Discussions supported that the three bonds about nitrogen in these compounds are coplanar with the plane of benzen ring.

§ 1. Introduction

Since the first successful experiments on nuclear quadrupole resonances of nitogen in BrCN, ICN, and $(CH_2)_6N_4$ were carried out by Watkins and Pound in 1952[1], a few work has been done with this nucleus. In recent years O'Konski and Flautt found the resonances in NH_3, ND_3, and $N(CH_3)_3$[2], and Casabella and Bray in ClCN[3], and then in CH_3CN, C_2H_5CN, and $CH_2(CN_2)_2$[4]**. The latter authors gave an important discussion on the shape of trace of the resonance line. Chiba, Toyama and Morino detected one of nitrogen resonances in $CO(NH_2)_2$[5]***.

The theory of nuclear quadrupole resonance predicts that in nitrogen, which has a spin of unity, a non-zero field gradient asymmetry parameter, η, gives rise to two resonance lines. Therefore, a pair of resonance lines would be expected in urea. If the pair of resonance lines were observed, the nuclear quadrupole coupling constant and the asymmetry parameter would be determined from their frequencies. Amino-compounds, such as para-bromoaniline, para-chloroaniline and para-phenylenediamine, seemed to have a relatively large asymmetry parameter. The present work has been attempted to detect pairs of resonance lines in those compounds. A brief account of this work was reported by Kojima, Tanaka and the present author[6]. In this paper, the method of detection and the analysis of the results are described in detail. Further experiments on the method of frequency modulation and discussions on the apparent intensity of the line are also reported here.

§ 2. Experimental Procedure

a) *Detection of the resonance lines*

The nitrogen resonances whose frequencies are in a region between 2 Mc and 4 Mc were detected with a recording spectrometer. The principle of the spectrometer was essentially same as the Pound-Watkins[7] type, but the circuit was somewhat modified[8]. An oscillator in the spectrometer was a cathode-coupled 6J6 type with a cathode resistance. A decoupling resistance which served to decouple the tuned circuit from the plate of the second half of the 6J6 was adjusted to the largest value that sustained oscillation. A single-stage r.f. amplifier followed the oscillator. Its output was rectified by a 6AL5 and a negative voltage was fed into the second grid of the 6J6 through a circuit of capacity and resistance with a time constant of one second. This feedback was useful to stabilize the amplitude of oscillation and to control the level of oscillation. In this experiment, the r.f. level was adjusted by the feedback control, and the bias control in the cathode of the 6J6 was shorted out. The sensitivity of the spectrometer was measured by a calibrator. A narrow band amplifier⁹⁾, a phase sensitive detector¹⁰⁾, and an integrating output circuit were used and the signal was displayed on a recording meter. As a Zeeman modulation an on-off square wave of magnetic field at 160 cps was applied on the sample. Since the compounds which were used in the present experiments were expected to have a large asymmetry parameter, the strength of the Zeeman modulation field was increased up to about 50 gauss. The most of the measurements were done at liquid nitrogen temperature, in order to avoid an effect of the internal rotation of the N-H bond and to improve the signal-to-noise ratio. Since a saturation effect, however, increased at a low temperature, the spectrometer had to be used at a sufficiently low power-level to avoid it. In the best condition of the spectrometer, the power-level of the oscillator was about 0.5 v (r.m.s.), and the frequency-sweep of the spectrometer was 4∼6 kc per minute. At

** When the present work had just been finished, we received the report of the experiment on CH_3CN, C_2H_5CN, and $CH_2(CN_2)_2$ by Casabella and Bray. They mentioned that in the compound having a large η the detection of resonance would be very difficult in the experimental technique.

*** The author wishes to thank to Professor Y. Morino, Dr T. Chiba, and Mr. M. Toyama who gave her the information of high frequency line of urea before publication.

such condition a slight saturation effect still remained. The frequency of resonance was measured by the method that frequency-markers from a signal generator whose frequency was calibrated with J. J. Y. were superposed on the resonance traces. The compounds investigated were commercial products*. As all compounds tend to decompose above the melting points, these were carefully melted in glass envelopes of about 10 cc. The results of measurements are given in Table 1, and the recorded spectra in these compounds are shown in Fig. 1.

^{a} Very week.

b) *Zeeman effect*

A single crystal of p-$BrC_6H_4NH_2$ could be prepared by the method of pointed-bottom crucible[11], then the Zeeman studies on bromine and nitrogen were attempted. A Helmholtz coil which was used to give a magnetic field could be rotated for full 360° in the horizontal plane. The crystal was mounted as the cylindrical axis was parallel to the r.f. field and to the horizontal plane. It could be rotated for full 360° about this axis, so that all orientations of the magnetic field with respect to the crystal would be obtained.

For Zeeman studies on the resonance line of 221.8 Mc of Br^{81}, the field strength of about 300 gauss was used. From the measured zero-splitting loci, the orientations of the principal axes of bromine were obtained. The results indicated that there are two principal axis systems x_1, y_1, z_1, and x_2, y_2, z_2, and that the angle between the Br-C bounds is $78°24'\pm30'$ and the axes, y_1 and y_2, which lie in a plane of the benzene ring, are parallel.

The Zeeman studies on the nitrogen resonance were carried out with respect to the high frequency line, by using frequency modulation. The magnetic field was applied on three special orientations, which correspond to a, b and c axes of the crystal. In this case a Helmholtz coil[12] used was larger than that of the previous experiment for Br^{81} in order to cool the sample with liquid nitrogen. From the shifts of the lines at the three orientations of the applied field, the principal axes of nitrogen were determined. Since the experiment was more difficult than that of bromine, the results of measurements had considerable experimental errors.

§ 3. Analysis

a) *Spectra*

The Hamiltonian for the interaction between the quadrupole moment Q and the electric field gradient q_{ii} is given by the following formula[13]:

$$\mathscr{H}=K[3\boldsymbol{I}_z^2-\boldsymbol{I}^2-\eta(\boldsymbol{I}_x^2-\boldsymbol{I}_y^2)]\ , \tag{1}$$

where

$$K=\frac{eQq_{zz}}{4\boldsymbol{I}(2\boldsymbol{I}-1)}$$

and

$$\eta=\left|\frac{q_{xx}-q_{yy}}{q_{zz}}\right| .$$

In nitrogen, which has a spin of unity, a non-zero asymmetry parameter removes the degeneracy of the $m=\pm1$ state, and causes the transition to split into two[7]. Thus a quadrupole spectrum of N^{14} consists of a pair of resonance lines. Their frequencies are given by

$$\nu_1=(3-\eta)K$$

and

$$\nu_2=(3+\eta)K\ . \tag{2}$$

A third transition exists at $2\eta K$, but usually occurs so low in frequency that it is unobservable. When a weak magnetic field is applied to the system, the perturbation term to be added to the Hamiltonian (1) is

$$\mathscr{H}^1=-\boldsymbol{\mu H}=D(\cos\theta\cdot\boldsymbol{I}_z+\frac{\sin\theta}{2}[e^{-i\phi}\boldsymbol{I}_+ +e^{i\phi}\boldsymbol{I}_-])\ . \tag{3}$$

When η is small, the frequencies of observable transitions are given by the followings[3]:

$$\left.\begin{aligned}\nu_1'&=3K-(\eta^2K^2+D^2\cos^2\theta)^{1/2}\\ \nu_2'&=3K+(\eta^2K^2+D^2\cos^2\theta)^{1/2}\ .\end{aligned}\right\} \tag{4}$$

---

* The sample of urea was provided by Toyo Koatsu Industries, Inc.

An upper limit on the values of η for which the small η approximation is valid is about 14%. For the case where η is larger than this value, the frequencies must be solved by the second-order perturbation theory. Then, the frequencies are given by

$$\left.\begin{aligned} \nu_1'' &= (3-\eta)K - \frac{D^2\cos^2\theta}{2\eta K} + \frac{2D^2\sin^2\theta\sin^2\phi}{(3-\eta)K} \\ &\quad + \frac{D^2\sin^2\theta\cos^2\phi}{(3+\eta)K} \\ \nu_1'' &= (3+\eta)K + \frac{D^2\cos^2\theta}{2\eta K} + \frac{2D^2\sin^2\theta\cos^2\phi}{(3+\eta)K} \\ &\quad + \frac{D^2\sin^2\theta\sin^2\phi}{(3-\eta)K} \end{aligned}\right\} \tag{4'}$$

In a single crystal, each resonance line shifts according to the angle, θ and φ, which are the usual spherical polar coordinates of the applied magnetic field referred to the principal axis system of the field gradient tensor. In a polycrystalline or a powdered sample it is smeared out, because the orientations of the Zeeman field to the principal axes are at random on each nucleus in the samples. In any cases the effects of the field on the lines, which split due to η, increase their separation. In the recorded spectra with Zeeman modulation, if $\eta \neq 0$, the high frequency line has a negative wing on the higher side and the low frequency line has it on the lower side as discussed by Casabella and Bray.

p-$BrC_6H_5NH_2$, p-$ClC_6H_4NH_2$, and $CO(NH_2)_2$ have a pair of lines with the shapes as shown in Fig. 1. Among these compounds the crystal structures of p-$BrC_6H_4NH_2$ and p-$ClC_6H_4NH_2$ are known by Zeeman studies of nuclear quadrupole resonance of bromine[14] and chlorine[15], and that of urea is well known by X-ray diffraction measurements[16], and all nitrogen atoms in the compounds are at equivalent positions in the crystals. Both facts suggest that these pairs are caused by the non-zero asymmetry parameters. Therefore, the values of eQq and η are obtained with Eqs. (2). The results are listed in Table II. If the crystal structure of p-$(NH_2)_2C_6H_4$ was similar to that of p-$BrC_6H_4NH_2$ and p-$ClC_6H_4NH_2$, the resonance lines of p-$(NH_2)_2C_6H_4$ in which the number of N atoms per molecule is twice would be strongest among them. The spectrum, however, is composed of three pairs of lines, whose intensity is weaker than that of others. This suggests that there are three non-equivalent positions of N atoms in a unit cell. Since the variations of eQq and η by the crystal effects seem to be small, the combinations of lines as described in Table I would be plausible. In Table II the constants, eQq and η for one pair are listed.

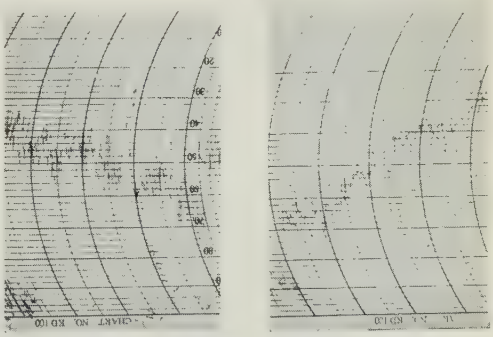
Table II. Quadrupole coupling parameters.

Compound	eQq (Mc/sec)	η (%)
p-$BrC_6H_4NH_2$	4.135	23.1
p-$ClC_6H_4NH_2$	4.117	24.3
p-$(NH_2)_2C_6H_4$	3.910	26.4
$CO(NH_2)_2$	3.507	32.3

On Zeeman powder pattern and on the shape of the negative wing, the detail discussions given by Casabella and Bray are applicable for the present cases.

b) *Strength of Zeeman modulation*

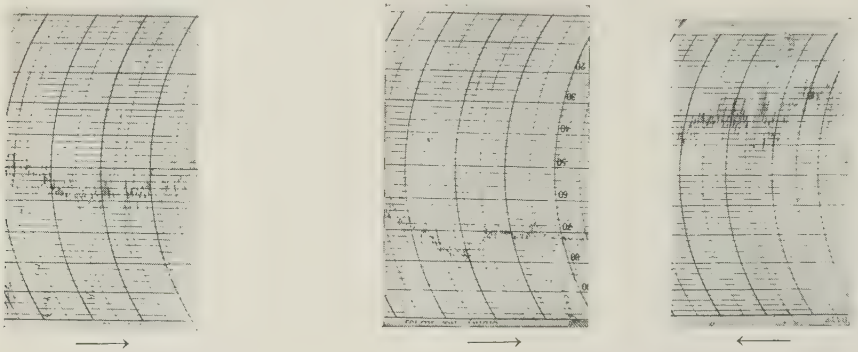
Since the Zeeman shift of the resonance frequency decreases when the asymmetry parameter increases, the Zeeman modulation of a large amplitude is necessary for the present cases. For an high frequency line in the powdered sample where η is 25 percent and K is about 1 Mc, the Zeeman modulation of amplitude of 100 gauss yields only an average shift of 1 kc, which is nearly equal to the line width. Therefore, the Zeeman modulation of amplitude of 50 gauss which was used in the present experiment should only give almost same intensity as the frequency modulation of amplitude of a half line width does. In fact, a comparison of the resonance lines of p-$BrC_6H_4NH_2$ between the Zeeman modulation and the frequency modula-



(a) Zeeman modulation. (b) Frequency modulation.

Fig. 2. Nitrogen resonances in p-$BrC_6H_4NH_2$.

tion shown in Fig. 2 indicates that the lines are nearly equal intensities. The more intense field will give the better signal-to-noise ratio. This will be also suggested from the intensity ratio between the negative wing and the positive main part, when the effect of saturation was removed. In the recording traces shown in Fig. 1, however, an extreme saturation appeares. For example, in urea, when the spectrometer was swept from low to high frequencies, the main positive part of the low frequency line and the negative wing of the high frequency line completely disappeared, and when the specrometer was swept from high to low frequencies, the situation was reversed. At room temperature where the relaxation time is short the negative wing appeared as shown in Fig. 3, even if the spectrometer was used at the same condition.



(a) Room temperature. (b) Liquid nitrogen temperature.

Fig. 3. Nitrogen resonances of high frequency lines in urea illustrating a saturation effects. The arrows indicates the direction of increasing frequency.

c) *Intensities of a pair of lines*

Under the same condition of spectrometer, in the same sensitivity, the same power level and the same rate of frequency sweep the intensities of a pair of lines were considerably different. The line of the high frequency was always stronger than the line of the low frequency. In the polycrystalline samples of the amino-compounds, the intensity ratio of the high frequency line to the low frequency line was from 1.5 to 1.7. In urea the ratio was about 2.5. The intensity difference can not be attributed simply to a saturation effect under the present experimental condition. The intensity difference sometimes comes from the difference of population of nuclei in the energy states. Since the ratio of the population-difference is approximately equal to the ratio of the resonance frequencies, a simple calculation yields that the intensity ratio of the two lines is about 1.25 for the case of urea. A large discrepancy between this value and the experimentally obtained value seems to depend on another mechanism. It may be an effect of the Zeeman modulation. When η is small enough, the Zeeman shifts are symmetrical as expressed by the second terms of Eqs. (4′). However, when η is large as the present cases, the third and fourth terms of the equations are not neglected. These terms result to asymmetrical shifts. The frequency shifts at the modulation field of 50 gauss were calculated for the polycrystalline samples of p-$BrC_6H_4NH_2$ and urea, where $\cos^2\theta$, $\sin^2\theta$, $\cos^2\varphi$ and $\sin^2\varphi$ in Eqs. (4′), were replaced by their average values,

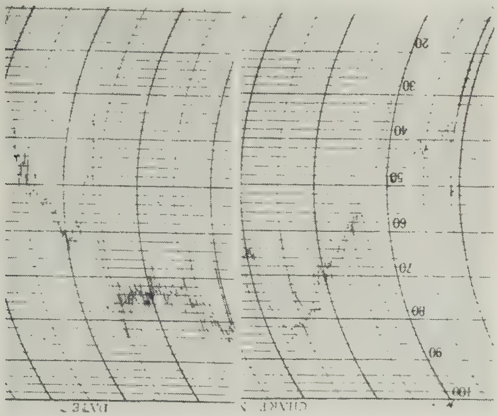
$$\langle \cos^2\theta \rangle_{av} = \langle \sin^2\theta \rangle_{av} = 1/2$$
$$\langle \cos^2\varphi \rangle_{av} = \langle \sin^2\varphi \rangle_{av} = 1/2 \, .$$

Table III. Zeeman shifts in polycrystal.

Compound	$\Delta\nu_1$ (c/sec)	$\Delta\nu_2$ (c/sec)
p-$BrC_6H_4NH_2$	215	341
$CO(NH_2)_2$	159	361

The calculated results are summerized in Table III. It shows that the Zeeman modulation field is less effective for the low frequency line than for the high frequency line. The pronounced difference of the intensities in urea is attributed to the effectiveness of the Zeeman field.

If the method of frequency modulation is applied, such a large intensity difference will not appear. Fig. 4 shows the traces of the nitrogen resonances in urea by this way. The intensity ratio of the two lines became about 1:2. This value agrees with that obtained from the simple calculation of population-ratio mentioned above.



Low frequency line High frequency line

Fig. 4. Nitrogen resonances in urea with frequency modulation.

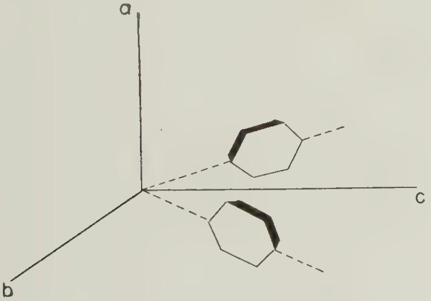


Fig. 5. Molecular arrangements in crystalline p-$BrC_6H_4NH_2$.

d) *Determination of principal axes*

If the r.f. field oriented to the x direction is applied to a single crystal, the high frequency line has the maximum intensity and the low frequency line vanishes. On the other hand, with the r.f. field in the y direction, the situation is reversed[17]. Therefore, the measurement of the intensity of resonance line in a single crystal is useful to determine the location of the principal axes. Beside this method the principal axes are also determined by Zeeman study. In this experiment both methods were applied for p-$BrC_6H_4NH_2$ which has two molecules with non-equivalent directions as shown in Fig. 5. The cylindrical axis of the single crystal prepared was nearly parallel to the a axis.

In this sample, the low frequency line was not detected while the high frequency line was stronger than that in other polycrystalline sample. This indicates that the orientation of the r.f. field to the cylindrical axis of the single crystal is nearly parallel to the x axis in the nitrogen atom.

The Zeeman studies on the nitrogen resonance were done at the three orientations described in the section 2 b, with the applied field of 68 gauss. The Zeeman shifts measured are listed in the last column of Table IV.

Table IV. Zeeman shifts in single crystal of p-$BrC_6H_4NH_2$.

Orientation			Frequency shift (c/sec)	
	θ	θ	calculated	observed
a	90°	0°	254	~100
b	39°12′	90°	700	~800
c	50°48′	90°	524	~500

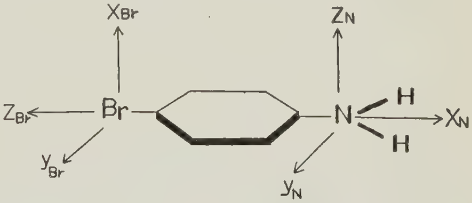

Fig. 6. Principal axis systems for bromine and nitrogen in p-$BrC_6H_4NH_2$.

The results are well interpreted by assuming that the z axis for the nitrogen atom is perpendicular to the plane of the benzene ring. The x and the y axes are discriminated from the intensity measurement of pair of lines. The principal axis system thus determined is shown in Fig. 6. Based upon this principal axis system, the Zeeman shifts at the three orintations were calculated with Eqs. (4′). In Table IV, the results are compared with the experimental results.

e) *Substituent Hammett's σ in amino-compounds*

In the cases of substituted chlorobenzenes, bromobenzenes and iodobenzenes, linear correlations between the resonance frequencies and the substituent parameters, sigma of

Hammett, have been noted[18)-22)]. The substituent constant is defined originally by the equation[23),24)]:

$$\log(K/K^\circ)\equiv\sigma \qquad (5)$$

where K° and K are the acid dissociation constants of benzoic acid and its monosubstituted derivatives, respectively. Eq. (5) implies an arbitrary definition of a reaction constant of unity for this reference series, and a substituent constant of zero for the unsubstituted compound. The relation between the resonance frequency and the substituent constant is attributed to the fact that the sigma value of substituent and quadrupole coupling constant of the halogen are both the measures of the electron density at the position of the halogen nucleus. Not only for halogen but also for nitrogen, that will be true. So the obtained coupling constants were compared with σ data in Table V. eQq increases as σ become greater. A correlation function as indicated by Bray and Barnes[22)] can not be determined accurately, because of small number of substances measured. However, it is shown that the tendency of the correlation function accords with that in case of halogen, although the nature of bonding in nitrogen differs considerably from that of halogen. According to the above correlation, the frequency of resonance line in p-$IC_6H_4NH_2$ is estimated to be somewhat higher than that in p-$BrC_6H_4NH_2$. The detection of the line has been carried out unsuccessfully.

Table V. Substituent constants at para position.

Substituent	σ_{para}	eQq (Mc/sec)
NH_2	−0.660	3.910
Cl	0.227	4.117
Br	0.232	4.135
I	0.276	

§ 4. Discussion

On amino-compound, it has not yet been established experimentally whether the bonds of nitrogen are strictly coplanar or not. However, the coplanarity is preferable for the arguments described in the following: Reaction constant at the para-position in the amino-compounds used, indicates the importance of the structure II shown in Fig. 7. If the valency angles at the nitrogen atom are the same as in ammonia, satisfactory resonance with the electron of the ring can not occur. In order to take account of the resonance structure the bonds of the nitrogen atom should be coplanar or nearly coplanar with the benzene ring. As Coulson has suggested[25)] it seems quite probable to consider the three bonds around the N atom as nearly coplanar.

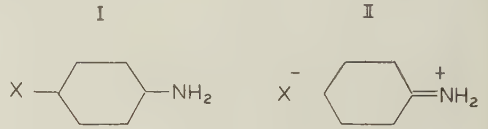

Fig. 7. Tetravalent resonance structure of nitrogen in aromatic molecules.

On urea, the evidence for the planar structure has been reported by Andrew and Hyndman[26)]. Though they assumed the three bonds of nitrogen are equivalent, the N-H bond and the N-C bond will be not necessarily equivalent. Therefore, the wave functions as the H-N-H angle is θ in a planar model are assumed. Then, they become

$$\left.\begin{aligned}
\psi_1&=p_z\\
\psi_2&=\sqrt{\alpha}\,s+\sqrt{1+\alpha}\,p_x\\
\psi_3&=\sqrt{\frac{1-\alpha}{2}}\,s-\sqrt{\frac{\alpha}{2}}\,p_x+\sqrt{\frac{1}{2}}\,p_y\\
\psi_4&=\sqrt{\frac{1-\alpha}{2}}\,s-\sqrt{\frac{\alpha}{2}}\,p_x-\sqrt{\frac{1}{2}}\,p_y
\end{aligned}\right\} \qquad (6)$$

where α is the s-character, being connected with θ as follows,

$$\tan\frac{\theta}{2}=\frac{1}{\sqrt{\alpha}}.$$

ψ_1 corresponds to the orbital of lone pair electron, ψ_2 to the N-C bond and ψ_3 and ψ_4 to the N-H bonds. The coordinate being chosen as shown in Fig. 8.

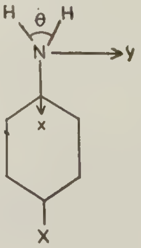

Fig. 8.

a) *Amino-compounds*

The bond structure can be considered to be made up of the five structures shown in Fig. 9, under which the fractional importance of each structure is described. β_1 and β_2 are assumed to be 13% and 35% respectively from electronegativity difference for the N-C and the N-H bonds[27]. The unbalanced electrons and the asymmetry parameter are calculated as follows;

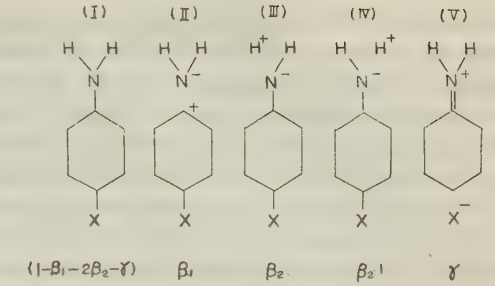

Fig. 9. Five resonance structures in p-$XC_6H_4NH_2$.

$$\left.\begin{aligned}
U_z&=-\left[1-\beta_1\left\{1-\frac{(1+\alpha)}{2(1+c)}\right\}-2\beta_2\left\{1+\frac{(3-\alpha)}{4(1+c)}\right\}-\gamma\right]\\
U_x&=\frac{1}{2}(1-\beta_1-2\beta_2-\gamma)-\frac{1}{2}(1-2\alpha)\frac{\beta_1}{1+c}+\frac{1}{2}(3-2\alpha)\frac{\beta_2}{1+c}\\
U_y&=\frac{1}{2}(1-\beta_1-2\beta_2-\gamma)+\frac{1}{2}(2-\alpha)\frac{\beta_1}{1+c}+\frac{\alpha\beta_2}{2(1+c)}\\
\eta&=\frac{U_x-U_y}{U_z}=\frac{3(1-\alpha)(\beta_2-\beta_1)}{2(1+c)U_z},
\end{aligned}\right\}\quad(7)$$

where c is the screening constant and estimated to be 0.32 for nitrogen[28]. Since the coupling constant for one unbalanced p-electron has not been measured for N^{14}, a value of 10 Mc was assumed[3]. The experimental values for eQq and η yield α and γ by the aid of Eqs (7). For p-$BrC_6H_4NH_2$ α is 0.6, corresponding to θ of 104°, and γ is 0.16. Table II indicates that eQq decreases gradually in the order of p-$BrC_6H_4NH_2$, p-$ClC_6H_4NH_2$, and p-$(NH_2)_2C_6H_4$ while η increases. If the atom X is substituted in p-$XC_6H_4NH_2$, the importance of the resonance structure V will vary with the atom X. As the atom X is more electron-attractive, the structure V is more important[28],[29]. Namely, when γ increases eQq decreases. This fact will be guessed from the substituent constants of Hammett's σ in the series of the side chain, for the constant indicates a measure of importance of the structure V depending on the atom X. Thus the results of amino-compounds can be reasonably interpreted.

b) *Urea*

For the reason as indicated before, discussions of the bonds around the nitrogen in urea can also be carried on with Eqs. (7). Using the experimental values for eQq and η, α is obtained to be 0.55 corresponding to θ of 107°, and γ to be 0.22. According to the analysis by X-ray, the length of the C-N bonds is 1.37 A[16], which indicates that the bonds have somewhat double bond character shown in Fig. 10. The fractional importance of this resonance structure calculated from the bond length is 0.27 which corresponds to γ. This agreement suggests that the consideration mentioned above seems to be reasonable.

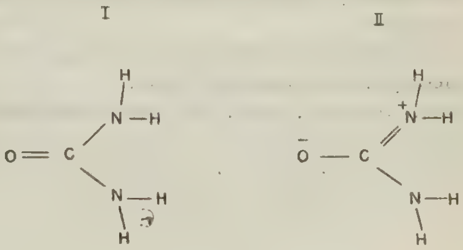

Fig. 10. Tetravalent resonance structure of nitrogen in urea.

§ 5. Conclusion

Pure quadrupole spectra of N^{14} in para-bromoaniline, para-chloroaniline, para-phenylenediamine, and urea were obtained. From the spectra, the quadrupole coupling constants and the asymmetry parameters were determined. The apparent intensity of the high frequency line was always greater than that of the low frequency line when the method of Zeeman modulation was applied. This was interpreted from the second-order perturbation theory of Zeeman effect. The principal axis system of nitrogen in p-$BrC_6H_4NH_2$ was determined, by using the method of frequency modulation. The results mentioned above seem to support that the three bonds about nitrogen in amino-compounds such as aniline are coplanar with the plane of benzene ring. The values of eQq and η for these compounds were analyzed by the aid of the planar model.

The author wishes to express her sincere thanks to Professor Shoji Kojima for his kind guidance and encouragement throughout the course of this work. She is also grateful to Mr. M. Tanaka for his helps on experiments and to other members of the laboratory for their valuable discussions.

Thomas-Fermi Model of Positive Ion

By Shigehiro KOBAYASHI

Department of Physics, Kagawa University, Takamatsu

(Received March 9, 1959)

Exact solutions of the Thomas-Fermi equation for positive ion have been obtained including their derivatives by the inward numerical integration. The whole range of the ionization degree of physical interest has been covered in sufficient detail to permit accurate interpolation for intermediate regions. Using these numerical solutions, several physical quantities of free positive ions have been investigated.

§ 1. Introduction

The statistical model of Thomas[1]-Fermi[2] (to be referred to as TF hereafter) has provided an important means for obtaining qualitative as well as semi-quantitative estimates of atomic behavior. Since it needs tedious numerical integration to solve the fundamental equation, the so-called TF equation, the accurate solutions for neutral atoms in compressed states as well as free states have been reported only several years ago by Latter[3] and others[4]. For the case of positive ions there were hitherto only a few typical solutions reported by Fermi[5], by Miranda[6] and by Feynman, Metropolis and Teller[7]. These were obtained by the *outward* integration of the TF equation. This method is available for not too small values of ionization degree because the integral curves then cut the x-axis in a fairly large angle at a finite distance from the origin. For smaller values of ionization degree, however, the curves meet the x-axis nearly tangentially so that the values of the boundary radius and the tangential slope there (or the ionization degree) cannot be accurately determined. In consequence, we have had no exact relationship between the boundary radius and the ionization degree, and some uncertainties have followed in the calculation of the physical quantities of the TF positive ions. The object of this paper is to remove these uncertainties by the adoption of the *inward* numerical integration and to obtain accurate information about the TF positive ions.

First, we have calculated exact solutions of the TF equation for positive ions in a systematic sequence of ionization degree by the inward numerical integration method (§ 2), which has been employed successfully to overcome the similar difficulty occuring in the case of the Thomas-Fermi-Dirac (TFD) model[8] as well as the TF model[9] for free neutral atoms.

Using the values of the TF functions and their derivatives obtained as solutions of the TF equation, we have investigated systematically such quantities of positive ions as Fermi coefficient (§ 3), boundary radius (§ 4), ionic radius (§ 5), energy and ionization potential (§ 6), mean excitation potential and energy (§ 7), diamagnetic susceptibility (§ 8), scattering factors (§ 9) and electric field at the nucleus of polarized ions (§ 10) as functions of ionization degree and atomic number, respectively.

As seen from the calculated values of some physical quantities, *e.g.* diamagnetic susceptibility of neon-like ions[10] etc., the TF method provides a better approximation for positive ions than for neutral atoms owing to the large electron density caused by strong contraction of the electron cloud.

§ 2. Method of Solution of the TF Equation

It is well known[11] that the potential V and the electron density ρ at the distance

$$x=r/\mu \tag{1}$$

measured in the TF unit

$$\mu=\frac{1}{4}\left(\frac{9\pi^2}{2Z}\right)^{1/3}a_0\,, \qquad \left(a_0=\frac{h^2}{4\pi^2me^2}\right) \tag{2}$$

within the ion having atomic number Z, electron number N and boundary radius $r_0=\mu x_0$, are expressed as follows:

$$V=\frac{Ze}{r}\varphi+V_0\,, \tag{3}$$

$$V_0=(Z-N)e/r_0 \tag{4}$$

$$\rho=\frac{Z}{4\pi\mu^3}\left(\frac{\varphi}{x}\right)^{3/2}. \tag{5}$$

Here φ is the TF function and satisfies the TF equation

$$\varphi''=\varphi^{3/2}/x^{1/2} \tag{6}$$

subject to the boundary conditions

$$\varphi(0)=1 \tag{7}$$

and

$$\varphi(x_0)=0,\ -x_0\varphi'(x_0)=\frac{Z-N}{Z}\equiv q\ . \tag{8}$$

Eq. (7) corresponds to the singularity of the electrostatic potential $V(r)\sim Ze/r$ at the nucleus $r\sim 0$. Eq. (8) results from the values of the potential and field strength at the boundary $x=x_0$ of the free ion with the ionization degree q.

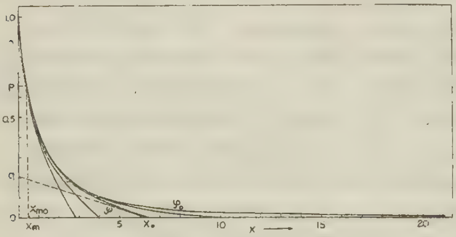

Fig. 1. Curves of the TF function $\varphi(x)$.
φ_0: for free neutral atom.
φ: for positive ion.
x_0: boundary radius.
q: ionization degree.
x_{m0}: atomic radius.
x_m: ionic radius. ($\overline{OP}:\overline{PQ}=3:1$)

To avoid the effect of the self-field of the electron from the original TF model represented by above Eqs. (1) to (8), Fermi and Amaldi[12] (FA) have proposed a modified TF model, by the use of which we can treat the free states of the singly ionized negative ions[13] as well as atoms and positive ions, as follows:

$$x=r/\mu^*\ , \tag{1'}$$

$$\mu^*=\left(\frac{N}{N-1}\right)^{2/3}\mu\ , \tag{2'}$$

$$V=\frac{Ze}{r}\varphi-\frac{e}{N}\int\frac{\rho}{r}dv+V_0^*\ , \tag{3'}$$

$$V_0^*=(Z-N+1)e/r_0\ , \tag{4'}$$

$$\rho=\frac{Z}{4\pi\mu^{*3}}\ \frac{N}{N-1}\left(\frac{\varphi}{x}\right)^{3/2}, \tag{5'}$$

$$\varphi''=\varphi^{3/2}/x^{1/2}, \tag{6'}$$

$$\varphi(0)=1\ , \tag{7'}$$

$$\varphi(x_0)=0,\ -x_0\varphi'(x_0)=q+\frac{1}{Z}\ . \tag{8'}$$

In order to solve, not outwardly but inwardly, the original TF Eq. (6) for positive ions subject to the boundary condition Eqs. (7) and (8) as stated above, we assume an appropriately chosen value of ionization degree for each of a number of starting points taken midway between $x=2$ and 36.5.

In accordance with the same numerical integration routine that we have used for free neutral atoms[9], the starting values of φ and its derivatives in the neighborhood of a chosen starting point x_0 were calculated with the use of series expansion

$$\begin{aligned}\varphi(x)=\ &q\left(1-\frac{x}{x_0}\right)+\frac{4}{35}(qx_0)^{3/2}\left(1-\frac{x}{x_0}\right)^{7/2}+\frac{2}{63}(qx_0)^{3/2}\left(1-\frac{x}{x_0}\right)^{9/2}\\&+\frac{1}{66}(qx_0)^{3/2}\left(1-\frac{x}{x_0}\right)^{11/2}+\frac{1}{175}q^2x_0^3\left(1-\frac{x}{x_0}\right)^{6}+\frac{5}{572}(qx_0)^{3/2}\left(1-\frac{x}{x_0}\right)^{13/2}\\&+\frac{1}{315}q^2x_0^3\left(1-\frac{x}{x_0}\right)^{7}+\frac{7}{1248}(qx_0)^{3/2}\left(1-\frac{x}{x_0}\right)^{15/2}+\frac{16}{8085}q^2x_0^3\left(1-\frac{x}{x_0}\right)^{8}\\&+\frac{1}{85}\left[\frac{21}{64}+\frac{22}{1225}qx_0^3\right](qx_0)^{3/2}\left(1-\frac{x}{x_0}\right)^{17/2}+\frac{4}{3003}qx_0^3\left(1-\frac{x}{x_0}\right)^{9}\\&+\frac{11}{17}\left[\frac{21}{4864}+\frac{1}{3675}qx_0^3\right](qx_0)^{3/2}\left(1-\frac{x}{x_0}\right)^{19/2}+\frac{128}{135135}q^2x_0^3\left(1-\frac{x}{x_0}\right)^{10}\\&+\cdots\cdots\cdots\ .\end{aligned} \tag{9}$$

The integral curve thus obtained, starting from an arbitrarily chosen point $x=\bar{x}_0$ with appropriately assumed ionization degree $\bar{q}$, cuts the φ-axis in a non-vanishing angle so that it is possible to determine accurately the point of intersection $\bar{\varphi}(0)$ as well as the slope $\bar{\varphi}'(0)$ there. Of course, $\bar{\varphi}(0)$ is not always unity as requested by the boundary condition

Table I. Values of $-\varphi'(0)$, $-\varphi'(x_0)$, $-k$, x_0, q, Z and $\int_0^{x_0}\varphi x dx$ for a sequence of different states of ionization of free positive ions.

Eq. (7). But it is possible to make the solution $\bar{\varphi}(\bar{x})$ satisfy Eq. (7) and get the normalized TF function $\varphi(x)$, if we apply the scale factor transformation based on the Sommerfeld invariance property[14] of the TF equation, as:

$$
\begin{aligned}
&[\bar{\varphi}(0)]^{1/3}\bar{x} \to x\,, \\
&\bar{\varphi}(x)/\bar{\varphi}(0) \to \bar{\varphi}(x)\,, \\
&\bar{\varphi}'(x)/[\bar{\varphi}'(0)]^{4/3} \to \varphi'(x)\,,
\end{aligned}
\qquad (10)
$$

and

$$\bar{q}/\bar{\varphi}(0) \to q\,.$$

The full tables of the obtained values of the normalized TF functions and their derivatives of free positive ions for twenty-eight different degrees of ionization have been published in a separate paper[15] which is available on request.

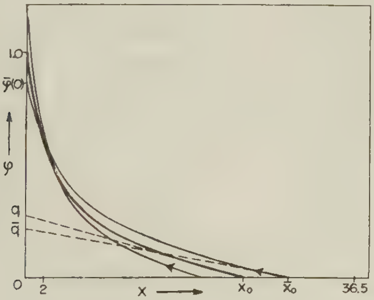

Fig. 2. Solution curves of the TF equation.

$\bar{x}_0$: starting point taken arbitrarily midway between $x=2$ and 36.5.
$\bar{q}$: ionization degree assumed appropriately for $\bar{x}_0$.
$\bar{\varphi}$: integral curve.
$\bar{\varphi}(0)$: final value ($\neq 1$).
φ: normalized TF function $\varphi=\bar{\varphi}/\bar{\varphi}(0)$.
x_0: boundary radius $x_0=[\bar{\varphi}(0)]^{1/3}\bar{x}_0$.
q: ionization degree $q=\bar{q}/\bar{\varphi}(0)$.

Two curves of $\varphi(x)$ and $\bar{\varphi}(\bar{x})$ always cross each other.

It is very convenient that these values for free positive original TF model can be directed to the FA-modified TF atoms and ions as well as compressed positive ions.

In Table I are columed the values of initial slope, Fermi coefficient, boundary radius, ionization degree and atomic number corresponding to the order of ionization from one to four for the calculated states mentioned above. For the sake of completeness the three states given by Miranda[6] are inserted. In Table II, we have these quantities as functions of ionization degree in a regular sequence.

§ 3. Fermi Coefficient

The TF function for positive ions can also be expressed approximately with the use the ordinary TF function φ_0 for free neutral atoms and the Fermi part η_0 as[6]

$$
\begin{aligned}
\varphi(x) &= \varphi_0(x) + k\eta_0(x)\,, \\
\varphi'(x) &= \varphi_0'(x) + k\eta_0'(x)\,.
\end{aligned}
\qquad (11)
$$

Since these values have been recently tabulated accurately by the present author[16], the inverted equation of Eq. (11)

$$k(x) = \frac{\varphi(x)-\varphi_0(x)}{\eta_0(x)} = \frac{\varphi'(x)-\varphi_0'(x)}{\eta_0'(x)} \qquad (12)$$

affords information about the constancy of the Fermi coefficient k, namely the validity of Eq. (11).

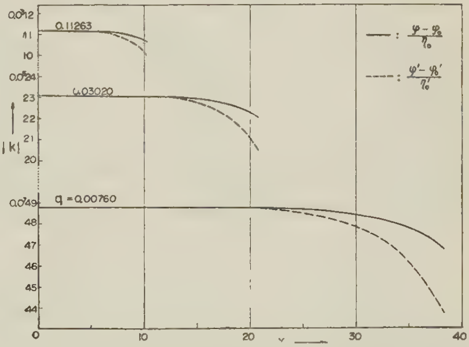

Fig. 3. Fermi coefficient $k(x, q=\text{const})$-curves. The turning point of two curves in each state corresponds to the position x where the value of $k\eta_0(x)$ equals to about 1/10 of $\varphi_0(x)$.

The values of k, thus obtained for three typical states, are plotted in Fig. 3 which shows that we can regard k as a constant in each state where the value of $k\eta_0(x)$ is small compared with that of $\varphi_0(x)$ by less than 1/10.

These constant values of k in each state are listed in Tables I and II. They are also plotted *versus* q in logarithmic scale in Fig. 4. In this figure, as Fermi and Amaldi[12] have pointed out, we find the existence of approximate linear relation between $\log|k|$ and $\log q$, which is determined by the method of least squares as

$$k = -0.0542\, q^{2.86}\,, \qquad (13)$$

while Fermi and Amaldi gave an expression with somewhat different numerical parameters

$$k=-0.083\,q^3\,. \tag{13'}$$

The exact relation Eq. (13) enables us to construct correctly the TF functions for positive ions with any ionization degree and to calculate easily various physical quantities concerned with positive ions. However, as it is an approximate expression, we cannot expect too much of the results evaluated along this line. All values of the physical quantities in the following sections have been directly calculated with the use of our tables[15] of the TF functions obtained as solutions of the TF equation for free positive ions. The full tables of them are available on request.

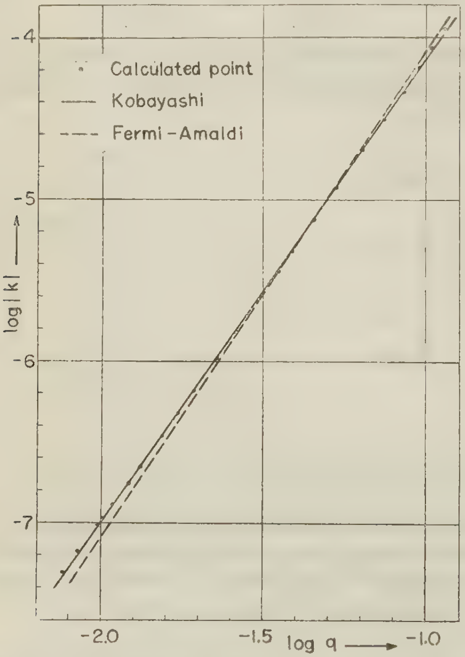

Fig. 4. Dependence on q of k.
The full line is determined by the method of least squares, while the dotted line by Fermi and Amaldi. Approximation degree of these lines is indicated by the numericals of the columns 3 and 4 in Table II.

§ 4. Boundary Radius

The dependence of boundary radius x_0 of free positive ions on initial slope $\varphi'(0)$, ionization degree q and atomic number Z is given by the numericals in Table I and II and shown in Figs. 5 and 6. In Table II, for reference, we have tabulated the values of boundary radius calculated by Fermi[6] and those recalculated by the present author with the Sommerfeld approximate formula[14]

$$\frac{z_0}{(1+z_0)^{1+\lambda_1/2}}=\frac{q}{\lambda_1}\,, \tag{14}$$

where

$$z_0\equiv(x_0/12^{2/3})^{\lambda_2}$$

and

$$\lambda_1\equiv7+\sqrt{73}\,,\quad \lambda_2\equiv-7+\sqrt{73}\,.$$

These values are also plotted in Fig. 5 which indicates that for smaller q the Sommerfeld approximate formula is better, and for larger q the calculated values by Fermi are nearer to the exact curve than the Sommerfeld formula. The reason for this fact lies in the circumstances that the Fermi values have been obtained by the outward integration which is applicable for larger q, while the Sommerfeld formula has an asymptotic

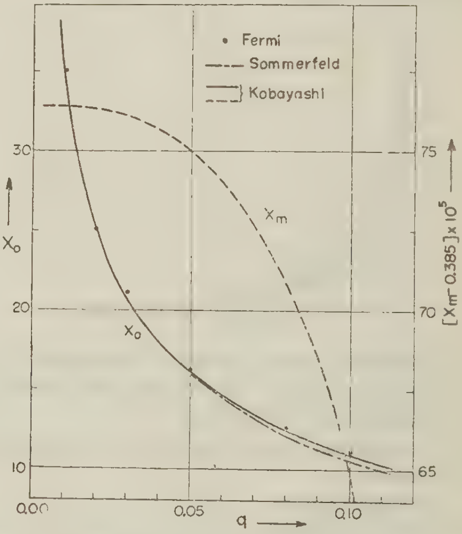

Fig. 5. Dependence of x_0 and x_m on q.

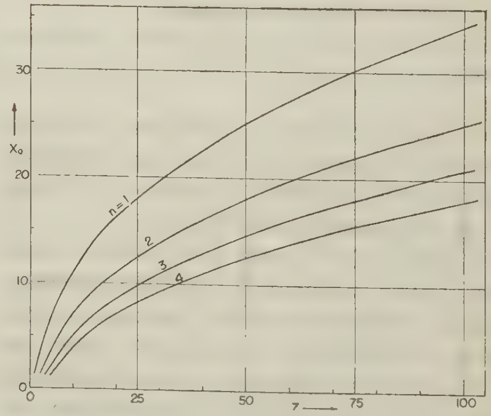

Fig. 6. Dependence on Z of x_0 for singly ($n=1$) to quadruply ($n=4$) ionized positive ions.

character valid for smaller q.

As seen in Figs. 5 and 6, the boundary radius x_0 of the TF ions monotonically decreases with the increase of ionization degree q and increases with the increase of atomic number Z for a fixed order of ionization n, and it is a defect of the TF model that it cannot explain the periodic properties.

In the FA-modified TF model, the above values of x_0 for free positive ions with atomic number $Z(n)$ turn out to be the boundary radius of free ions with atomic number $Z(n-1)$, and $Z(0)$ means the atomic number Z of free neutral atoms. Our numerical values of several atoms are given in Table III, with the Fermi coefficient k for them.

§ 5. Ionic Radius

By the radius corresponding to the maximum of radial electron density, we define ionic radius of the TF ions in the same manner as for neutral atoms[17]. Since the radial density is given by $4\pi\rho r^2=(\varphi^3x)^{1/2}Z/\mu$, the ionic radius x_m is the root of the equation

$$\varphi(x)+3x\varphi'(x)=0 \qquad (15)$$

which, as seen in Fig. 1, the geometrical meaning that $\varphi(x_m)=\overline{OP}=3\overline{PQ}=3x_m|\varphi'(x_m)|$.

The numerical values of the ionic radius of ions for various states of ionization follow from our tables of the TF functions, and are columned in Table II, which shows that the ionic radii x_m in different states of ionization differ only slightly from the atomic radius x_{m0} of free neutral atoms.*

Taking into consideration that this difference $\delta=x_m-x_{m0}$ and the Fermi coefficient k are both small quantities, we can also determine these values by the following approximate method. If we rewrite and expand Eq. (15) with the use of δ and k and neglect the higher order terms of small quantities, we obtain

$$\varphi_0(x_{m0})+3x_{m0}\varphi_0'(x_{m0})=0$$

and

$$k\eta_0(x_{m0})+\varphi_0'(x_{m0})\delta+3\varphi_0'(x_{m0})\delta$$
$$+3x_{m0}[k\eta_0'(x_{m0})+\varphi_0'(x_{m0})\delta]=0\,.$$

The former is the equation that gives the atomic radius and from the latter δ is determined as

$$\delta=-\frac{\eta_0(x_{m0})+3x_{m0}\eta_0'(x_{m0})}{4\varphi_0'(x_{m0})+3x_{m0}^{1/2}[\varphi_0(x_{m0})]^{3/2}}$$
$$=1.42\,k=-0.0770\,q^{2.86}. \qquad (16)$$

In Table II, there are columned the values of δ/k as well as x_m/x_0 as functions of ionization degree q. We have also listed the values of the ionic radius which are obtained by the same method applied to the Sommerfeld asymptotic solution for ions[14]

---

* The value of the atomic radius of free neutral TF atoms obtained by the present author is 0.3857 6441, while it is 0.3857 653 by Matsukuma[18].

$$\varphi=\frac{1}{(1+z)^{\lambda_1/2}}\left[1-\left(\frac{1+z}{1+z_0}\right)^{\lambda_1/\lambda_2}\right]. \tag{17}$$

The disagreement between these values and the exact ones results from the fact that the ionic radii are ordinarily small and the Sommerfeld solution does not give a good approximation for these small x owing to its asymptotic character.

The dependence of the ionic radius x_m on ionization degree q is also shown in Fig. 5. It is natural that the ionic radius of the TF ions decreases monotonically with the increase of ionization degree.

§ 6. Energy and Ionization Potential

The energies of n-ply ionized positive ions with atomic number Z[11]

$$E(Z,n)=\frac{12}{7}\left(\frac{2}{9\pi^2}\right)^{1/3}Z^{7/3}\left[\varphi'(0)+\frac{n^2}{Z^2x_0}\right]\frac{e^2}{a_0}$$
$$=13.172\left(\frac{n}{q}\right)^{7/3}\left[\varphi'(0)+\frac{q^2}{x_0}\right]eV \tag{18}$$

have been evaluated with the use of Table I. The values of $E(Z, n)$ obtained for various order of ionization n are, in spite of their small differences, on one straight line drawn in Fig. 7 in logarithmic scale.*

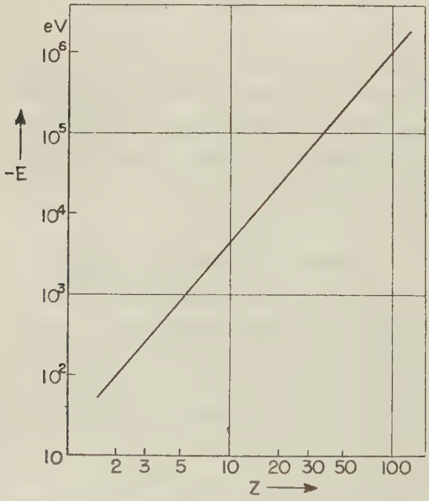

Fig. 7. Dependence on Z of E.
The energies $E(Z, n)$ for singly to quadruply ionized positive ions as well as atoms are shown by one straight line in spite of their small differences.

The total or successive ionization potential (that is, the energy required to remove n electrons in all, or the n-th electron alone, from the atoms or ions) is given respectively by

$$Q(Z,n)=E(Z,n)-E(Z,0)$$
$$=13.172\left(\frac{n}{q}\right)^{7/3}\left[\varphi'(0)+\frac{q^2}{x_0}\right]eV \tag{19}$$

or

$$J(Z,n)=Q(Z,n)-Q(Z,n-1)\,. \tag{20}$$

The results obtained for the former are shown in Fig. 8 and those for the latter are tabulated in Table IV. The excessive smallness of these values as compared with the experimental values[19] seems to be due to the omission of the exchange and correlation energies in the TF model.

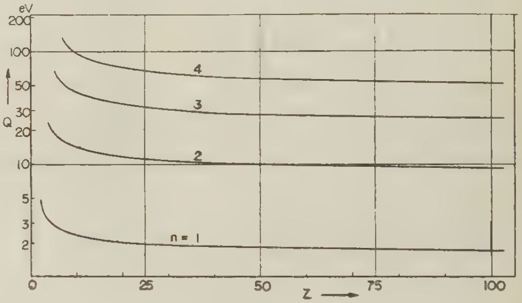

Fig. 8. Dependence on Z of Q.

§ 7. Mean Excitation Potential and Energy

Using our tables of the TF functions for free positive ions, we have calculated the mean excitation potential and energy which are defined by Bethe[20] and Sommerfeld[14] as a logarithmic mean

$$\log V_M=\int_0^{r_0}\log V\cdot\rho r^2\,dr\Big/\int_0^{r_0}\rho r^2 dr$$

and

$$\log E_M=\int_0^{r_0}\log|E|\cdot\rho r^2\,dr\Big/\int_0^{r_0}\rho r^2 dr\,.$$

Here V and E are the electrostatic potential and mean total energy per electron at distance r from the nucleus,

$$V=\frac{Ze}{r}\varphi+V_0=\frac{Ze}{\mu}\left[\frac{\varphi}{x}+\frac{q}{x_0}\right]$$

and

$$E=\frac{3e}{5}(V-V_0)-eV=-\frac{2Ze^2}{5\mu}\left[\frac{\varphi}{x}+\frac{5}{2}\frac{q}{x_0}\right],$$

respectively.

---

* Our value of energy for free atoms

$E(Z,0)=-0.76875\,Z^{7/3}=-20.917\,Z^{7/3}$ eV

is also represented with same line in Fig. 7.

Table IV. Ionization potential $J(n)$.

Z	atom	J $(n=1)$		J $(n=2)$		$J(3)$	$J(4)$
		cal.	exp.	cal.	exp.		
10	Ne	2.36	21.56	12.04	41.07	29.3	51.8
18	A	2.11	15.76	10.09	27.62	22.8	40.5
36	Kr	1.91	14.00	8.73	24.56	19.0	31.5
54	Xe	1.82	12.13	8.19	21.21	17.4	29.1

If we evaluate

$$\gamma_V(q)=\int_0^{x_0}\varphi^{3/2}x^{1/2}\log\left[\frac{\varphi}{x}+\frac{q}{x_0}\right]dx \div\int_0^{x_0}\varphi^{3/2}x^{1/2}dx$$

and

$$\gamma_E(q)=\int_0^{x_0}\varphi^{3/2}x^{1/2}\log\left[\frac{\varphi}{x}+\frac{5}{2}\frac{q}{x_0}\right]dx \div\int_0^{x_0}\varphi^{3/2}x^{1/2}dx$$

both of which depend only on ionization degree q, we can express the mean excitation potential and energy as

$$\left.\begin{aligned} V_M(Z,\ n)&=\frac{Ze}{\mu}\cdot 10^{\gamma_V}\\ &=4\left(\frac{2}{9\pi^2}\right)^{1/3}\cdot 10^{\gamma_V}Z^{4/3}\frac{e}{a_0}\\ \text{and}\qquad&\\ E_M(Z,\ n)&=\frac{2Ze^2}{5\mu}\cdot 10^{\gamma_E}\\ &=\frac{8}{5}\left(\frac{2}{9\pi^2}\right)^{1/3}\cdot 10^{\gamma_E}Z^{4/3}\frac{e^2}{a_0}\,. \end{aligned}\right\}\qquad(21)$$

Existence of the simple relations $V_M(Z,\ n)=n^{4/3}V_M(Z/n,\ 1)$ and $E_M(Z,\ n)=n^{4/3}E_M(Z/n,\ 1)$, which are characteristic of the TF model and cannot be found in the TFD model[21], makes it easy for us to calculate the values of V_M and E_M for larger n. The curves that indicate the dependence on Z of E_M for singly to quadruply ionized positive ions are shown in Fig. 9, in which we have drawn the line for free neutral atoms* for reference.

The V_M and E_M curves for n-ply ionized positive ions become infinite for $Z=n$, *i.e.* bare ions with no electron, as well as $Z=\infty$, and have the minimum for a definite intermediate value of Z, say $Z_{\min}$, while in the case of neutral atoms V_M and E_M vanish owing to the singularity of its bare states, *i.e.* $Z=0$. Fig. 9 shows that the values of $Z_{\min}$ and $E_M(Z_{\min})$ increase with the increase of n, respectively.

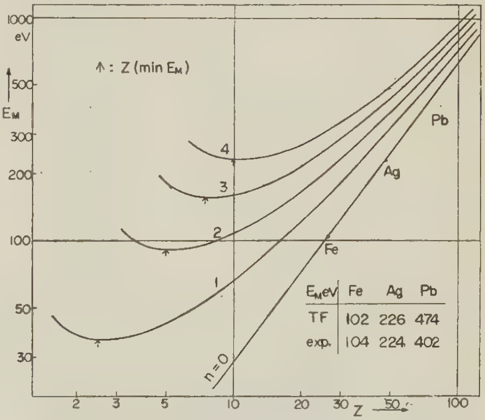

Fig. 9. Dependence on Z of E_M.

§ 8. Diamagnetic Susceptibility

The molar diamagnetic susceptibilities[11]

$$\chi=-\frac{Le^2}{6mc^2}\int_0^{r_0}4\pi\rho r^4dr$$

with L=Loschmidt number and c=light velocity, have been computed for positive ions. As is well known, the original TF model is inadequate for this purpose because of the overspreading of the electron cloud within the model. So we have calculated them with the use of the FA-modified TF model for free neutral atoms and for singly to quadruply ionized positive ions. Then, the formula to be used is given by

$$\chi(Z,\ n)=-0.62105Z^{1/3}\left(\frac{Z-n}{Z-n-1}\right)^{7/3}\times\left[6\int_0^{x_0}\varphi x dx-x_0^3\varphi'(x_0)\right]\times 10^{-6}\ \text{cm}^3,\quad(22)$$

---

* Our recalculated values using the exact table of the ordinary TF function for free neutral atoms

$$V_M(Z,\ 0)=0.12222\,Z^{4/3}\cdot e/a_0$$

and

$$M_M(Z,\ 0)=0.48887\,Z^{4/3}\cdot e^2/a_0 =1.3302\,Z^{4/3}\,\text{eV}$$

have reproduced Gombás' values[11].

and the term in the bracket depends on ionization degree q only. We have added to Table I the values of $\int_0^{x_0}\varphi x\,dx$, evaluated for the different states of ionization by the extended Simpson rule.*[,22)]

In comparison with the other theoretical[10),23)] and experimental values[24)], our numerical values are tabulated in Table V for the inert gas atoms and ions homologous to the inert gas, for which only the spherically symmetrical TF model is legitimately valid. As seen from the table, our results are fairly good. From the standpoint of the diamagnetic susceptibility, the FA-modified TF model seems to have a little more overspreading of the electron cloud than the TFD model[23)].

Table V. Comparison of the molar diamagnetic susceptibility $-\chi\times10^6$ cm^3.

* The experimental values for ions are the estimated ones for compressed state in solid and liquid, while all theoretical values are for free ions.

§ 9. Scattering Factor

The X-ray scattering factors, coherent and incoherent, of the free positive TF ions at rest have been investigated.

The coherent scattering factor[25)] of positive ions is given by

$$f_0=\int_0^{x_0}\frac{\sin\kappa r}{\kappa r}4\pi\rho r^2dr$$

$$=Z\left[1-q\frac{\sin(\kappa\mu x_0)}{\kappa\mu x_0}-\kappa\mu\int_0^{x_0}\varphi\sin(\kappa\mu x)\,dx\right]\qquad(23)$$

with $\kappa=4\pi\sin\theta/\lambda$ and $\theta=$half scattering angle.

For very small scattering angles[20),26)], Eq. (23) can be approximated as

$$f_0\approx Z\left[1-q-(\kappa\mu)^2\int_0^{x_0}\varphi x dx\right]$$

the coefficient $\int_0^{x_0}\varphi x dx$ appears also in the calculation of the diamagnetic susceptibility Eq. (22) and is given as function of q in Table I.

For the convenience of comparison with the incoherent scattering factor, we do not use the scattering factor per electron $\mathfrak{f}_0=f_0/N$ defined by Bethe[20)], but rather the scattering factor per atomic number $\boldsymbol{f}_0=f_0/Z=N/Z\mathfrak{f}_0$. This quantity $\boldsymbol{f}_0$ depends only on the ionization degree q and on $\kappa\mu\propto Z^{-1/3}\sin\theta/\lambda$, and has been calculated for twenty eight different states of ionization degree q and for $\kappa\mu=0°$ (5°) 40°, 50° (12.5°) 200°. The dependence of $\boldsymbol{f}_0$ on $\kappa\mu$ (or $Z^{-1/3}\sin\theta/\lambda$) and on q is shown in Figs. 10 and 11. The numerical values are tabulated in Table VI for regular intervals of q.

---

* This rule may be used for numerical integrations with roughly divided intervals, and has also been applied to all other integrals in this paper.

As is seen in these figures and in the table, the coherent scattering factor per atomic number f_0 has the following features:

(1) $f_0(q=0,\ \kappa\mu=0°)=1$

(2) $f_0(q,\ \kappa\mu=0°)=1-q$,
$f_0(q,\ \kappa\mu=0°)=Z(1-q)=N$

(3) $f_0(q=1,\ \kappa\mu)=0$

(4) $f_0(q,\ \kappa\mu=\infty)=0$

(5) $f_0(q,\ \kappa\mu>50°)$ is nearly independent of small q or large x_0.

(6) $f_0(q=\text{const},\ \kappa\mu)$ is a monotonically decreasing function of $\kappa\mu$.

The comparison of the calculated values of f_0 with those[28)] calculated using the Hartree-Fock field for several positive ions is shown in Fig 12. We find the agreement is qualitatively sufficient.

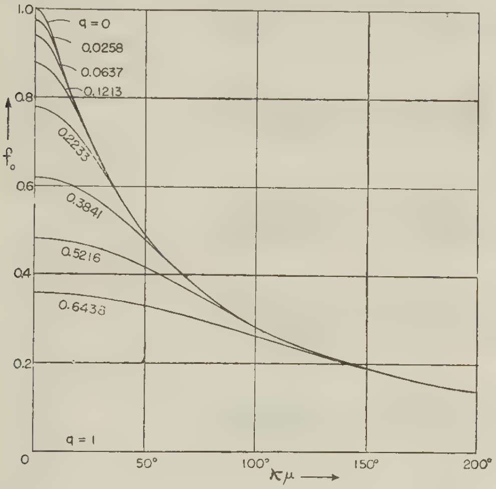

Fig. 10. $f_0(\kappa\mu,\ q=\text{const})$-curves.

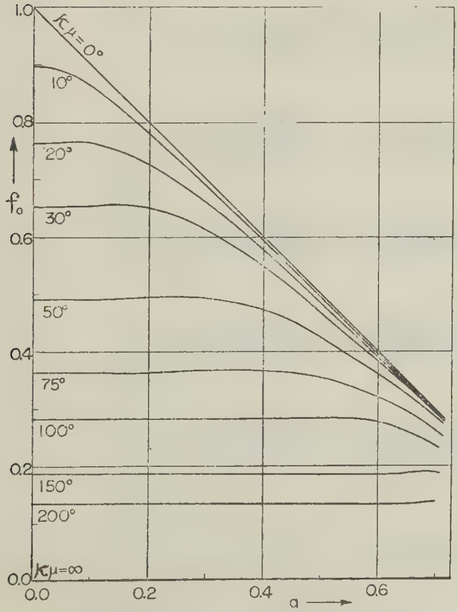

Fig. 11. $f_0(q,\ \kappa\mu=\text{const})$-curves.

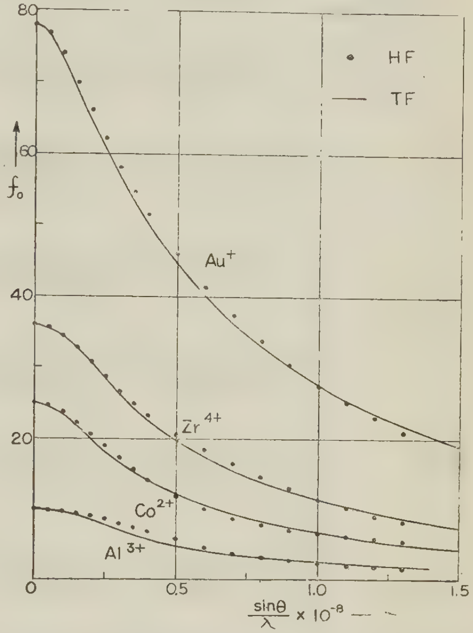

Fig. 12. Comparison of f_0 curves based on the TF model and Hartree-Fock field for singly to quadruply ionized positive ions.

The incoherent scattering factor per electron[29)] can be calculated from the expression

$$\begin{aligned} s_0^2(w) &= 1-\int_0^{\xi_0}[\sqrt{\varphi/x}-w]^2\left[\sqrt{\varphi/x}+\frac{w}{2}\right]x^2dx \\ &= 1-\frac{1}{6}(w\xi_0)^3+\int_0^{\xi_0}\left[\frac{3}{2}w\varphi x-\varphi^{2/3}\,x^{1/2}\right]dx \\ &= \varphi(\xi_0)-\xi_0\varphi'(\xi_0) \\ &\quad -\frac{1}{6}(w\xi_0)^3+\frac{3}{2}w\int_0^{\xi_0}\varphi x dx\ , \end{aligned} \tag{24}^*$$

where ξ_0 is the root of the equation

$$\sqrt{\varphi(\xi)/\xi}=w=\frac{\kappa\mu}{(6\pi Z)^{1/3}}\ .$$

The obtained numericals are given in Table VII and their dependence on w (or $Z^{-2/3}\sin\theta/\lambda$) and on q is shown in Figs. 13 and 14.

The incoherent scattering factor per electron

---

* For very small scattering angles,

$$S_0^2 \approx q+\frac{3}{2}w\int_0^{x_0}\varphi x dx\ .$$

q \ w	3.	5.	∞
0~0.12	0.9974	0.9994	1.0000

* The values for atom as the limit are in good agreement with those calculated by Tietz[30] for various ξ_0's not for various w's as in our calculation.

s_0^2 has the following features:

(1) $s_0^2(q=0,\ w=0)=0$

(2) $s_0^2(q,\ w=0)=q$

(3) $s_0^2(q=1,\ w)=1$

(4) $s_0^2(q,\ w=\infty)=1$

(5) $s_0^2(q,\ w>0.2)$ is nearly indpendent of small q or large x_0.

(6) $s_0^2(q=\text{const},\ w)$ is a monotonically increasing function of w.

It is noticeable that the coherent scattering factor per atomic number f_0 and the incoherent scattering factor per electron s_0^2 have quite antagonistic characters as seen in the above tables and figures, *i.e.* one increases while the other decreases, or one is high while the other is low.

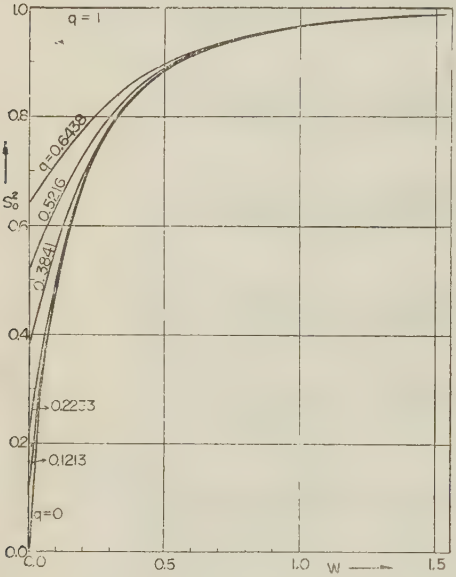

Fig. 13. $s_0^2(w, q=$bonst)-curves.

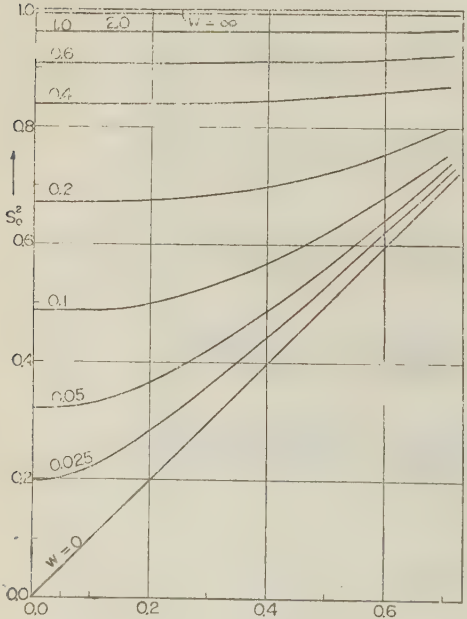

Fig. 14. $s_0^2(q, w=$const)-curves.

The total X-ray intensities scattered by an ion with atomic number Z and electron number N are proportional of $f_0^2+Ns_0^2=Zf^2{}_0^2+Ns_0^2$ and their values for Cs atom and ions, which is usually taken as the standard element for the calculation of the scattering factors, are shown in Fig. 15. We find that the scattered intensities are almost independent of the order of ionization n of ions except for the very small $\sin\theta/\lambda\times10^{-8}$ (<0.1) cm^{-1}.

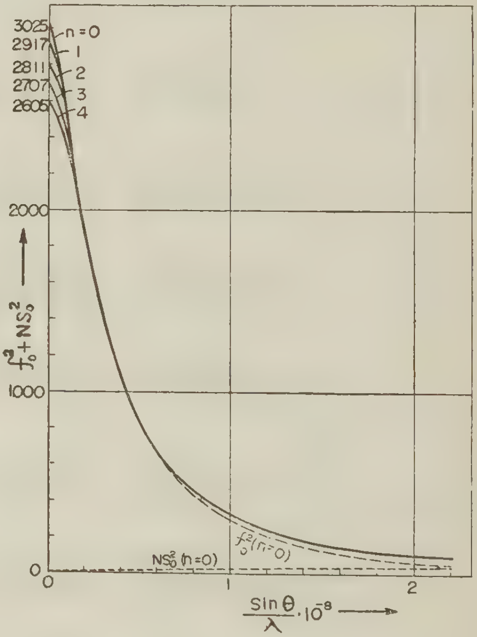

Fig. 15. Comparison of the factor $f_0^2+Ns_0^2$ proportional to the total X-ray intensity scattered by Cs ions, standard element, with order of ionization zero to four.

§ 10. Electric Field at the Nucleus

It was pointed out by Sternheimer[31)] that the electric field at the nucleus of the TF model polarized in the presence of the unit external electric field, is given by

$$\overline{E}_{\text{ind}}(0)=\frac{1}{2}\int_0^{x_0}\sqrt{\varphi x}\,dx \tag{25}$$

and that it does not allow us to calculate $\overline{E}_{\text{ind}}(0)$ for neutral TF atoms, because in this case the integral diverges logarithmically at the upper limit of the integral $x_0=\infty$. For positive ions as well as the FA-modified model, however, this integral does not diverge because of the finiteness of the upper limit x_0*.

We have investigated systematically the dependence of $\overline{E}_{\mathrm{ind}}(0)$ on ionization degree q and atomic number Z using our tables of the TF functions for free positive ions. The variation of the obtained values of $\overline{E}_{\mathrm{ind}}(0)$ values Z is shown in Fig. 16.

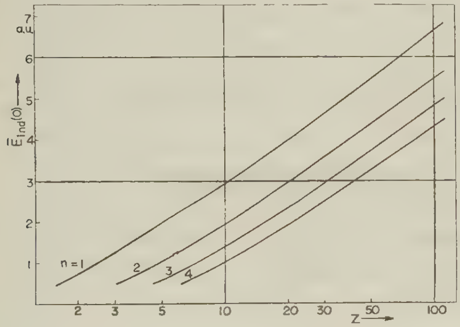

Fig. 16. Dependence on Z of $\overline{E}_{\mathrm{ind}}(0)$.

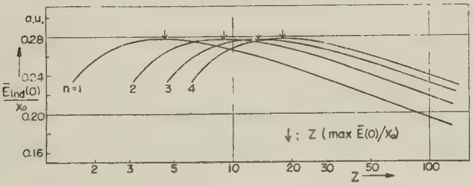

Fig. 17. Variation of $\overline{E}_{\mathrm{ind}}(0)/x_0$ *versus* Z.

Sternheimer, and later Umeda and the present author$^{32)}$ more definitely, remarked that the value of $\overline{E}_{\mathrm{ind}}(0)/x_0$ for the TFD ions are nearly constant, independent of Z, n and x_0. This seems to be also valid for the TF ions as indicated in Fig. 17, though the curves of $\overline{E}_{\mathrm{ind}}(0)/x_0$ versus Z have a weak maximum at an intermediate value of Z, say $Z_{\max}$, which increases with the increase of n.

Acknowledgements

The author wishes to express his sincere thanks to Professor K. Umeda of Okayama University for suggesting this problem, and for his continued guidance and encouragement throughout this work. His thanks are also due to Professors M. Kotani, P. Gombás and C. A. Coulson for their kind interests. He is also indebted to the Ministry of Education for the Scientific Research Fund granted to the Research Group for the Study of Atomic and Molecular Structure. Further thanks are due to the Matsudaira Fund at Takamatsu for the donation of an electric calculator which helped him very much in this investigation.

Higher Order Transitions in Double Resonance

By Ko SUGIHARA

Physical Institute, Nagoya University, Nagoya

(Received March 13, 1959)

Saito et al have observed anomalous behaviours in the double resonances in metal halides in the early stage of saturational narrowing. They have reported following observations, which remained unexplained.

(1) The resonance line of the traced nucleus (B) becomes asymmetric and simultaneously shows shift, when the frequency of the nucleus (A) irradiated by the strong r.f. field is slightly off-resonant.

(2) In the case of the exact resonance, the intensity of the B-resonance decreases and the line disappears from observation. They called this phenomenon "collapsing".

(3) In some crystals (e.g. Li F) having short spin lattice relaxation time, anomalous effects (1) and (2) do not appear. Recently Bloembergen and Sorokin have observed a large dispersive polarization of the saturated Cs^{133} in Cs^{133} Br^{81} double resonance by applying a r.f. field precessing near the Br^{81} resonance. At first sight, above mentioned two phenomena appear to be very different, however, they are closely related to each other. It is the purpose of this paper to propose a general theory unifying the two different situations by taking into consideration the effect of the higher order transitions introduced by Bloembergen in discussing the "Overhauser Induction".

By using a generalized Solomon equation derived from a density matrix, the behaviours of the coupled spin system is discussed.

§1. Introduction

In a double resonance experiment in the coupled spin system A B, a weak resonance of the B-system is traced under an irradiation of a strong r.f. field resonating to the A-spin. Recently the technique of the double resonance has been used to investigate various problems. In these experiments two different phenomena appear according to the relative magnitudes of the intensity of the fluctuation of the lattice system and the spin coupling. One of them is the so-called Overhauser effect1) and is shown in lithium metal, remarkable enhancement of the nuclear polarization results from the increasing of the electron-spin resonance and the same effect is expected in nuclear double resonance although the magnitude of the induced polarization is much smaller[2)]. The other phenomenon is the saturational narrowing[3)]. The application of a strong r.f. field resonating to A nuclei induces rapid transitions between the A spin Zeeman levels, and averages out the local fields produced at the position of B nuclei by the magnetic moments of A nuclei. Then the narrowing of the B resonance line is observed.

Recently Bloch[4)] has proposed a theory of saturational narrowing. A general treatment unifying the two different situations has been proposed by Tomita[5)].

Above mentioned phenomena are the problems which can be treated in the frame of the second order perturbation of the mutual interaction. Recently, however, new effects, which can not be understood by these theories, have been observed experimentally.

Saito, Masuda and Kanda[6)*)] have found anomalous behaviours in the double resonances in metal halides in the early stage of saturation. They have reported following observations:

(1) The B resonance becomes asymmetric and simultaneously shows shift, when the r.f. frequency ω of the A-system is slightly off-resonant from the resonance frequency ω_A.

(2) In the exact resonance case $\omega=\omega_A$, the intensity of B resonance decreases and the line becomes broad. They called this phenomenon as "collapsing".

(3) In some crystal (Li F) having short spin-lattice relaxation time, anomalous effects (1) and (2) do not appear.

Bloembergen and Sorokin[7)†)] have observed a large transverse magnetization of the saturated nuclei Cs^{133} in $Cs^{133}Br^{81}$ nuclear double resonance by applying slightly off resonant frequency from the Br precessional frequency. The sign of the transverse magnetization reverses according to the difference of the r.f. frequency from the exact resonant one is positive or negative.

Purcell proposed the name "Overhauser Induction" to this effect[7)]. It will be shown that interesting phenomena discovered by B.S. and S.M.K. are both attributed to the higher order transitions in double resonances.

Bloembergen[8)] has proposed a simple theory to interpret the experiment of S.M.K. as follows:

In the process of sweeping the r.f. frequency ω', suppose that ω' is related to the resonance frequency ω_B by the following relation,

$$\omega'=\omega_B\pm\tilde{\omega}_A\,,\quad \tilde{\omega}_A=\sqrt{\Delta_A{}^2+\omega_{1A}{}^2}\,, \qquad (1.1)$$

where $\Delta_A=\omega_A-\omega$ and ω_{1A} is the amplitude in frequency scale of the r.f. field acting on A.

Here $\tilde{\omega}_A$ corresponds to the effective field in the rotating frame with angular velocity ω around the static field. If the condition (1.1) is satisfied, it is permissible energetically to induce the double transition in which A and B flip simultaneously and the total energy changes by $\hbar\omega'$.

Regarding the r.f. field energy of the B nuclei and the mutual interaction as together constituting the perturbation, the double transition results from a fourth order perturbation calculation. In the case $\Delta_A=0$, triple and more higher order processes will also become important, so the collapsing can be expected as a result of the line broadening by double and higher order transitions. In the case $\Delta_A\neq0$, there is a region in which $\tilde{\omega}_A$ surpass the mutual interaction and the double transition is responsible for the skewness of the absorption line, though it is not so intense to induce the collapsing. The author does not agree with the Bloembergen's simple discussion for the skewness of the absorption line. By our theory it is explained as follows: The absorption mode (or dispersion mode) of the B-system is proportional to its polarization which is composed of the three terms. The first is the proper contribution from the B-system and corresponds to the polarization to be realized when the A nuclei are in the thermal equilibrium state. The asymmetry does not result from this term. The other is the part produced by the double transition. Since this is proportional to the polarization of the A-system parallel to the effective field $\tilde{\omega}_A$, x-component in the rotating frame has non-vanishing value in the case of a exact resonance while z-component appears only in the case of a off-resonance.

In the case $\Delta_A\neq0$, the x-component is unimportant except in the case in which the dispersion mode is enhanced as a result of the Overhauser induction and the contribution of the z-component is rather important. Moreover this term reverses its sign according to whether ω' equals to $\omega_B+\tilde{\omega}_A$ or $\omega_B-\tilde{\omega}_A$, so that it will be responsible for the asymmetry of the resonance line around the center frequency ω_B.

---

*) Hereafter this work will be referred to as S.M.K.

†) Hereafter this work will be referred to as B.S.

When the spin-lattice relaxation process of the B-system is so rapid that the proper contribution from the B-system is predominant, then the anomalies should disappear. If the intensity of the double transition is comparable to that of the center line, then the resonance line will shift toward the more intense side among the two double transitions. If the double transition is so frequent that it determines the balancing between A and B, and B is approximately in a thermal equilibrium, the magnetization of the A-system parallel to the effective field $\tilde{\omega}_A$ should be very large and comparable to the thermal equilibrium value of the B-system.

This is the "Overhauser Induction". The theory given by B.S. in the case spin 1/2 is insufficient since they neglect the spin-relaxation process relevant to the A-system. In the following sections we will intend to construct a macroscopic Solomon equation which describes the coupled spin system A B. This is derived from a microscopic density matrix following the method developed by Wangsness-Bloch⁹⁾, Bloch¹⁰⁾ and Tomita⁵⁾ by taking into consideration the effect of the double transition.

§ 2. Equation of Motion of the Density Matrix

The Hamiltonian of the total system is given by

$$\mathscr{H}=\hbar(H_A+H_B+G+F)\,, \tag{2.1}$$

where

$$\left\{\begin{array}{l} H_A=E_A+D_A+G_A\,, \\ H_B=E_B+D_B+G_B\,. \end{array}\right. \tag{2.2}$$

Here E stands for the Zeeman energy

$$\left\{\begin{array}{l} E_A=-\gamma_A H_0 \sum\limits_j I_{Aj}{}^0=-\omega_A \sum\limits_j I_{Aj}{}^0\,, \\ E_B=-\gamma_B H_0 \sum\limits_k I_{Bk}{}^0=-\omega_B \sum\limits_k I_{Bk}{}^0\,, \end{array}\right. \tag{2.3}$$

and D is the energy associated with the radio-frequency field H_{1A} and H_{1B},

$$\left\{\begin{array}{l} D_A=-(\omega_{1A}/2) \sum\limits_j (I_{Aj}{}^+e^{i\omega t}+I_{Aj}{}^-e^{-i\omega t})\,, \\ D_B=-(\omega_{1B}/2) \sum\limits_k (I_{Bk}{}^+e^{i\omega' t}+I_{Bk}{}^-e^{-i\omega' t})\,, \end{array}\right. \tag{2.4}$$

where $\omega_{1A}=\gamma_A H_{1A}$ and $\omega_{1B}=\gamma_B H_{1B}$ and γ_A and γ_B gyromagnetic ratios of A and B spin respectively.

G_A and G_B are the proper interactions of A and B responsible for the spin-spin and spin-lattice relaxations and here let us assume for simplicity the local field picture

$$\left\{\begin{array}{l} G_A=\sum\limits_j \sum\limits_{\mu_j} I_{Aj}{}^{\mu_j}F_A{}^{\bar{\mu}_j}\,, \\ G_B=\sum\limits_k \sum\limits_{\mu_k} I_{Bk}{}^{\mu_k}F_B{}^{\bar{\mu}_k}\,, \quad (\mu_j,\ \mu_k=0,\ \pm 1) \end{array}\right. \tag{2.5}$$

where $\bar{\mu}_j$ and $\bar{\mu}_k$ denote $-\mu_j$ and $-\mu_k$ and I^μ stands for the spin operator corresponding to the quantum jump μ. G is the spin coupling between the two system and is written in the form,

$$G=\sum_j \sum_k \sum_{\mu_j} \sum_{\mu_k} I_{Aj}{}^{\mu_j} I_{Bk}{}^{\mu_k} F_{jk}{}^{\bar{\mu}_j\bar{\mu}_k}\,, \tag{2.6}$$

which includes an indirect exchange and a pseudo-dipolar coupling. Finally F is the energy of the lattice system. Then the density matrix ρ describing the whole system obeys the equation of motion

$$\frac{d}{dt}\rho=i[\rho,\ H_A+H_B+G+F]\,. \tag{2.7}$$

When a strong r.f. field is applied to the A-system, it is not permissible to regard D_A as a small perturbation so that it is convenient to make the transformation to the coordinate system which makes D_A as time-independent¹¹⁾.

They by way of the transformation

$$A^T=\exp(iE't)A\exp(-iE't)\,, \tag{2.8}$$

where

$$E'=-\omega(\sum_j I_{Aj}{}^0+\sum_k I_{Bk}{}^0)\,, \tag*{(2.8)$'$}$$

the density matrix ρ^T in the new frame is found to obey the following equation

$$\frac{d}{dt}\rho^T=i[\rho^T,\ E_A{}^{Te}+E_B{}^{Te}+D_B{}^T+G_A{}^T+G_B{}^T+G^T+F]\,, \tag*{(2.7)$'$}$$

where

$$\left\{\begin{array}{ll} E_A{}^{Te}=-(\varDelta_A \sum\limits_j I_{Aj}{}^0+\omega_{1A} \sum\limits_j I_{Aj}{}^x)\,, & (\varDelta_A=\omega_A-\omega) \\ E_B{}^{Te}=-\varDelta_B \sum\limits_k I_{Bk}{}^0\,, & (\varDelta_B=\omega_B-\omega) \end{array}\right. \tag{2.9}$$

$$D_B{}^T=-(\omega_{1B}/2)\sum_k (I_{Bk}{}^+\exp i(\omega'-\omega)t+I_{Bk}{}^-\exp -i(\omega'-\omega)t)\ , \tag{2.10}$$

$$G_A{}^T=\sum_j\sum_{\mu_j} I_{Aj}{}^{\mu_j}F_A{}^{\bar{\mu}_j}\exp(i\omega_{\mu_j}t)\ , \qquad (\omega_{\mu_j}=-\mu_j\omega) \tag{2.11}$$

$$G_B{}^T=\sum_k\sum_{\mu_k} I_{Bk}{}^{\mu_k}F_B{}^{\bar{\mu}_k}\exp(i\omega_{\mu_k}t)\ , \qquad (\omega_{\mu_k}=-\mu_k\omega) \tag{2.12}$$

$$G^T=\sum_j\sum_k\sum_{\mu_j}\sum_{\mu_k} I_{Aj}{}^{\mu_j}I_{Bk}{}^{\mu_k}F_{jk}{}^{\bar{\mu}_j\bar{\mu}_k}\exp i(\omega_{\mu_j}+\omega_{\mu_k})t\ . \tag{2.13}$$

In order to diagonalize $E_A{}^{Te}$, we will carry out a further transformation to a new coordinate system whose z-axis coincides with the effective field direction in the rotating system, and whose y-axis remains unchanged. This transformation corresponds to the rotation of angle $\Theta=\tan^{-1}(\omega_{1A}/\Delta_A)$ about y-axis. In this way we get

$$E_A{}^{Te}=-\tilde{\omega}_A\sum_j I_{Aj}(0) \tag{2.14}$$

In general the spin operators of the A-system are written in the form

$$I_{Aj}{}^{\mu_j}=\sum_{\nu_j=0,\pm1} a_{\mu_j\nu_j}I_{Aj}(\nu_j)\ , \tag{2.15}$$

where $I_{Aj}(\nu_j)$ is the spin operator associated with ν_j quantum jump in the new coordinate system and the explicit representation of (2.15) is

$$\begin{bmatrix} I^0 \\ I^+ \\ I^- \end{bmatrix}=\begin{bmatrix} \cos\Theta & -\sin\Theta/2 & -\sin\Theta/2 \\ \sin\Theta & (\cos\Theta+1)/2 & (\cos\Theta-1)/2 \\ \sin\Theta & (\cos\Theta-1)/2 & (\cos\Theta+1)/2 \end{bmatrix}\begin{bmatrix} I(0) \\ I(+) \\ I(-) \end{bmatrix}. \tag{2.16}$$

$G_A{}^T$ and G^T in the new coordinate system are given by

$$G_A{}^T=\sum_j\sum_{\mu_j}\sum_{\nu_j} a_{\mu_j\nu_j}I_{Aj}(\nu_j)F_A{}^{\bar{\mu}_j}\exp(\mathrm{i}\omega_{\mu_j}t)\ , \tag{2.17}$$

$$G^T=\sum_j\sum_k\sum_{\mu_j}\sum_{\mu_k}\sum_{\nu_j} a_{\mu_j\nu_j}I_{Aj}(\nu_j)I_{Bk}{}^{\mu_k}F_{jk}{}^{\bar{\mu}_j\bar{\mu}_k}\exp i(\omega_{\mu_j}+\omega_{\mu_k})t\ . \tag{2.18}$$

If H_{1A} is large (but still much less than the static field H_0), $D_B{}^T$, $G_A{}^T$, $G_B{}^T$ and G^T may be regarded as small perturbation as compared with the remaining parts in (2.7)′. Then we take the interaction representation using the operation

$$A^*=\exp i(E_A{}^{Te}+E_B{}^{Te}+F)tA\exp -i(E_A{}^{Te}+E_B{}^{Te}+F)t\ . \tag{2.19}$$

By way of (2.19), (2.7)′ is transformed into

$$(d/dt)\rho^{T*}=i[\rho^{T*},\ G_A{}^{T*}+G_B{}^{T*}+G^{T*}+D_B{}^{T*}]\ , \tag{2.20}$$

where

$$D_B{}^{T*}=-(\omega_{1B}/2)\sum_k \{I_{Bk}{}^+\exp i(\omega'-\omega_B)t+I_{Bk}{}^-\exp -i(\omega'-\omega_B)t\}\ , \tag{2.21}$$

$$G_A{}^{T*}=\sum_j\sum_{\mu_j}\sum_{\nu_j} a_{\mu_j\nu_j}I_{Aj}(\nu_j)F_A{}^{\bar{\mu}_j*}\exp i(\omega_{\mu_j}+\omega_{\nu_j})t\ , \quad (\omega_{\nu_j}=-\nu_j\tilde{\omega}_A)\ . \tag{2.22}$$

$F_A{}^{\bar{\mu}_j}$ is decomposed into the frequency spectrum as

$$F_A{}^{\bar{\mu}_j*}=\exp(iFt)F_A{}^{\bar{\mu}_j}\exp(-iFt)=\sum_\lambda F_A{}^{\bar{\mu}_j}(\lambda)\exp(i\omega_\lambda t)\ . \tag*{(2.22)′}$$

Similarly,

$$G_B{}^{T*}=\sum_k\sum_{\mu_k}\sum_\lambda I_{Bk}{}^{\mu_k}F_B{}^{\bar{\mu}_k}(\lambda)\exp i(\omega_{\mu_k}{}^0+\omega_\lambda)t\ , \tag{2.23}$$

where

$$\omega_{\mu_k}{}^0=-\mu_k\omega_B\ .$$

Since the lattice part of G is nearly rigid, $F_{jk}{}^{\bar{\mu}_j\bar{\mu}_k}$ may be regarded as constant, so that we have

$$G^{T*}=\sum_j\sum_k\sum_{\mu_j}\sum_{\mu_k}\sum_{\nu_j} a_{\mu_j\nu_j}I_{Aj}(\nu_j)F_{jk}{}^{\bar{\mu}_j\bar{\mu}_k}\exp i(\omega_{\mu_j}+\omega_{\mu_k}{}^0+\omega_{\nu_j})t\ . \tag{2.24}$$

To take into consideration the effect of tne double transition, it is necessary to develop up to the fourth order perturbation containing G^{T*} and D^{T*} in (2.20), but we can obtain the same result in the approximation of the second order perturbation by introducing the effective Hamiltonian like

$$K^T=(\omega_{1B}/2)\sum_j\sum_k\sum_{\nu_j\neq 0} a_{0\nu_j}F_{jk}{}^{00}\{I_{Bk}{}^+\exp i(\omega'-\omega)t+I_{Bk}{}^-\exp -i(\omega'-\omega)t\}I_{Aj}(\nu_j)I_{Bk}{}^0(\omega_{\nu_j})^{-1}\,, \tag{2.25}$$

$$K^{T*}=(\omega_{1B}/2)\sum_j\sum_k\sum_{\nu_j\neq 0} a_{0\nu_j}F_{jk}{}^{00}\{I_{Bk}{}^+\exp i(\omega'-\omega_B+\omega_{\nu_j})t+I_{Bk}{}^-\exp -i(\omega'-\omega_B+\omega_{\nu_j})t\}$$
$$\times I_{Aj}(\nu_j)I_{Bk}{}^0(\omega_{\nu_j})^{-1}\,. \tag{2.25$'$}$$

K^T, which is derived from the second order perturbational calculation regarding $D_B{}^T$ and G^T as small perturbation, has matrix elements which induces the double transition. The contributions from G_A, G_B and G up to the second order perturbation have been discussed in detail by Tomita[5] and here we shall not touch on these terms further in this section. Short time development of the density matrix regarding K^{T*} as a small perturbation is

$$\rho^{T*}(t)=\rho^{T*}(0)+\varDelta_1\rho^{T*}+\varDelta_2\rho^{T*}\,, \tag{2.26}$$

where

$$\left\{\begin{aligned}\varDelta_1\rho^{T*}&=-i\int_0^t dt_1[K^{T*}(t_1),\ \rho^{T*}(0)]\,,\\ \varDelta_2\rho^{T*}&=-\int_0^t dt_1\int_0^{t1} dt_2[K^{T*}(t_1),\ [K^{T*}(t_2),\ \rho^{T*}(0)]]\,,\end{aligned}\right. \tag{2.26$'$}$$

The contribution from $\varDelta_1\rho^{T*}$ may be neglected in (2.26), and inserting (2.25)′ into (2.26)′ the second order term is explicitly given by

$$\varDelta_2\rho^{T*}=-(\omega_{1B}/2)^2a_{01}a_{0\bar{1}}\sum_j\sum_k\sum_{\nu_j\neq 0}|F_{jk}{}^{00}|^2\int_0^t dt_1\int_0^{t1}dt_2\{\exp i(\omega'-\omega_B+\omega_{\nu_j})(t_1-t_2)$$
$$\times[I_{Bk}{}^+I_{Bk}{}^0I_{Aj}(\nu_j),\ [I_{Bk}{}^-I_{Bk}{}^0I_{Aj}(\bar{\nu}_j),\ \rho^{T*}(0)]]+\exp -i(\omega'-\omega_B+\omega_{\nu_j})(t_1-t_2)$$
$$\times[I_{Bk}{}^-I_{Bk}{}^0I_{Aj}(\nu_j),\ [I_{Bk}{}^+I_{Bk}{}^0I_{Aj}(\rho^{T*}(0)]]\}(\omega_{\nu_j}\omega_{\bar{\nu}_j})^{-1}\,. \tag{2.27}$$

By using (2.19), we shall again come back to the rotating coordinate system. Let us suppose that the density matrix describing the whole system can be factorized into the spin part σ—Bloch[9),10)] proposed the name "distribution matrix"—and the lattice part ρ_F which is practically independent of the behavior of the spin system and may be assumed as the canonical distribution corresponding to the lattice energy F.

Inserting the relation $a_{01}=a_{0\bar{1}}=-(\sin\Theta/2)$ obtained from (2.16) and averaging over the lattice part, it is easily shown that the time derivative of the second order term of σ^T is given by

$$\frac{d}{dt}\varDelta_2\sigma^T=t\left(\frac{\omega_{1B}}{\tilde{\omega}_A}\right)^2\frac{\sin^2\Theta}{16}\sum_j\sum_k\sum_{\nu_j\neq 0}\sum_{\lambda=\pm 1}\langle|F_{jk}{}^{00}|^2\rangle_F\delta_{\omega',\omega_B-\omega_{\nu_j}}$$
$$\times[I_{Bk}{}^{\lambda}I_{Bk}{}^0I_{Aj}(\lambda\nu_j),\ [I_{Bk}{}^{\bar{\lambda}}I_{Bk}{}^0I_{Aj}(\overline{\lambda}\nu_j),\ \sigma^T(0)]\,, \tag{2.28}$$

where $\langle\ \ \rangle_F$ denotes the operation averaging over the lattice states.

§ 3. Solomon Equation

In this section, the Solomon equation describing a macroscopic motion of the coupled spin system A B is derived on the basis of (2.28).

Taking an average the product of (2.28) and a spin function $Q_A(Q_B)$ over the B(A) system, the macroscopic equation of $Q_A(Q_B)$ due to the interaction K is easily obtained. At first we shall derive the equation of Q_B.

Coming back to the static coordinate system*), $\langle Q_B\rangle$ obeys the following equation

---

*) The term appearing due to coming back to the static system will be contained in considering the effects of G_A, G_B and G.

$$\left.\frac{d}{dt}\right)_k\langle Q_B\rangle=t\left(\frac{\omega_{1B}}{\omega_{1A}}\right)^2\frac{\sin^2\Theta}{16}\sum_j\sum_k\sum_{\nu j=\pm1}\sum_{\lambda=\pm1}\langle|F_{jk}{}^{00}|^2\rangle_F\delta_{\omega',\omega_B-\omega\nu_j}$$
$$\times\{\langle[[Q_B,\ I_{Bk}{}^{\lambda}I_{Bk}{}^0],\ I_{Bk}{}^{\bar\lambda}I_{Bk}{}^0]\rangle\langle I_{Aj}(\lambda\nu_j)I_{Aj}(\bar\lambda\nu_j)\rangle$$
$$+\langle I_{Bk}{}^{\bar\lambda}I_{Bk}{}^0[Q_B,\ I_{Bk}{}^{\lambda}I_{Bk}{}^0]\rangle\langle[I_{Aj}(\lambda\nu_j),\ I_{Aj}(\bar\lambda\nu_j)]\rangle\}\ . \tag{3.1}$$

We should be be remembered that the linear equation associated with the spin operator holds in the case of $I_B=1/2$ and in the approximation retaining the terms up to the first order in $\hbar\omega_A/kT$, $\hbar\omega_B/kT$ and $\hbar\omega_{1A}/kT$.

Putting $Q_B=I_{Bz}=\sum_k I_{Bk}{}^0$, the equation (3.1) becomes

$$\left.\frac{d}{dt}\right)_k\langle I_{Bz}\rangle=-t\frac{\sin^4\Theta}{24}I_A(I_A+1)\left(\frac{\omega_{1B}}{\omega_{1A}}\right)^2\sum_j\langle|F_{jk}{}^{00}|^2\rangle^2\langle I_{Bz}\rangle\sum_{\lambda=\pm1}\delta_{\omega'\omega_B+\lambda\tilde\omega_A}$$
$$-t\frac{\sin^4\Theta}{32}\left(\frac{\omega_{1B}}{\omega_{1A}}\right)^2\sum_j\langle|F_{jk}{}^{00}|\rangle_F\langle I_A(0)\rangle\sum_{\lambda=\pm1}\lambda\delta_{\omega',\omega_B+\lambda\tilde\omega_A}\ , \tag{3.2}$$

where j and k denote the suffixes of A and B respectively and $I_A(0)=\sum_j I_{Aj}(0)$.

In order to observe the qualitative behaviour, we may replace the Gaussian line constituted by the rigid lattices regularly distributed by the Lorentzian line which has an equal half value width. This simplification corresponds to the approximation using one operator T_2 in Bloch equation to represent the spin-spin relaxation process. Therefore, the following replacement is introduced

$$t\sum_j\langle|F_{jk}{}^{00}|^2\rangle_F(1/3)I_A(I_A+1)\to1.175[\langle\varDelta\omega_B\rangle^2]^{1/2}\ , \tag{3.3}$$

where $\langle\varDelta\omega_B\rangle^2=\sum_j\langle|F_{jk}{}^{00}|\rangle_F(1/3(I_A(I_A+1)$ is the second moment of the local field at the position of a B spin produced by the A nuclei.

A similar approximation as (3.3) is used like

$$t\sum_k\langle|F_{jk}{}^{00}|^2\rangle_F(1/3)(1/2)(3/2)\to1.175[\langle\varDelta\omega_A\rangle^2]^{1/2}\ , \tag*{(3.3)$'$}$$

where $\langle\varDelta\omega_A\rangle^2=\sum_k\langle|F_{jk}{}^{00}|^2\rangle_F(1/3)(1/2)(3/2)$ is the second moment of the local field at the position of an A spin produced by the B nuclei.

(3.3) and (3.3)′, (3.2) is simplified in Bloch type like

$$\left.\frac{d}{dt}\right)_k\langle I_{Bz}\rangle+\sum_{\lambda=\pm1}\delta_{\omega',\omega_B+\lambda\tilde\omega_A}\{s^4\varPhi_B{}'\langle I_{Bz}\rangle+\lambda s^4\varPhi_A{}'(s\langle I_{Ax}\rangle+c\langle I_{Az}\rangle)\}=0\ , \tag{3.2}$$

where

$$s=\sin\Theta\ ,\qquad c=\cos\Theta\ ,$$
$$\varPhi_A{}'=\frac{1.175}{2\sqrt{2}}\left|\frac{\omega_{1B}}{\omega_{1A}}\right|[\langle\varDelta\omega_A\rangle^2]^{1/2}\ ,\qquad \varPhi_B{}'=\frac{1.175}{2\sqrt{2}}\left|\frac{\omega_{1B}}{\omega_{1A}}\right|[\langle\varDelta\omega_B\rangle^2]^{1/2}\ .$$

It should be remembered that the A-system is described with regard to the rotating system. Then the differential equation governing the motion of the B-system becomes

$$\left.\frac{d}{dt}\right)_k\begin{bmatrix}\langle I_{Bx}\rangle\\ \langle I_{By}\rangle\\ \langle I_{Bz}\rangle\end{bmatrix}+\begin{bmatrix}(1/2)s^4\varPhi_B{}' & 0 & 0\\ 0 & (1/2)s^4\varPhi_B{}' & 0\\ 0 & 0 & s^4\varPhi_B{}'\end{bmatrix}\begin{bmatrix}\langle I_{Bx}\rangle\\ \langle I_{By}\rangle\\ \langle I_{Bz}\rangle\end{bmatrix}+\lambda\varPhi_A{}'\begin{bmatrix}0\\ 0\\ s^5\langle I_{Ax}\rangle+s^4c\langle I_{Az}\rangle\end{bmatrix}=0\ , \tag{3.4}$$

where for simplicity $\delta_{\omega',\omega_B+\lambda\tilde\omega_A}$ is omitted. It is worth noticing that the coupling terms with the A-system contain the sign λ. Similarly the equation governing the A-system is easily derived from (2.28)

$$\left.\frac{d}{dt}\right)_k\langle Q_A\rangle=t\left(\frac{\omega_{1B}}{\tilde\omega_A}\right)^2\frac{\sin^2\Theta}{16}\sum_j\sum_k\sum_{\nu j=\pm1}\sum_{\lambda=\pm1}\langle|F_{jk}{}^{00}|^2\rangle_F\delta_{\omega',\omega_B-\omega\nu_j}$$
$$\times\{\langle I_{Bk}{}^{\lambda}I_B{}^{k0}I_{Bk}{}^{\bar\lambda}I_{Bk}{}^0\rangle\langle[[Q_A,\ I_{Aj}(\lambda\nu_j)],\ I_{Aj}(\bar\lambda\nu_j)]\rangle$$
$$+\langle[I_{Bk}{}^{\lambda}I_{Bk}{}^0,\ I_{Bk}{}^{\bar\lambda}I_{Bk}{}^0]\rangle\langle I_{Aj}(\bar\lambda\nu_j)[Q_A,\ I_{Aj}(\lambda\nu_j)]\rangle\}\ . \tag{3.5}$$

the steady-state solution of (3.9)

$$\langle I_{Ax}\rangle=\frac{\Phi_{Ax}{}^{0}}{\Phi_{Ax}+\Phi_{A}'+\Phi_{A}'+a(\Phi_{B}'+\phi_{B}')}\langle I_{Ax}\rangle_{0}$$

$$-\lambda\frac{\Phi_{Bz}{}^{0}(\Phi_{B}'+\phi_{B}')}{(\Phi_{Bx}+\Phi_{B}'+\phi_{B}')\{\Phi_{Ax}+\Phi_{A}'+\phi_{A}'+a(\Phi_{B}'+\phi_{B}'\}}\langle I_{Bz}\rangle_{0}\,, \tag{4.4}$$

$$\langle I_{Az}\rangle=\frac{\Phi_{Az}{}^{0}\{\Phi_{Ax}+(1/2)(\Phi_{A}'+\phi_{A}')\}}{\{\Phi_{Ax}+(1/2)(\Phi_{A}'+\phi_{A}')\}\{\Phi_{Az}+(1/2)(\Phi_{A}'+\phi_{A}')\}+\omega_{1A}{}^{2}}\langle I_{Az}\rangle_{0}\,. \tag{4.4$'$}$$

The Overhauser induction is the effect in which the second term in (4.4) is much larger than the first and $\langle I_{Ax}\rangle$ becomes to be nearly equal to $\langle I_{Bz}\rangle_0$ in magnitude and the conditions to be satisfied in order to induce the effect is summarized as follows:

(i) The spin-lattice relaxation constant Φ_{Bz}*) is so large that the condition $\Phi_{Bz}\gtrsim\Phi_{B}'$\**) is satisfied and this condition means that $\langle I_{Bz}\rangle_e$ is nearly equal to $\langle I_{Bz}\rangle_0$.

(ii) The spin-spin relaxation of the A-system is supressed due to the strong resonant r.f. field and the condition $\Phi_{A}'\sim\Phi_{Ax}$ is satisfied.

Then

$$\langle I_{Ax}\rangle\approx-\lambda\langle I_{Bz}\rangle_0\,, \tag{4.5}$$

and $\langle I_{Ax}\rangle$ reverses its sign around the center frequency ω_B due to the existence of sign λ.

(2) *Experiment of* S.M.K.

In discussing the experiment of S.M.K., it is necessary to study the behaviour of $\langle v\rangle$. As is shown in (4.3) and (4.2), $\langle v\rangle$ is proportional to $\langle I_{Bz}\rangle$ which is composed of three parts. According to the relative magnitude between them, various situations are realized and the asymmetry of the line shape is ascribed to the term $\lambda s^4ca\langle I_{Az}\rangle$ which appears only in the off-resonant case. In the experiment on *TlF*, the asymmetry has been observed when $\Delta_A=\pm2\pi\times5$ kc and the amplitude of the r.f. field of the A-system is 1∼3 gauss. Suppose that H_{1A} equals to 3 gauss, since $s\doteqdot1$ and $c\doteqdot\Delta_A/\omega_{1A}=0.15$ in this case†), it may be permissible to replace by the quantities in exact resonance in evaluating $\langle I_{Bz}\rangle_e$, a, $\langle I_{Az}\rangle$ and $\langle I_{Ax}\rangle$.

Here we may classify three different cases:

(i) The case in which the spin-lattice relaxation of the B-system is sufficiently rapid.

In this case the term $\langle I_{Bz}\rangle_e$ is superior to the other terms among $\langle I_{Bz}\rangle$, and so the appearance of the normal line shape is expected. In lithium fluoride crystals it has been observed that the sample which has short relaxation time does not show any anomalous behaviour and the situation corresponds precisely to the case above mentioned.

(ii) The case in which the Overhauser induction occurs and the condition

$$\langle I_{Ax}\rangle\approx-\lambda\langle I_{Bz}\rangle_0\gg\langle I_{Az}\rangle\,, \tag{4.6}$$

holds.

Then, $\langle I_{Bz}\rangle$ is given by

$$\langle I_{Bz}\rangle\doteqdot\langle I_{Bz}\rangle_e-s^5a\langle I_{Bz}\rangle_e\,, \tag{4.6$'$}$$

and any skewness in the resonance line will not appear.

(iii) The case in which in (4.2) the term proportional to $\langle I_{Az}\rangle$ surpasses the term proportional to $\langle I_{Ax}\rangle$ and contributes to $\langle I_{Bz}\rangle$ in the same order magnitude as $\langle I_{Bz}\rangle_e$. In this case $\langle v\rangle$ depends upon the sign λ appreciably and the asymmetry will result from the differences of the absorption intensity around the center frequency ω_B and simultaneously the position of intensity maximum may be pulled up nearer to the side at which the absorption is more intense. This is the anomaly observed in the off-resonant case. In the exact resonance the asymmetry and the shift will disapper and, as has already been pointed out by Bloembergen in this region the relation $\omega_{1A}\lesssim|F_{jk}{}^{00}|$ is satisfied and the "collapse" results from a severe broadening of the line by second and higher order transitions.

§ 5. Conclusion

We have not made a quantitative analysis of the experiments, but it appears that they are in agreement qualitatively with the predictions of our theory. To represent the equation in Bloch type, we have been forced to use the approximations like (3.3) and (3.3)′

---

*) $\Phi_{Bz}\doteqdot\Phi_{Bz}{}^0$; **) Usually $(\Phi_A', \Phi_B')>(\phi_A', \phi_B')$.

†) A-system is F^{19} nucleus and the magnetic moment of F^{19} equals to 2.6273 nuclear magneton.

ut the treatment presented here should be mproved mathematically. The restriction ssuming $I_B=1/2$ is inevitable to represent he equation in linear form of spin operators. ince the experiment of S.M.K. has been one under the circumstance in which theoetical background is obscure, it is desirable o research further in this stage.

On the Dynamic Mechanical Properties of Polymers at Ultrasonic Frequencies in Relation to Their Glass Transition Phenomena

By Yasaku WADA, Hidenori HIROSE, Taro ASANO
Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo, Japan
and Seita FUKUTOMI
Department of Physics, Faculty of Liberal Arts,
University of Oita, Oita, Japan

(Received April 6, 1959)

Complex Young's modulus, rigidity and bulk modulus are measured at 33 kc/s, 66 kc/s and 1 Mc/s for polystyrene, polymethyl methacrylate, polyvinyl acetate and phenol resin. In each material, the storage modulus-temperature curve has a discontinuity in the slope, irrespective of frequency and type of modulus, at the glass transition temperature T_g determined from thermal expansion. This discontinuity takes place through a strong dependence of the modulus on the specific volume.

Besides, the first three materials exhibit secondary discontinuities at T_g', about thirty degrees below T_g, both in thermal expansion and modulus-temperature curve. Some possible interpretations are given to this secondary discontinuity, resulting in the conclusion that the glass transition occurs over a rather wide range of temperature and is completed at T_g with increasing temperature.

The ratio of the temperature coefficients of the modulus, taken below and above T_g, agrees well with that of volume expansion curve. This is also the case about T_g', being indicative of predominantly energetic nature of elasticity.

The loss factor begins to rise slightly at T_g', then rapidly at T_g as the temperature is elevated, suggesting that local motions of molecular chains are first encountered at T_g'.

The real part of Poisson's ratio seems nearly constant through the temperatures studied, including the glass transition temperature, whereas the imaginary part is found to vanish.

§ 1. Introduction

A very wide class of substances which fall in the supercooled state, such as silicate and selenium glasses, glucose, glycerine, and so on, exhibit glass transition phenomena. Among them, organic substances composed of long chain molecules have so far been most widely investigated.

As a high polymeric substance is cooled down from its rubbery state, the activation energy for the rotation of polymer chains increases as a consequence of decrease in the intermolecular free volume. When the critical temperature is attained where the activation energy for the free rotation of backbone chains becomes so large that the rotation can no more take place within the time of observation, the free volume is frozen in and kept unchanged below this temperature. This temperature is usually called "glass transition temperature" and is the dividing line between glass-like and rubber-like properties of a polymer. Experimentally, the glass transition temperature is in most cases determined from the discontinuity in thermal expansion.

The glass transition of a polymer is usually considered as a predominantly rate and not equilibrium phenomenon. The transition temperature, however, only slightly depends on the rate of cooling within the usual range of rate at least, apparently because the activation energy for molecular rotation, in the neighborhood of this temperature, very rapidly increases with decrease in the free volume. Probably, a change of 1°C corresponds to the change of an order of the magnitude in the relaxation time. From the same reason, this temperature also remains almost constant for either cooling or heating process. The description in a subsequent paper is always given for heating process, namely, for "loosening" of free volume, not for freezing-in.

It has been well confirmed by numerous investigators that a marked change is observed in many physical properties at the glass temperature. Fig. 1 illustrates an over-all behavior of the real and imaginary part of complex modulus, say complex rigidity, of a linear amorphous polymer at constant frequency, together with the volume expansion curve.

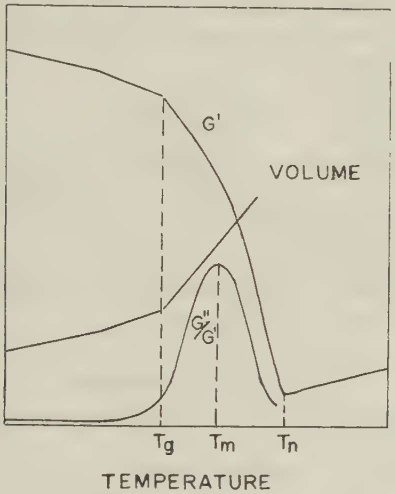

Fig. 1. Over-all behaviors of complex rigidity $G'+iG''$ and specific volume of a linear amorphous polymer near glass transition temperature.

As has been in recent years firmly established[1-7], the storage modulus-temperature curve exhibits a discontinuity in the slope at the glass transition temperature T_g. One of the present authors[4,5] and Work[3] have pointed out that this break takes place through a strong dependence of the modulus on the specific volume and is simply a manifestation of the break in volume-temperature curve at T_g. Consequently, as has been verified by many authors, the break temperature is independent of a wide range of time or frequency, from even the static measurement[6] up to the range of megacycles[5].

In many of the existing reports, the glass transition temperature has often been referred to the temperature where the loss modulus G'' or loss factor G''/G' becomes maximum (T_m in Fig. 1). This temperature is characteristic of the relaxational effect of segmental motions of polymer chains and essentially depends on frequency of observation. Some other authors[8] have given the name of glass transition temperature to the point where G' becomes minimum, in other words, equilibrium rubber elasticity is first encountered (T_n in Fig. 1). These scattered definitions of the transition temperature seem to come from the confusion between the loosening of free volume at T_g and the relaxational phenomena of segmental motions *above* T_g. In as much as the glass transition is a change of state of a substance, if not in the sense of thermodynamics, the transition temperature should be independent of the method or time scale of measurement, if it may depend on the rate of heating or cooling.

The purpose of this paper is, first, to investigate the temperature variation of various types of complex moduli, Young's modulus, rigidity, bulk modulus etc., and to afford a quantitative basis to the above discussions. Second, some suggestions will be given to the anomalies observed in the modulus-temperature curves below the glass transition temperature.

§ 2. Experimental

The real and imaginary parts of complex Young's modulus and rigidity were measured by the composite oscillator method at a frequency of 33 kc/s for all samples and at 66 kc/s for polystyrene alone. Details of experimental techniques of the method have been described in the previous papers.[5,9,10]

Fig. 2 shows a block diagram of the measuring apparatus at 33 kc/s. Essentially, it consists of a device for applying voltage of variable frequency to a composite oscillator system and observing the frequency depend-

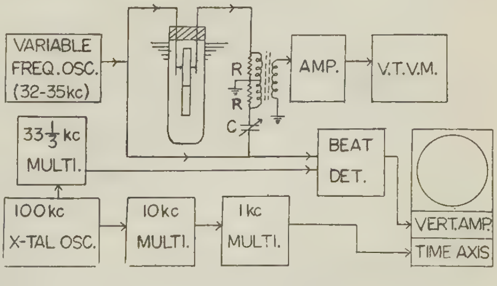

Fig. 2. Block diagram of composite oscillator method at 33 kc/s.

ence of the resultant current. A composite oscillator system was made by cementing a piezoelectric oscillator to a specimen rod of a similar resonant frequency and was set into vibration, the nodal points of the oscillator being supported. The bridge circuit including C and R eliminated the clamped admittance of the oscillator and only the motional admittance *vs.* frequency was read on the vacuum tube voltmeter. The storage modulus and loss factor of the specimen were evaluated from the resonant frequency and half-width of the composite system respectively. The frequency of the oscillator circuit was compared with a standard quartz oscillator and was calibrated to a few cycles by the beat method.

Measurements of Young's modulus were made by use of an ammonium dihydrogen phosphate (ADP) 45° Z-cut longitudinal oscillator, whereas a quartz torsional oscillator was employed in measurements of rigidity. An ADP oscillator has lower density and lower elastic modulus than quartz and consequently has a better acoustic matching with a polymer specimen⁽¹⁰⁾. In the case of measurements of rigidity, an ADP torsional oscillator was not advantageous over quartz on account of the complicated construction of the former.

The cross section of the specimen rod used in the composite oscillator method was identical with the piezoelectric oscillator, $3\times5\,\mathrm{mm}^2$ for longitudinal oscillation and 6 mm in diameter for torsion. The length of the specimen was adjusted so as to make the resonant frequencies of the piezoelectric oscillator and composite oscillator system lie within a few percent. The specimen was cemented to the oscillator by means of styrenated alkyd resin.

The real parts of bulk modulus and rigidity, K' and G', at 1 Mc/s were computed from longitudinal and transversal wave velocities, c_l and c_t respectively, by the following equations:

$$K'=\rho\left(c_l^2-\frac{4}{3}c_t^2\right), \qquad G'=\rho c_t^2, \tag{1}$$

where ρ=density.

Measurements of sound velocities were made using pulse technique (see Fig. 3). A pulsed compressional wave was generated and received in a water tank by a pair of transducers. The time shift of the received signal when a sample was inserted in the path of the beam was compensated by a calibrated delay circuit. From the time shift when the sample plate was set perpendicular to the sound beam, c_l was obtained by means of the relationship

$$c_l=\frac{dc_0}{d-c_0\Delta t}, \tag{2}$$

where d=sample thickness, c_0=velocity in water, and Δt=time shift. When the incident angle θ of sound to the plate was larger than the total reflection angle $\theta_t=\sin^{-1}(c_0/c_l)$, transversal wave alone is transmitted into the plate and c_t was calculated as

$$c_t=\frac{dc_0}{d\cos(\theta-\varphi)-c_0\Delta t\cos\varphi}, \tag{3}$$

where φ is refraction angle and given by

$$\sin\varphi=\frac{c_t}{c_0}\sin\theta\,. \tag{4}$$

The value of c_t was evaluated from Eqs. (3) and (4) by a successive approximation, first assuming an appropriate value for c_t. Δt in eq. (3) is numerically negative for polystyrene in water.

The longitudinal wave velocity was also obtained from the total reflection angle θ_t,⁴⁾,⁵⁾ being in good agreement with that from eq. (2).

Cubical thermal expansion was determined by placing a specimen in the bulb of a Pyrex dilatometer, surrounding it with mercury, and reading the level of mercury in the capillary of the dilatometer as the temperature was varied. The volume of the dilatometer bulb was ca. 15.6 cc and the diameter of the capillary was 2.52 mm. The freezing point of mercury imposed limitations on low temperature measurements.

Density at 15°C was measured by the floatation method in aqueous solutions of sugar.

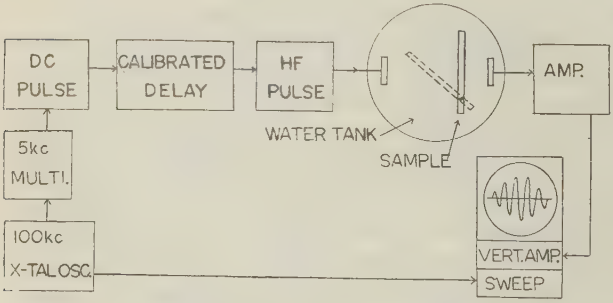

Fig. 3. Block diagram of pulse transmission method.

The rate of heating and cooling was kept almost constant, 10 deg/hr, both in the ultrasonic measurements and in the dilatometry. This rate was sufficient to ensure the uniformity of temperature in the specimen.

§ 3. Sample

Experiments were made on polystyrene (abridged by PS in the following), polymethyl methacrylate (PMMA), polyvinyl acetate (PVAc) and phenol-formaldehyde resin (PhF). PS sample was moulded from pellets, PMMA and PVAc were cast from monomer by block polymerization, PhF was prepared from phenol and formaldehyde of equal mole with ammonium catalyst. Another polystyrene sample (PSa), prepared by block polymerization, was used only in thermal expansion.

Original stocks of each sample except PVAc were in a form of plate, specimens being cut out of the central part of the plate and annealed at 100°C for several hours in order to avoid possible residual stress and volatile impurities. The stock of PVAc was of a form of a short circular rod, thus the measurement of Young's modulus was impossible.

Intrinsic viscosity $[\eta]$ of PS, PSa, PMMA and PVAc was measured at 30°C in benzene solutions. The results are tabulated in Table I, with the viscosity average molecular weight $\bar{M}$ computed by use of the conventional $[\eta]-\bar{M}$ relations.[11)-13)]

Table I. Viscosity average molecular weight and density of samples.

Substance	Symbol	$[\eta]$	$\bar{M}$ (10^5)	ρ (g/cc, 15°C)
Polystyrene	PS	1.15	3.2	1.056
	PSa	0.89	2.3	1.054
Polymethyl methrcrylate	PMMA	3.47	14	1.185
Polyvinyl acetate	PVAc	1.95	5.1	1.194
Phenol formaldehyde resin	PhF	—	—	1.273

Rigidity G' of the same lot of phenol-formaldehyde resin as used in the present experiment was obtained by Hideshima at 0.5 c/s[14)] and it was found that G' becomes proportional to absolute temperature above 120°C. Since $G'=2.8\times10^7$ dyn/cm^2 at 160°C, we can estimate the average molecular weight of a segment between neighboring crosslinks as $M=1.3\times10^3$, using the well known formula $G'=\rho RT/M$, where ρ=density, R=universal gas constant, T=absolute temperature.

§ 4. Volume-Temperature Relation

Fig. 4 shows the volume-temperature curves for five samples. Two samples of polystyrene (PS and PSa) caused no appreciable difference in thermal expansion.

Remarkable discontinuities in the slope of the curves are observed at 81°C for PS, 28°C for PVAc and 53°C for PhF. These points are the glass transition temperature T_g as listed in the literature[15)]. In the case of PMMA, the glass transition is said to be encountered at ca. 100°C,[14)] the high temperature end of this experiment.

The volume-temperature curves in Fig. 4

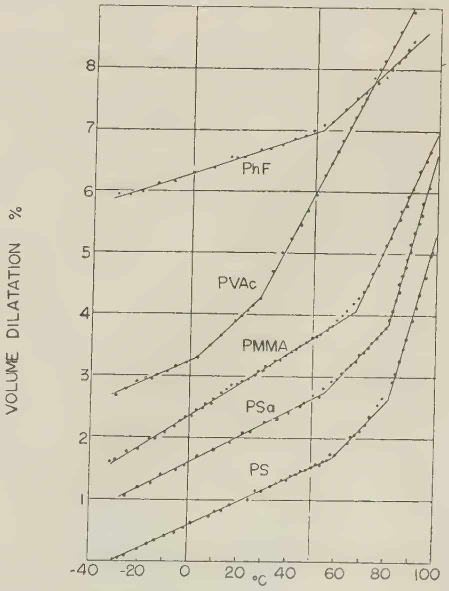

Fig. 4. Volume-temperature curves of five specimens.

are not entirely linear in the range below T_g, but less remarkable discontinuities in the slope can be found at 56°C for PS, 67°C for PMMA and 3°C for PVAc. Possible interpretations to these discontinuities, here named "secondary discontinuity temperature (T_g')," will be later referred to in detail. It might be noted, however, that T_g' lies about thirty degrees lower than T_g for the three polymers.

The behavior of PhF is somewhat different from other three and will be discussed in the last section.

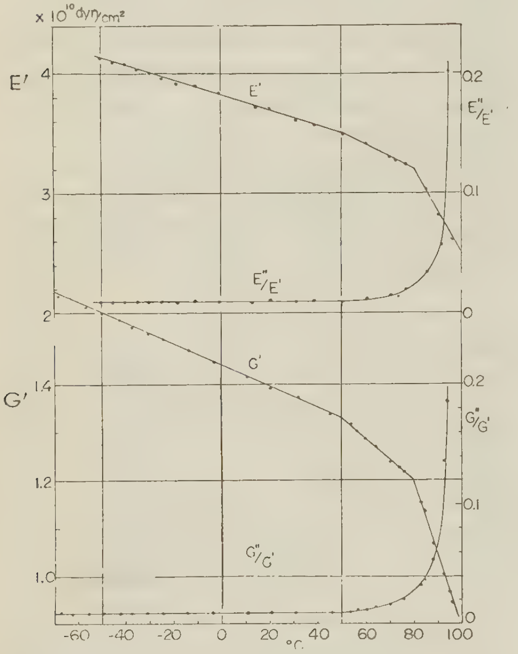

Fig. 5. Complex Young's modulus and rigidity of PS at 33 kc/s.

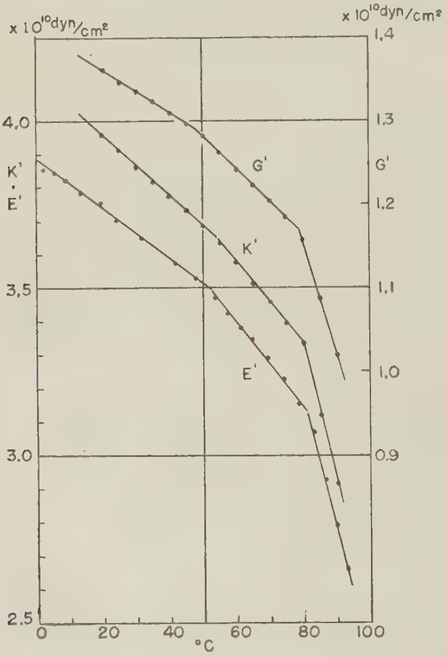

Fig. 6. Young's modulus at 66 kc/s, rigidity and bulk modulus at 1 Mc/s of PS.

§ 5. Temperature Dependence of Storage Modulus

Experimental results of the real part (sto-

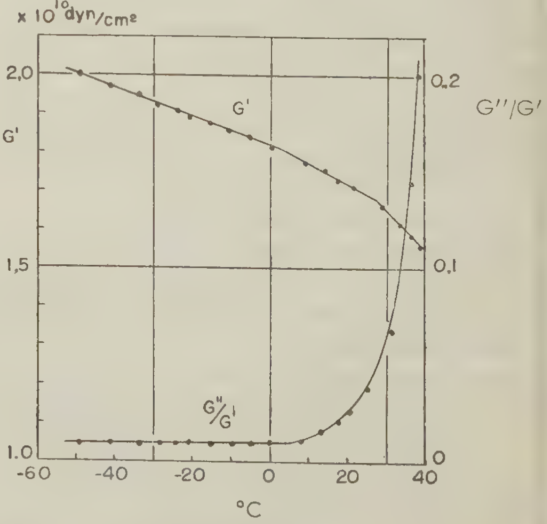

Fig. 8. Complex rigidity of PVAc at 33 kc/s.

rage modulus) of Young's modulus E', rigidity G', and bulk modulus K' are shown in Figs. 5, 6, 7, 8 and 9. K' and G' at 1 Mc/s were obtained only for PS, evaluated from the smoothed curves of c_l and c_t.

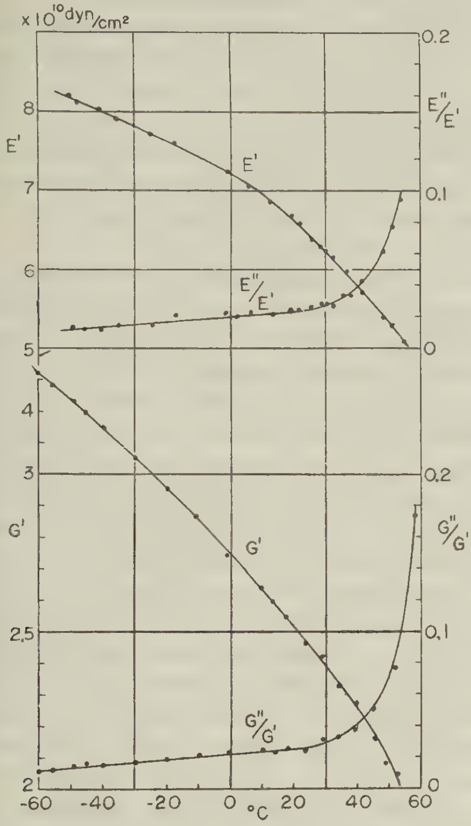

Fig. 9. Complex Young's modulus and rigidity of PhF at 33 kc/s.

As is readily seen in Figs. 5, 6, 7 and 8, E', G' and K' *vs.* temperature curves of PS, PMMA and PVAc all exhibit discontinuities at the temperatures which agree with T_g and T_g' within the experimental accuracy. In the case of PhF alone, a rapid increase in loss made the measurement of modulus impossible above T_g, so the discontinuity was not verified.

In Table II are listed these discontinuity temperatures, T_g and T_g', and the temperature coefficients, α, β and γ, of the linear portions of the curve below T_g', between T_g' and T_g, and above T_g, respectively.

Taking into account a rather large experimental error in the temperature coefficient, it may be permissible to deduce the following rules from the data in Table II. (1) The discontinuity occurs at the same temperature for thermal expansion and for ultrasonic measurement, irrespective of frequency and type of modulus. (2) The temperature coefficients α, β and γ respectively are common among three moduli, E', G' and K'. (3) The ratios β/α and γ/β are the same with volume as with modulus.

According to the simple theory Work[3] has developed, these three rules point to the conclusion that the three types of storage moduli are all of energetic nature and the temperature dependence of moduli is simply a mani-

Table II. Temperatures of discontinuity and temperature coefficients.

Sample	Observed quantity	Temp. of discontinuity (°C)		Temp. coefficients (10^{-3}/deg)			Ratio	
		T_g'	T_g	α	β	γ	β/α	γ/β
PS	volume	56	81	0.19	2.38	1.48	2.0	3.9
	E (33 kc)	50	81	1.7	2.7	13.4	1.6	4.9
	G (33 kc)	50	79	1.6	3.2	13.2	2.0	4.2
	E (66 kc)	53	81	2.0	3.9	13.0	1.9	3.3
	G (1 Mc)	48	79	2.0	3.1	14.3	1.6	4.6
	K (1 Mc)	54	80	2.4	3.2	13.3	1.4	4.2
PMMA	volume	67	—	0.25	0.70	—	2.8	—
	E (33 kc)	67	—	4.5	12.2	—	2.7	—
	G (33 kc)	68	—	5.2	11.1	—	2.2	—
PVAc	volume	3	28	0.19	0.35	0.75	1.8	2.2
	G (33 kc)	3	26	2.0	3.5	10.0	1.8	2.8
PhF	volume	—	53	—	0.13	0.39	—	3.0
	E (33 kc)	—	—	—	7.0	—	—	—
	G (33 kc)	—	—	—	7.8	—	—	—

festation of that of volume. Entropic elasticity and its relaxation effect might add an appreciable contribution to the modulus only well above the temperatures studied.

Fig. 10 shows the real part of Poisson's ratio σ' calculated from E' and G' and from K' and G' by the following equations which are valid for loss factor $\ll 1$ as is our case,

$$\sigma'=\frac{E'}{2G'}-1 \tag{5}$$

and

$$\sigma'=\frac{3K'-2G'}{3(3K'+G')}\,. \tag{6}$$

The σ'-temperature curves have no discontinuity at T_g as well as T_g', being a natural consequence of the rule (2) above mentioned.

As can be seen in the data for PS (Figs. 5, 6 and 10), no frequency dependence of E', G' and σ' is appreciable, being also characteristic of energetic elasticity.

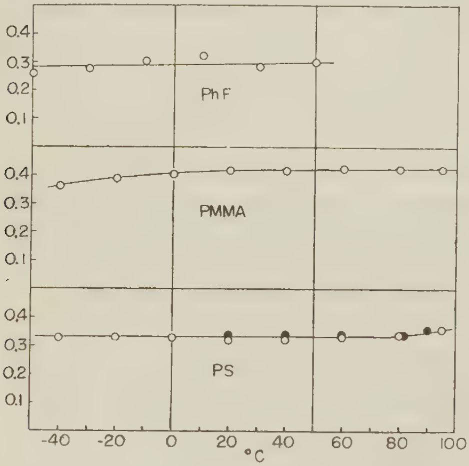

Fig. 10. Real part of Poisson's ratio calculated from E' and G' at 33 kc/s (circle) and from K' and G' at 1 Mc/s (point).

§ 6. Molecular Interpretation of Secondary Discontinuity

It has been suggested by many investigators that the glass transition arises from loosening of free volume accompanied by the free rotation of backbone chains of polymers. Besides this transition, as pointed out in the preceding sections, a secondary discontinuity temperature T_g' was observed below T_g in the case of PS, PMMA and PVAc. This discontinuity probably cannot be ascribed to any shortcomings of experimental procedures, because the discontinuity occurs in quite a similar way both in thermal expansion measurement as well as in measurement of various types of moduli.

In fact, this secondary discontinuity has been observed in most of the existing reports. In the case of polystyrene, for example, Hideshima and Okano[6] have found it in their study of creep compliance. A similar phenomenon is seen in the data of thermal expansion measured by Jenckel and Überreiter[16], Spencer and Boyer[17], though they took no special interest in it.

It is of course difficult to decide experimentally whether a true discontinuity in the slope occurs at T_g', or only a rapid but continuous increase takes place. It may be sure, however, that the partial loosening of free volume begins near T_g'.

There are two possible interpretations to the molecular mechanism involved with this phenomenon, namely, the rotation of side groups of chain polymers and the rotation of the end parts of backbone chains.

The concept of the rotation of side groups has frequently been employed in the interpretation of transitions below T_g. In the present case, this concept encounters some difficulties, if not decisive ones, as follows. First, the C–C bond between benzene ring and another radical has been considered as rigid in a molecule of low molecular weight at least. In the case of polystyrene, this conclusion should be altered, if the side group, benzene ring, actually rotates before the rotation of backbone chains begins. Second, in the case of polymethyl methacrylate, the existing interpretation[18] that the so-called "β-transition" comes from the rotation of side group as a whole should be revised, if $T_g'=$ ca 70°C is due to this rotation.

An alternative possibility to the secondary discontinuity is that a local loosening of free volume first appears at T_g' in regions surrounding chain ends. This idea was suggested by Meares[19] in a study of diffusion of gas in a polyvinyl acetate film. If so, the discontinuity at T_g' should be depressed for the fractionated sample including few number fraction of short chain molecules. In fact, the discontinuity does not take place so markedly in the thermal expansion measurement with well fractionated polystyrenes by Fox and Flory[20]. It may be reasonably assumed that the kinetic motions of segments first begins at T_g' in the vicinity of "network defects," chain ends for example, where the mobility of segments is larger than else, and then these rubber-like regions grow co-operatively as temperature is raised, until at T_g they constitute a continuous phase. This point of view results in the conclusion that the glass transition do not necessarily occur at a very narrow range of temperature, but in a rather wide range.

Anyway, more definite conclusions will probably have to await an investigation with samples of a wider range of chemical constitutions and of known molecular weight distributions. Precise measurements of certain other properties such as line-width of nuclear magnetic resonance will be also very desirable to this purpose.

§ 7. Temperature Dependence of Loss Factor

The data of loss factor are presented in Figs. 5, 6, 7, 8 and 9. For each polymer, two loss factors, E''/E' and G''/G', are almost equal to each other within the experimental error in the temperature studied. This results in the fact that the imaginary part of Poisson's ratio σ'' is nearly zero, following the equation below,

$$\sigma''=\frac{E'}{2G'}\frac{(E''/E'-G''/G')}{1+(G''/G')^2} . \qquad (7)$$

Temperature dependence of loss factor exhibits features quite different from that of storage modulus, because the energetic elasticity greatly contributes to the modulus, but very little to the loss. Therefore, the entropic elasticity in turn, if slightly intermixed with the energetic one, may be revealed clearly in the latter, but not in the former. The rapid increase of loss factor from T_g as found in the data may be safely regarded as a result of onset of segmental motions at T_g. A slow increase is also observed at T_g', affording an additional basis to the conclusion in the preceding section that the motions of chains locally starts at T_g'.

As mentioned in the introduction of this paper, the glass transition temperature has often been referred to the temperature of loss maximum. However, in our standpoint of view, it may be rather reasonable to say that the transition temperature corresponds to the point where the loss factor begins to rise, though this point is experimentally difficult to identify exactly.

Finally, some supplementary remarks will be given about PMMA and PhF. In the case of PMMA (see Fig. 7), a slight increase in the slope of the loss factor-temperature curve is observed at −40°C, which may presumably be allied with the so-called β-transition, though the corresponding maximum of the loss factor shifts to a much higher temperature at ultrasonic frequencies and becomes undistinguishable from the primary glass transition.

For the PMMA specimen, which was cut out of the same stock as the present study, but had been left for two months in an atmosphere of high humidity, a slight peak of the loss factor was observed as illustrated in Fig. 11. As Yamamoto and Wada have said in the previous report⁹⁾, this peak probably arises from water included in the specimen.

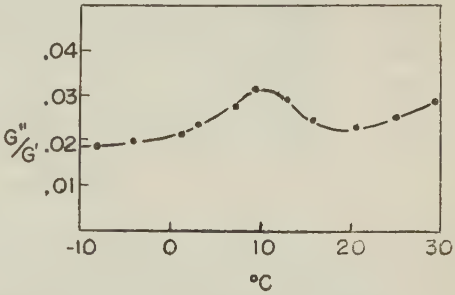

Fig. 11. G''/G' of PMMA including water at 33 kc/s.

The behaviors of PhF are somewhat different from other three samples both in the storage modulus and loss factor. The modulus-temperature curve of PhF (see Fig. 9) has no distinct discontinuity below T_g, but the slope continuously decreases with lowering temperature. The loss factor steadily decreases with decreasing temperature and shows no indication to level off, even at the lowest end of the temperature studied, in contradistinction to other samples. These behaviors may presumably be caused from permanent crosslinks in this polymer. The permanent crosslinks hinder the molecular motions above T_g, resulting in a rather large number of "network defects" in the glassy state and, as a consequence, a perfect freezing-in of free volume is not reached until the temperature is lowered far below T_g.

Acknowledgements

The authors are deeply indebted to Dr. S. Iwayanagi, Messrs. T. Hideshima and K. Okano at the Institute of Physical and Chemical Research for many valuable suggestions during the course of this work. The aid of Dr. K. Kawada at the same institute in obtaining the samples is gratefully acknowledged. Dr. Y. Kunisaki at the Nihon Denki Co. Ltd. furnished ADP oscillators used in in this work, for which we thank him.

X-Ray Study on the Molecular Rotation in Cubic Ammonium Nitrate

By Yasuhiro SHINNAKA

Faculty of Literature and Science, Yamaguchi University

(Received February 27, 1959)

Molecular rotation in cubic ammonium nitrate was studied by using a single crystal obtained by slow cooling from the melt. The observed X-ray scatterings of two different kinds were used: one is the Laue-Bragg scattering and another the diffuse scattering. The first and the second order diffuse scatterings of disk-like shape $(\sin(\varphi/2)/\lambda\times10^{-8}=0.1945,\ 0.3089)$ perpendicular to the direction $\boldsymbol{a}^*$ and its equivalents in the reciprocal lattice were observed in addition to the diffuse scattering due to ordinary thermal vibration. These diffuse scatterings were considered to be due to the rotation of nitrate groups.

By the study on the Laue-Bragg scattering two models of the hindered rotation were selected and it was found by the study on the diffuse scattering that one of these two models is most probable. Further, the correlation among the individual rotating nitrate groups was considered for interpreting the characteristic intensity distribution of the first order diffuse scattering as well as the existence of the second order diffuse scattering. One type of the correlations which is specified by a parameter $\boldsymbol{P}$ denoting the degree of the randomness in the distribution of the rotation-axes was taken into consideration for the analysis of the diffuse scattering. The model thus obtained is closely connected with the model of the rotation in the tetragonal ammonium nitrate and it seems that there still exists correlation not only between the neighbouring nitrate groups but also between remoter ones.

§ 1. Introduction

It is known that ammonium nitrate has five modifications and among them the cubic modification is stable in the temperature range of 125.2°C～169°C (melting point). With respect to the cubic modification the rotation of nitrate groups has been considered by S. B. Hendricks and his coworkers1) from the fact that X-ray powder photographs have required the cubic unit cell containing a single molecule. But, on account of the unreliability of the intensity measurement due to the high rate of crystal growth, they could not obtain any appropriate model of the rotation. Also, with respect to the cubic modifications of other nitrates such as $RbNO_3$, $CsNO_3$ and $T1NO_3$ the rotation of nitrate groups has been considered in the same manner by other workers2),3). On the other hand, by the use of X-ray powder method U. Korhonen4) reported recently that the cubic nitrates $RbNO_3$ and $CsNO_3$ have the larger cubic unit cells containing eight molecules (space group Pa3) in which there does not exist the rotation of nitrate groups.

In a previous paper5) by the present author it was considered that the nitrate groups of ammonium nitrate are in hindered rotation in the tetragonal modification (84.2°C～125.2°C). And so it seems that the rotation is violent in the cubic modification. It is therefore interesting to study more in detail the behaviour of nitrate groups in cubic ammonium nitrate.

In order to avoid the difficulty of the intensity measurement in the powder method and further to get the pattern of X-ray diffuse scattering arising from the disorder of nitrate grougs, in case when the nitrate groups are in rotation, the present study was carried out by using a single crystal of the cubic modification. And the crystal structure of the cubic ammonium nitrate was studied by the Laue-Bragg scattering and the observed diffuse scattering.

In this paper the results derived from the Laue-Bragg scattering and the diffuse scattering will be shown in Parts **I** and **II** respectively.

I. Study on Laue-Bragg Scattering

§ 2. Preparation of Single Crystal

Since single crystals of the cubic modification could not be obtained from other modifications owing to the destruction of crystal in phase transitions, they were prepared as follows. Dry sample placed in a sealed small glass tube was mounted on the sample holder of camera and was repeated to melt and solidify in order to exclude the bubble in the sample. And the sample was melted carefully so as to remain a small crystal and then by slow cooling a crystal grew up along the direction of the axis of glass tube on account of the temperature gradient existing in that direction in the furnace. This procedure was observed with a telescope. After having annealed the sample for about one day at about 150°C a good single crystal was obtained. By such a method crystals with the direction ⟨001⟩ or ⟨011⟩ near the axis of glass tube were often obtained and by the help of Laue photographs the axis of the crystal was corrected so as to have the direction ⟨001⟩ or ⟨011⟩ along the rotation-axis of the camera.

§ 3. Determination of the Structure

The rotation photographs were taken with the direction ⟨001⟩ or ⟨011⟩ vertical by using X-ray Cu$K\alpha$ and Mo$K\alpha$ (filtered). The data require a cubic unit cell of the structure with $a=4.37$Å at 140°C containing a single molecule, and Bragg spots suggesting a larger unit cell could not be observed. The intensities measured by the microphotometer are shown in Table I under the heading $|\overline{F}|_{\mathrm{obs.}}$, the mean structure factor.

Such unit cell suggests that the nitrate groups are in rotation, where the term "rotation" means not only the dynamical rotation but also the statistical disorder. The structure factors were calculated for the assumed several models of the rotation. In all models it was assumed that a nitrate group holds the form of planar equilateral triangle with N–O distance of 1.22Å as found in other nitrates6) and that the atomic scattering factor f_{NH_4} for Cu$K\alpha$ is approximately the same as determined for Mo$K\alpha$ diffracted from NH_4Cl7), and f_{N} and f_{O} of the nitrate group are the same as those used for cubic $RbNO_3$4).

The centers of ammonium groups can be taken at 000 and those of the nitrate groups at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ statistically. If the correlation between each rotating group is neglected, the several modes of the rotation will be specified by the distribution of the rotation-axes.

At first, the following two models were considered on the basis of the assumption that N atoms of the nitrate groups are at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ and that the rotation-axes are perpendicular to NO_3 planes through the N atoms;

model (1): the rotation-axes are oriented at random,

model (2): the rotation-axes are parallel to three orthogonal directions ⟨100⟩ and its equivalents,

where the nitrate groups are rotating with constant angular velocity about the rotation-axes.

(400)	*v.w.*	3.8	4.5	3.3	2.6	2.0

$\overline{F}(i)$ represents the calculated mean structure factor for (i) model and all values are arranged relatively by taking $\overline{F}(200)=10.0$.

The calculated structure factors for these models are shown in Table I. They are not in good agreement with the observed ones and it is noticed that among the structure factors of the main reflection planes the calculated $\overline{F}(111)_{\mathrm{cal}}$ of both models are so weaker than the observed one. It is found from several further numerical trials that if the N atom is at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ such tendency is hold for the other models. Therefore the position of N atoms must be slightly displaced from the body center of cubic unit cell.

Then it was considered to be probable that the nitrate groups take successively some equivalent quasi-stable configurations with the same probability in each unit cell. As to the configurations of the nitrate group which seem to be quasi-stable, the configurations similar to those in the other modifications of ammonium nitrate were chosen as follows.

From the tetragonal modification, the model (3) with twelve equivalent configurations was considered and one of which is shown in Fig. 1. This model is similar to the model (2).

From the orthorhombic modification (32.3°C ~84.2°C) of the type NiAs, the model (4) having eight equivalent configurations was considered and one of which is shown in Fig. 2. This model is similar to that of cubic $RbNO_3$, that is, in cubic $RbNO_3$ these eight equivalent nitrate groups are arranged under the space group Pa3 in larger unit cell. Also it is considered that this model is similar to the model in which the rotation-axes are parallel to the direction $\langle 111 \rangle$ and its equivalents.

From the orthorhombic modification (32.3°C ~−18°C) of the type CsCl, the model (5) having twelve equivalent configurations was considered and one of which is shown in Fig. 3. This model is similar to the model in which the rotation-axes are parallel to the direction $\langle 110 \rangle$ and its equivalents.

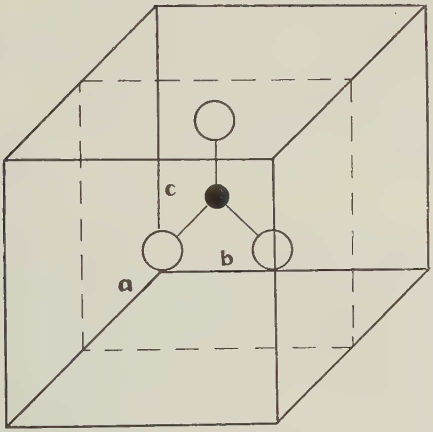

Fig. 1. One of the twelve equivalent configurations of the nitrate group for model (3). Positions of atoms in the nitrate group: N:(0.5, 0.5, 0.5+v); O:(0.5, 0.5, 0.779+v), (0.5, 0.742, 0.36+v), (0.5, 0.258, 0.36+v).

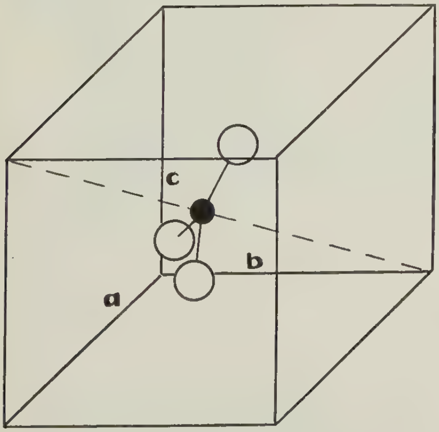

Fig. 2. One of the eight equivalent configurations of the nitrate group for model (4). Positions of atoms in the nitrate group: N:$(x, \bar{x}, x)$; O:$(u, \bar{u}, z)$, $(u, \bar{z}, u)$, $(z, \bar{u}, u)$.

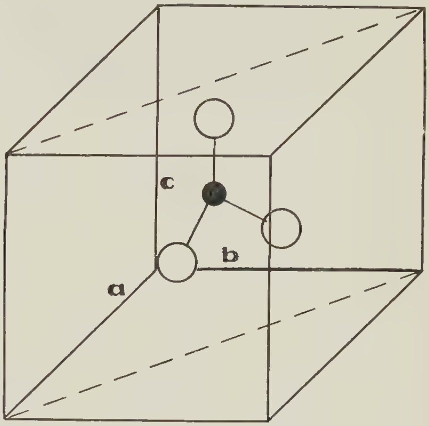

Fig. 3. One of the twelve equivalent configurations of the nitrate group for model (5). Positions of atoms in the nitrate group: N:(0.5, 0.5, 0.5+v); O:(0.5, 0.5, 0.779+v), (0.329, −0.329, 0.36+v), (−0.329, 0.329, 0.36+v).

Table II.

Model (3):	$v=0.05$		
Model (4):	$x=0.554$,	$u=0.44$,	$z=0.782$
Model (5):	$v=0.10$		

In these models the atomic positions were determined so as to be in agreement with the experimental data as good as possible. The atomic positions of each one of equivalent configurations for these models are shown in Table II and the corresponding calculated structure factors are shown in Table I. Among them both the calculated structure factors for models (3) and (4) were in fairly good agreement with the observed ones.

While, it may be still possible that as in the case of $RbNO_3$ the unit cell of ammonium nitrate is larger and contains eight molecules. However, no Bragg spots suggesting a larger unit cell could be observed in the present experiment.

Judging from the above results it can be considered that in the cubic modification the nitrate groups are in rotation and the mode of rotation is quite similar to either of the models (3) and (4). Of course the rotation will be more complex on account of several factors such as correlation, hindrance and thermal vibration. Therefore it is hard to say whether the structure of cubic modification is more closely connected with the structure of tetragonal modification or with that of orthorhombic modification (NiAs type). In order to obtain the more informations on the rotation the observed diffuse scattering will be discussed in the following Part **II**.

In closing this Part **I**, a few words should be added on an anistropic effect of extinction. In many rotation photographs taken with the good crystals annealed enough, it was found that the extinctions in the equatorial reflections, particularly those of {100} and {110}, were often stronger than the extinctions of the other layer lines (see Photo. 1). The ratios of intensity (I) between the reflections of each equivalent plane $\{hkl\}$ in zero layer line and first layer line were measured as follows:

situation of sample	$\{hkl\}$	$\frac{I(\text{zero layer})}{I(\text{first layer})}$
⟨001⟩ vertical	{110}	~1/2
⟨011⟩ vertical	{100}	~1/2

These ratios have been corrected by *rho* factor that depends upon the angle of inclination ρ of the reflecting planes to the vertical rotation-axis. Many factors may be supposed as the cause of this effect, for example, some imperfections in crystal growth, the strain which is likely caused easily by some weak forces on account of the softness of the crystal, and so on. The anisotropic effect of the extinction is now under investigation.

II. Study on Diffuse Scattering

According to the variety of crystal imperfections there are many types of the diffuse scattering[8),9)], so that the interpretation of the observed diffuse scattering is difficult. Among these types only a few experimental researches[10)] and theoretical discussions[11),12)] seem to have been carried out so far on the type corresponding to the molecular rotation in crystal.

The diffuse scatterings observed in the present experiment, in addition to the ordinary diffuse scattering due to thermal vibration, in cubic ammonium nitrate may be considered to be due to the rotation of the nitrate groups. Therefore, the present study may be of interest in that it gives us additional informations on the diffuse scatterings due to the molecular rotation in crystal.

§ 4. Observation of the Diffuse Scattering

Many Laue photographs were taken with cubic axis vertical at about 2° intervals over the whole rotational range by using filtered CuKα and MoKα on cylindrical films (camera radius = 50.7 mm). The interval between each photograph was calibrated by measuring the positions of Laue spots, and the distribution

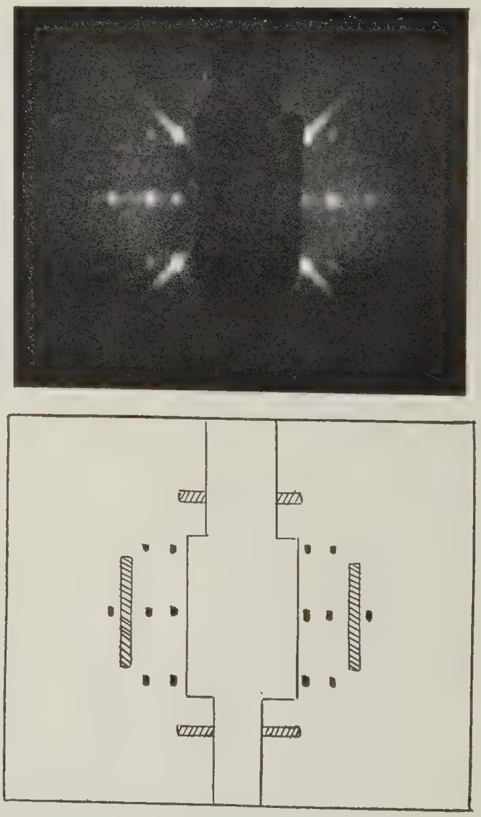

Photo. 1. Rotation photograph taken with cubic axis vertical by using filtered MoKα, showing the anisotropic extinction and the diffuse scattering.

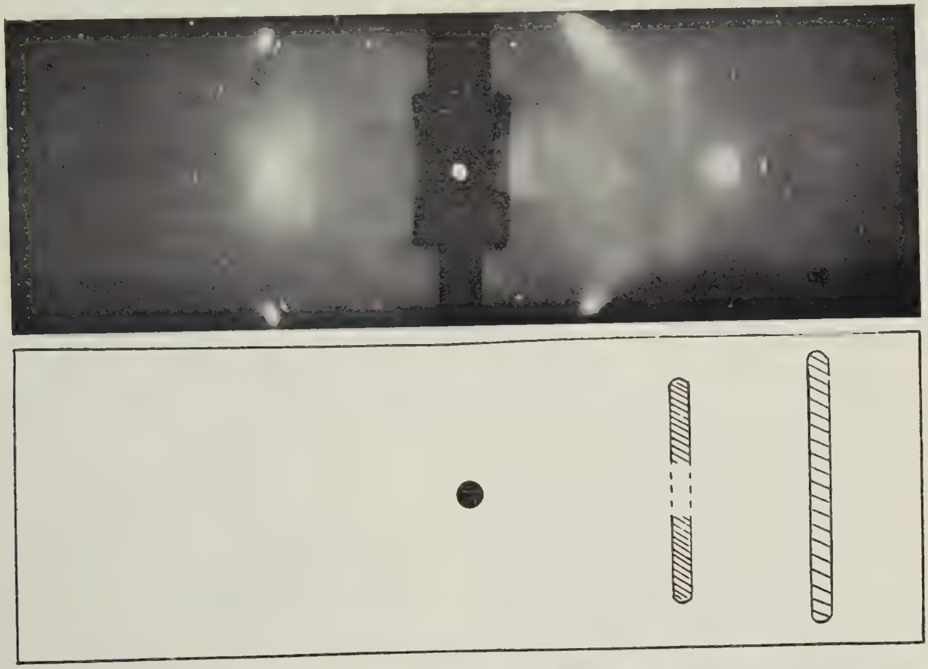
of diffuse scattering in a reciprocal-lattice was obtained by the usual geometrical method.

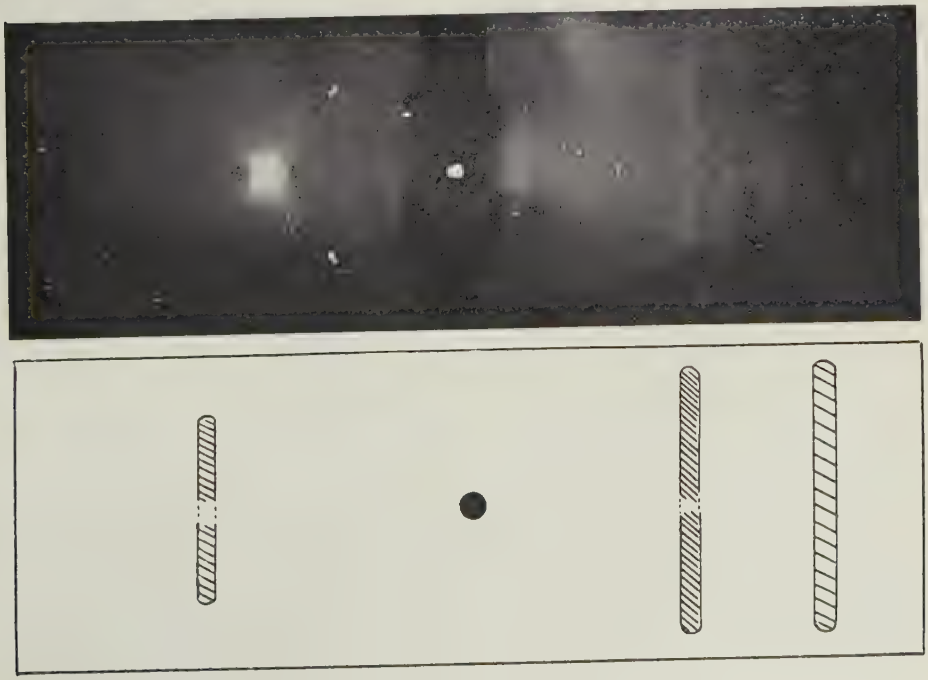
Photographs 1 and 2 are typical examples of the photographs and Fig. 4 is the illustration of Photo. 2. The obtained reciprocal-lattice representation of the diffuse scattering is shown in Figs. 5 and 6; but the ordinary thermal vibration diffuse scatterings observed in the neighbouring region of the reciprocal-lattice points are omitted. The ordinary thermal diffuse scatterings in the neighbouring region of the reciprocal-lattice points {100}, {110}, {111} and {200} were remarkable, but they had no particular correlation with another disk-like diffuse scattering in question.

In each direction of three primitive translations of the reciprocal lattice ($\boldsymbol{a}^*$, $\boldsymbol{b}^*$ and $\boldsymbol{c}^*$) two disk-like diffuse scatterings were observed

(1)



(2)



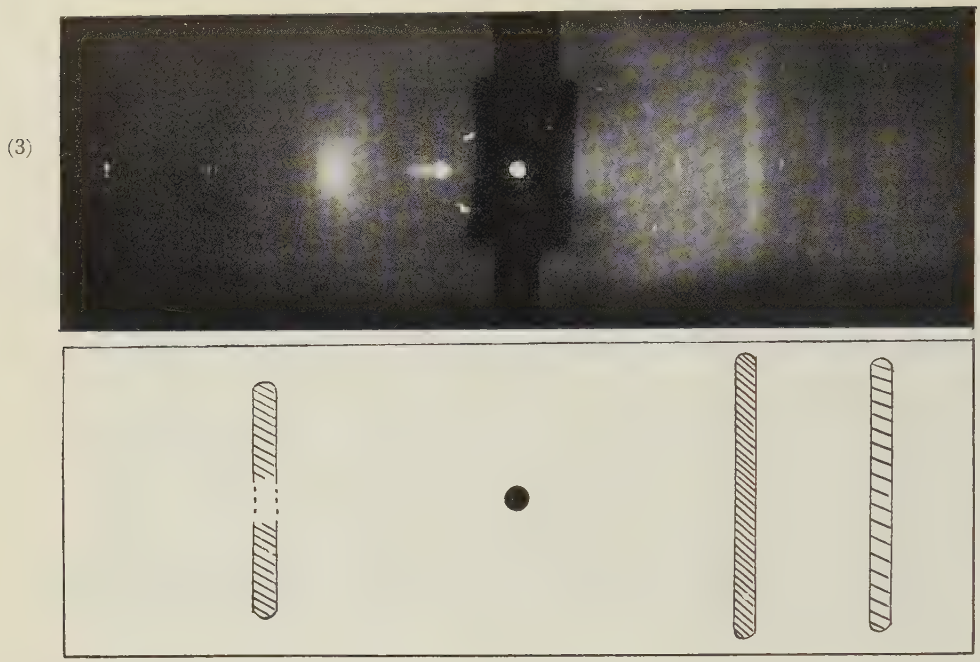


Photo. 2. Photographs showing the variety of the Laue spots and the diffuse maxima when the angle of incidence was changed. Filtered Cu radiation.

to be perpendicular to each direction and hereafter one of them will be called the first order diffuse scattering and the other the second order diffuse scattering. The values of $\sin(\varphi/2)/\lambda\times10^{-8}$ at the centers of the two disk-like diffuse scatterings are 0.1945 and 0.3089 respectively, where λ is the wave length of incident beam and φ an angle of scattering. Though the intensity distribution of these diffuse scatterings could not be determined in detail owing to the weakness of their intensities, it was noticed that the intensity distribution of the first order diffuse scattering was particularly characteristic: the intensity at its central part was weak.

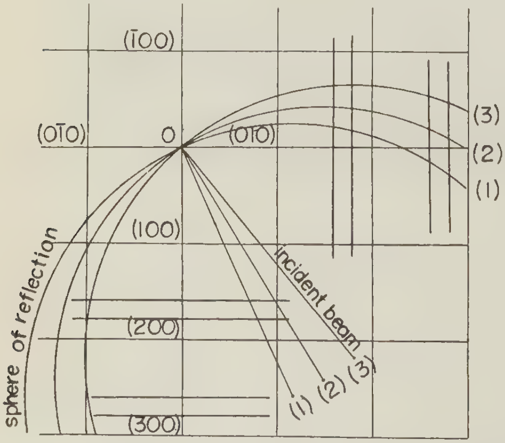

Fig. 4. The reciprocal-lattice diagram corresponding to Photo. 2.

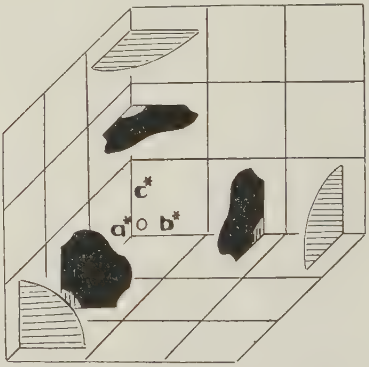

Fig. 5. Schematical reciprocal-lattice representation of the X-ray diffuse maxima.

It seems that the first and the second order diffuse scattering are due to the rotation of the nitrate groups.

§ 5. Interpretation of Diffuse Scattering

As the first step to analyze the observed diffuse scattering, any correlation among the individual rotating nitrate groups was neglected. In this case the intensity I of the diffuse scattering is given by[8),9)]

$$I=K[\overline{|F^n|^2}-|\overline{F}|^2](1+\cos^2\varphi)/2\ , \qquad (1)$$

where K is a constant for a given crystal and the same value of K will be used throughout this paper.

The distribution of the diffuse scattering in the reciprocal lattice were evaluated in several models. It was temporarily assumed for the convenience of the evaluation that the center of each N atom of the nitrate group is at body center in each cubic unit cell as assumed in the first part of Part **I**. In practice such simplification will be admitted, for it is clear from the several numerical trials that the distribution of the diffuse scattering derived from the above assumed models is not so different from the distribution of the similar models obtained in the latter part of Part **I**; the positions of diffuse maxima and the feature of the intensity distribution are not so different except for the absolute value of the intensity. General feature of the diffuse scattering is more sensitive to the kinds of models than to the approximation above mentioned.

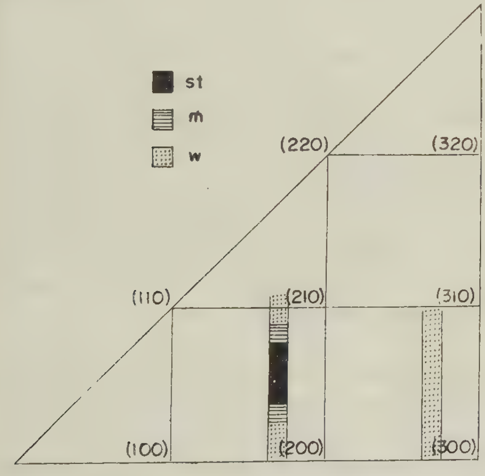

Fig. 6. Reciprocal net showing positions of diffuse maxima in central layer lines of Laue photographs taken with cubic axis vertical.

The models of the rotation evaluated are as follows.

a) When the rotation-axes of the nitrate groups are oriented at random, formula (1) becomes

$$I=Kf_0^2\left[3+6\frac{\sin sr'}{sr'}-9\left(\frac{\sin sr}{sr}\right)^2\right](1+\cos^2\varphi)/2\,, \tag{2}$$

$$s=4\pi\sin(\varphi/2)/\lambda\,, \tag{3}$$

where r is the N–O distance of 1.22Å and r' the O–O distance in a nitrate group. Equi-reflection contours in the reciprocal net $l=0$ is shown in Fig. 7 a).

b) When the rotation-axes are parallel to three directions ⟨100⟩ and its equivalents,

c) when the rotation-axes are parallel to four directions ⟨111⟩ and its equivalents,

d) when the rotation-axes are parallel to six directions ⟨110⟩ and its equivalents,

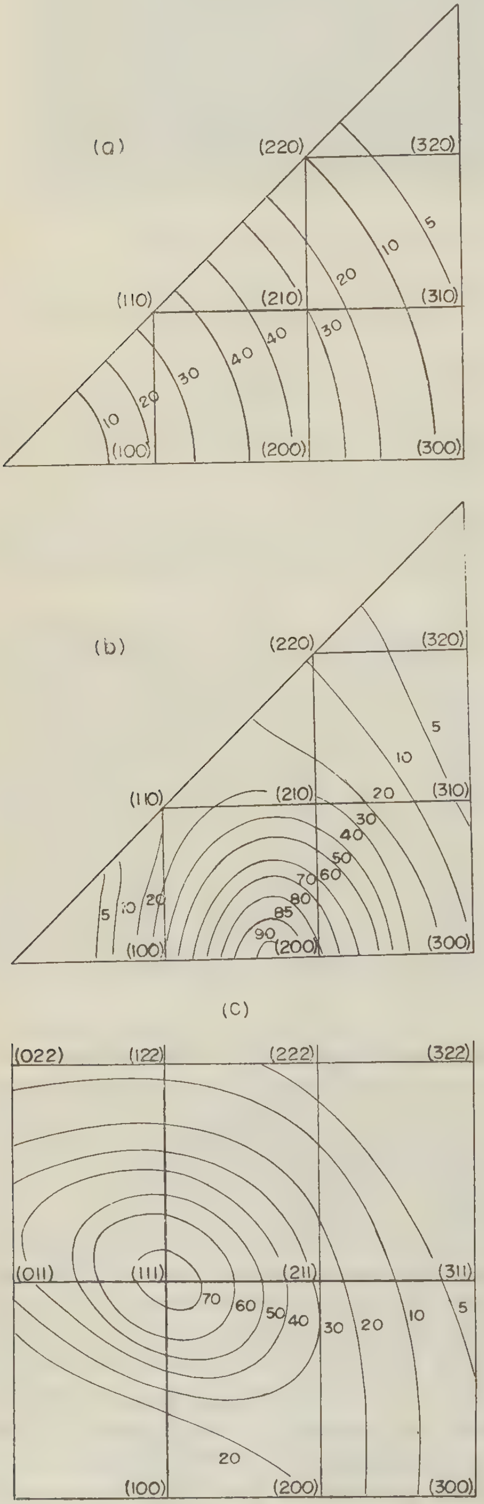
formula (1) for each model is given in the form:

$$I=Kf_0^2\left[3+\frac{1}{n}\sum_{i=1}^{n}6J_0(sr'\sin\psi^i)-\left\{\frac{1}{n}\sum_{i=1}^{n}3J_0(sr\sin\psi^i)\right\}^2\right](1+\cos^2\varphi)/2\,, \tag{4}$$

where n is the number of rotation-axes of each model, J_0 the Bessel function of order zero and ψ^i the angle between the rotation-axis and $\boldsymbol{h}=\boldsymbol{k}-\boldsymbol{k}_0$ ($\boldsymbol{k}_0$: the wave vector of the incident beam, $\boldsymbol{k}$: the wave vector of the scattered beam). Equi-reflection contours calculated for b), c) and d) models are shown in Figs. 7 b), 7 c) and 7 d).

Among these models, general feature of the diffuse scattering calculated for b) model is most similar to the observed one. Equi-reflection contours for the model (3), one of the two probable models obtained in Part **I** similar to b) model, are also calculated and shown in Fig. 7 e). However, the distributions represented in Fig. 7 b) and Fig. 7 e) are different from the observed one in the following two points: the characteristic distribution of the first order scattering is not represented and the second order diffuse scattering is absent.

It will be found from the above calculation that the diffuse maxima in the reciprocal net for each model appear in the direction of the rotation-axes of each model. And for the purpose of explaining the characteristic distribution of the first order, the steady precessional motion about each of the directions ⟨100⟩ and its equivalents was considered in order to make the directions of the rotation-axes run parallel with the directions of the observed diffuse maxima in the first order diffuse scattering. Moreover, the motions consisting of the combination of the nutation with the precession were considered. But the correspondency of the directions of the diffuse maxima to the rotation-axes exists only in b), c) and d) models, and the distribution obtained by the approximate calculation for these models is similar to that of the weighted mean of the distribution for b), c) and d) models. And any noticeable distribution comparable with that of b) model could not be obtained from these distributions.



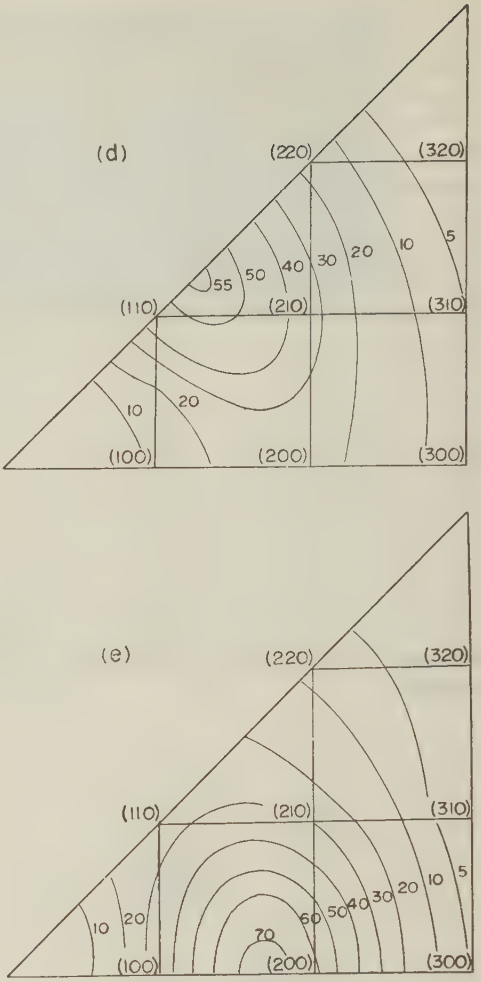


Fig. 7. A set of intensity contours of the models (a), (b), (c), (d) and (3).

The failure may be due to the neglect of the correlation. But it is supposed that b) model is to some extent close to the actual rotation judging from the similarity of the general feature and the position of the first order diffuse scattering in both of the diffuse scatterings. The b) model might be taken as the first approximate model.

As the second step to the analysis, the correlations among the individual nitrate groups were taken into consideration. When the observed diffuse scattering (Fig. 6) was compared with the calculated one for b) model (Fig. 7 b)), there seemed not to exist so strong correlation, but from the fact that the broadness of the observed diffuse maxima seems to be very narrow in contrast with that of the calculated one, it may be assumed that there still exists the correlation not only in the neighbouring nitrate groups but also in the remoter ones. Various types of correlation are supposed to exist, and only a simple case will be taken up here as an example to see how these correlations affect the diffuse scattering. Suppose that, in b) model, each adjacent nitrate group is more likely to have the rotation-axis of different direction than that of the same direction, the phase in the rotation about each axis being however assumed to be independent of one another. The degree of the correlation will be specified by mentioning that the probability of finding out that both nitrate groups in any n, n'th unit cells are rotating about the axes of the same direction, is $\boldsymbol{P}(|\boldsymbol{R}_n-\boldsymbol{R}_{n'}|)$ as a function of the interdistance $|\boldsymbol{R}_n-\boldsymbol{R}_{n'}|$, where $\boldsymbol{R}_n$, $\boldsymbol{R}_{n'}$ are the position vectors of n, n'th unit cells. Now it will be assumed as a temporary measure that the values of $\boldsymbol{P}(|\boldsymbol{R}_n-\boldsymbol{R}_{n'}|)$ at $|\boldsymbol{R}_n-\boldsymbol{R}_{n'}|=a$, $\sqrt{2}a$, $\sqrt{3}a$ are α, β, γ respectively, where a is the axis length of cubic ammonium nitrate, and that the nitrate groups at larger distances have independent directions each other ($\boldsymbol{P}=1/3$). The elementary model b), which has three directions of the rotation-axes and has not any correlation, corresponds to the model for $\alpha=\beta=\gamma=1/3$. Next, the models for $1/3>\alpha>0$, $1/3<\beta<1$ and $1/3>\gamma>0$ will be considered. Of course the model having such rotation is not considered to be so reasonable; even if only the ionic radii of atoms were taken into consideration, improbable arrangements occur in no small probability on account of disregarding the phase relation in rotation, although the chances of taking such improbable arrangements are much less than in b) model which has no correlation.

Now, the intensity of the coherent X-ray scattering for the disorder crystal is in general given by

$$I=I_e\sum_n\sum_{n'}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'})\langle F^n(F^{n'})^*\rangle\,, \tag{5}$$

where

I_e : the Thomson factor,

$\boldsymbol{R}_n$: the position vector of the nth lattice point,

F^n : the structure factor of the nth unit cell,

$\langle\ \rangle$: the mean process under the condition that $|\boldsymbol{R}_n-\boldsymbol{R}_{n'}|$ is fixed,

$\sum\limits_n\sum\limits_{n'}$: summation is taken over all the lattice points.

In the present problem this formula gives

$$\begin{aligned}I=I_e\Big[&\langle F^n(F^{n'})^*\rangle\sum_{\substack{n\ \ n'\\(|\boldsymbol{R}_i|>\sqrt{3}a)}}\exp(2\pi i\boldsymbol{h}\cdot R_n-\boldsymbol{R}_{n'})+\langle F^n(F^{n'})^*\rangle\sum_{\substack{n\ \ n'\\(|\boldsymbol{R}_i|=\sqrt{3}a)}}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'})\\&+\langle F^n(F^{n'})^*\rangle\sum_{\substack{n\ \ n'\\(|\boldsymbol{R}_i|=\sqrt{2}a)}}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'})+\langle F^n(F^{n'})^*\rangle\sum_{\substack{n\ \ n'\\(|\boldsymbol{R}_i|=a)}}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'})\\&+\langle F^n(F^{n'})^*\rangle\sum_{\substack{n\ \ n'\\(|\boldsymbol{R}_i|=0)}}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'})\Big]\,,\end{aligned}\tag{6}$$

where $\sum\limits_{\substack{n\ \ n'\\(|\boldsymbol{R}_i|=a)}}$ denotes the summation taken over the lattice points which satisfy the relation $|\boldsymbol{R}_n-\boldsymbol{R}_{n'}|=|\boldsymbol{R}_i|=a$ and so on.

These summations can be calculated for the given crystal. Each value of $\langle F^n(F^{n'})^*\rangle$ in (6) is given as follows:

$$\left.\begin{aligned}&\langle F^n(F^{n'})^*\rangle_{(|\boldsymbol{R}_i|>\sqrt{3}a)}=|\overline{F}|^2\,,\\&\langle F^n(F^{n'})^*\rangle_{(|\boldsymbol{R}_i|=\sqrt{3}a)}=\frac{(3\gamma-1)}{2}\left\{\frac{1}{3}(|F_1|^2+|F_2|^2+|F_3|^2)-|\overline{F}|^2\right\}+|\overline{F}|^2\,,\\&\langle F^n(F^{n'})^*\rangle_{(|\boldsymbol{R}_i|=\sqrt{2}a)}=\frac{(3\beta-1)}{2}\left\{\frac{1}{3}(|F_1|^2+|F_2|^2+|F_3|^2)-|\overline{F}|^2\right\}+|\overline{F}|^2\,,\\&\langle F^n(F^{n'})^*\rangle_{(|\boldsymbol{R}_i|=a)}=\frac{(3\alpha-1)}{2}\left\{\frac{1}{3}(|F_1|^2+|F_2|^2+|F_3|^2)-|\overline{F}|^2\right\}+|\overline{F}|^2\,,\\&\langle F^n(F^{n'})^*\rangle_{(|\boldsymbol{R}_i|=0)}=\overline{|F^n|^2}\,,\end{aligned}\right\}\tag{7}$$

where F_i $(i=1, 2, 3)$ is the mean structure factor of the unit cell with only i rotation-axis.

Thus the formula (6) becomes finally

$$I=I_1+I_2\ , \tag{8}$$

with

$$I_1=I_e|\overline{F}|^2\sum_{n}\sum_{n'}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'})\ , \tag{9}$$

$$\begin{aligned}I_2=I_eN\Big[\overline{|F^n|^2}-|\overline{F}|^2+\Big\{\frac{1}{3}(|F_1|^2+|F_2|^2+|F_3|^2)-|\overline{F}|^2\Big\}\Big\{(3\alpha-1)\sum_{\substack{i=1\\(|\boldsymbol{R}_i|=a)}}^{3}\cos 2\pi\boldsymbol{h}\cdot\boldsymbol{R}_i\\ +(3\beta-1)\sum_{\substack{i=1\\(|\boldsymbol{R}_i|=\sqrt{2}\,a)}}^{6}\cos 2\pi\boldsymbol{h}\cdot\boldsymbol{R}_i+(3\gamma-1)\sum_{\substack{i=1\\(|\boldsymbol{R}_i|=\sqrt{3}\,a)}}^{4}\cos 2\pi\boldsymbol{h}\cdot\boldsymbol{R}_i\Big\}\Big]\ ,\end{aligned} \tag{10}$$

where I_1 represents the lattice spectra and have been discussed in Part **I**; I_2 represents the diffuse scattering and N the total number of the lattice points. In the calculation of I_2, I_eN was replaced by $K(1+\cos^2\varphi)/2$ as done in formula (1).

Three parameters α, β and γ were chosen so as to satisfy the experimental data as best as possible. The calculated intensity contours are shown in Fig. 8 a) ($\alpha=0.13$, $\beta=0.37$, $\gamma=0.33$). And also the intensity contours were derived in the same way from the model (3) obtained in Part **I**. The obtained contours are shown in Fig. 8 b) ($\alpha=0.13$, $\beta=0.35$, $\gamma=0.33$).

These intensity contours as shown in Figs. 8 a), 8 b) have the characteristic feature of the intensity distribution of the observed first order diffuse scattering and show the possibility of the appearance of the second order diffuse maxima by taking such a correlation into consideration. From this point of view, the present model is considered to be more appropriate as the model of the rotation in cubic ammonium nitrate than the elementary b) model. However the positions of the first order and the second order maxima are slightly different from the observed ones. The cause of this discrepancy may be chiefly due to the approximation of the correlation. The correlation, especially, the phase differences among the individual rotating nitrate groups and the correlation between remoter ones will have to be taken into consideration. Therefore a significant meaning will not be given to the values of these parameters α, β and γ, but they will still be useful to see the degree of the correlation.

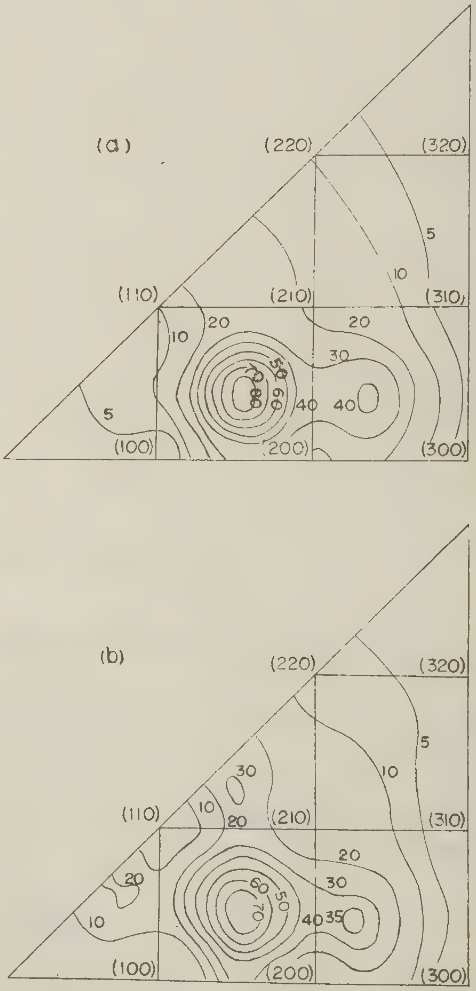

Fig. 8. A set of intensity contours of the models in which the correlation is taken into consideration by introducing three parameters α, β and γ.
(a) $\alpha=0.13$, $\beta=0.37$, $\gamma=0.33$.
(b) $\alpha=0.13$, $\beta=0.35$, $\gamma=0.33$.

§ 6. Discussion

From the analysis of the diffuse scattering in Part **II**, it is considered that the assumption that the diffuse scattering is due to the disorder of nitrate groups is correct. Therefore, with respect to the structure of the cubic ammonium nitrate, the model (3) in Part **I** which has a sort of correlation as discussed in § 5 of Part **II** is considered to be most probable between two models which had been left undetermined in Part **I**. This model is best connected with the tetragonal modification among various modifications in ammonium nitrate.

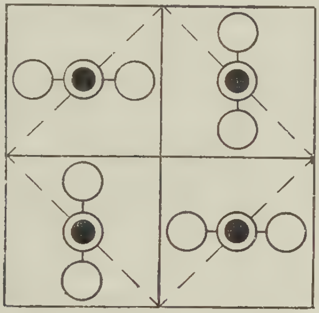

Fig. 9. Showing the arrangement of the nitrate groups in the tetragonal modification projected on (001). Full line represents the unimolecular pseudocell and broken line the true unit.

When, in the tetragonal modification, the unimolecular pseudocells are considered, the rotation-axes are arranged regularly as shown in Fig. 9, in which the rotation-axes of two directions ⟨100⟩ and ⟨010⟩ are arranged so as to have the different directions in each neighbouring unit cell. In the present model of the cubic modification the rotation-axes are arranged almost at random; namely, the rotation-axes of three directions ⟨100⟩, ⟨010⟩ and ⟨001⟩ are arranged under the weak correlation of the tendency similar to that in the tetragonal modification. Such behaviour of the nitrate group is very different from that in other nitrates such as $NaNO_3$⁶⁾ $KNO_3$⁶⁾, $RbNO_3$⁴⁾ and $CsNO_3$⁴⁾.

In general it cannot be expected that neighbouring groups will rotate independently of one another in crystals. The correlations among the rotators exert a great influence on the diffuse scattering. In the case of thermal vibration, the thermal diffuse scattering cannot be interpreted at all without taking the correlation into consideration, but it is considered from this study that the diffuse scattering due to the molecular rotation in most crystals will be able to find in itself some detectable amounts of the feature which will be expected to arise when correlation is neglected. Therefore, it is expected that the diffuse scattering is useful for determining the mode of the rotation and the correlation among the rotators.

With respect to the rotation of the nitrate groups, the more complex mechanism are to be considered in cubic ammonium nitrate. In order to obtain more informations about the rotation it is hoped to have the more detailed intensity measurement and the informations of interatomic forces. And also the study on an anistropic diffuse scattering expected in the tetragonal modification will be useful to find how the phase differences between the rotating nitrate groups affect the diffuse scattering. This subject is now under investigation.

The author expresses his cordial thanks to Prof. K. Tanaka of Kyoto University for his kind guidance and discussion throughout the course of this research. He also wishes to thanks Mr. M. Minami and Mr. G. Nakagawa for their assistance. A part of this work was supported by the Scientific Research Expenditure of the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 8, AUGUST, 1959

On the Anomalous Dispersion of n-Primary Alcohols

By Kenjiro ASAI

Department of Physics, Faculty of Science, Kyoto University

(Received May 2, 1959)

Mechanisms proposed for the dielectric anomaly observed in the low temperature form of *n*-primary alcohols are re-examined, considering especially the influence of thermal history of a sample. The slowly cooled sample gives the longer relaxation time τ and wider distribution of τ than the rapidly cooled one. The activation energy for the dipole orientation depends upon the number of carbons in the alcohol molecule. Results obtained are different from those of previous investigators, but a reasonable model is obtained for this Debye-type abnormal dispersion.

§ 1. Introduction

The dielectric properties of long-chain n-primary alcohols have been investigated by many researchers,[1~5] but they dealt only with the "waxy form" (i.e. α form). Systematic investigation on the low temperature form have done by Meakins and others[6~9] for a series of *n*-primary alcohols. These works are interesting on account of revealing the existence of the abnormal dispersion of Debye-type in the low temperature form, and offering a model of co-operative orientation of O–H···O chain formed by the hydroxyl groups of alcohol molecules. Dryden[8] obtained a value of about 15 Kcal/mol for the activation energy of dipolar orientation, irrespective of the number of carbon atoms in alcohol molecules.

Independently, Takamatsu[10] observed an abnormal dispersion of Debye-type in the low temperature form of C$_{32}$ alcohol, and gave a value of 26.4 Kcal/mol for the activation energy. He explained this result by torsional motion of alcohol molecules. Two different experimental results and corresponding models were presented, namely the co-operative orientation model and single molecule model.

In order to examine these apparently contradicting results, a study on the dielectric properties of n-primary alcohols has been carried out for a series of different carbon numbers which were obtained by synthesis.

§ 2. Experimental Procedure

The measurements were made on eleven *n*-primary alcohols (C$_{18}$, C$_{21}$, C$_{22}$, C$_{27}$, C$_{28}$, C$_{29}$, C$_{31}$, C$_{32}$, C$_{33}$, C$_{34}$, C$_{35}$). Methods of preparation of samples will be explained in another paper.[11]

The temperature and frequency dependencies of dielectric constant and loss were measured by bridge method for the frequency range 50 c/s∼50 Kc/s, and for the frequency range above 100 Kc/s Q meter was used. The phase transformation caused by temperature change was also examined by X-ray diffraction by other members in our laboratory. Dielectric measurements were done referring to the results of X-ray investigation. Data on the phase change of these alcohols are given in Table I, in which α form is a high temperature form and β, γ and δ forms are low temperature modifications. Hitherto α form has been considered to be vertical form with rotational molecular motion about the long axis of the molecule, but by the present structure analysis of a single crystal it was found to be a tilted form. β is a vertical form and γ is a tilted form, the latter having been often designated as β_2 by Smyth and others. Another tilted form δ exists in the odd members above C$_{31}$. More detailed informations about the crystal structures and polymorphism of these alcohols have been given in other papers[12~14]. The values in Table I were obtained by X-ray photographs recording continuously the phase changes of alcohols, so the accuracy of them is not so good, being about ±1°C, as restricted by the construction of X-ray camera. The value in the brackets are those obtained in cooling stage and the bars in the columns show that such transformations do not occur in either case of heating or cooling.

Sample was melted and solidified in a test condenser which was made from copper plated with nickel. Cooling speed from the

molten state to solid phase was varied from 0.5°C/min to about 100°C/min.

§ 3. Results and Discussion

Typical results on the frequency dependencies of dielectric constant and loss are given in Fig. 1. In this case, sample was cooled rather slowly. ϵ'' and ϵ' decrease gradually with increasing frequency in the frequency range of observation. This result is very different from the results reported by Meakins and others. Namely, the marked loss maximum reported by them was not observed in this frequency range. Such tendency did not change so remarkably by varying the temperature to transformation point. This characteristic was commonly observed for every n-primary alcohol in its low temperature form.

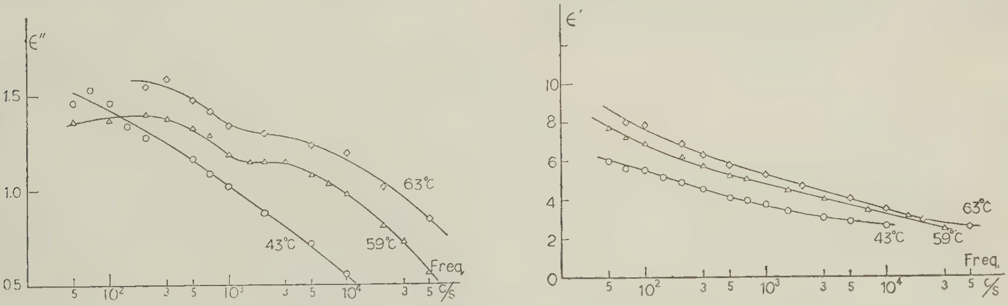

Fig. 1. Frequency dependencies of ϵ'' and ϵ' of $C_{34}H_{69}OH$. The cooling rate from the melt is about 0.5°C/min.

The discrepancy between the experimental results obtained by Meakins and by the present author seems to depend on the difference in the treatment of samples. Meakins and others pulverized the solidified alcohol and pressed it in the form of a circular disk, and measured with it between mercury electrodes. Such procedure does not seem to be adequate in considering a sample as uniform dielectric material. Moreover, the intimate contact at the interfaces between sample and electrodes will not always be secured. Heterogeneity in dielectrics and loose contact at the electrode surface give sometimes confusing results. It is known that *n*-alcohol gives occasionally several modifications of crystal structure with varieties in tilt angle of *c*-axis by rolling. In spite of these confusing factors in experimental procedure, the explanation given by Meakins and Sack[15), 16)] is very interesting and seems to be fruitful. They considered the co-operative rotation of dipoles, connected to each other by hydrogen bonds, as a cause of Debye-type abnormal dispersion observed in their measurements for the low temperature form of C_{18}, C_{22} and C_{26} alcohols.

The curves given in Fig. 1 are very different from the usual ε″–frequency curves indicating Debye-type dispersion. But quite different result was obtained in the case of a rapidly cooled sample of the same material (Fig. 2). Typical Debye-type dispersion curves were observed as in the case of the measurements by Meakins and others.

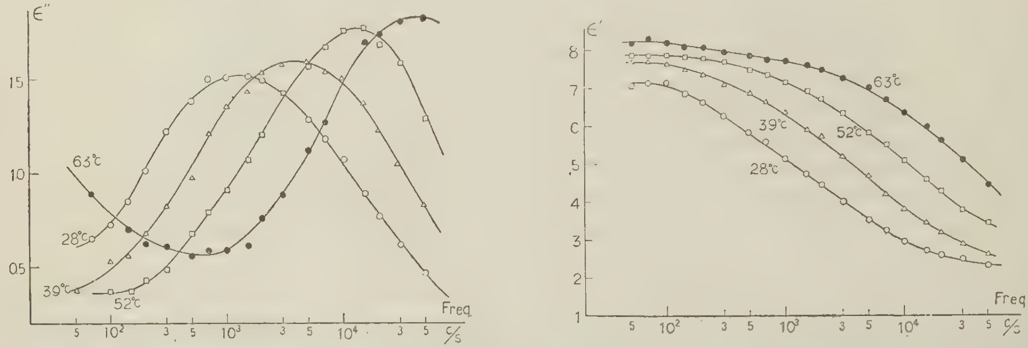

Fig. 2. Frequency dependencies of ε″ and ε′ of $C_{34}H_{69}OH$. The cooling rate from the melt is about 50°C/min.

Next, this sample was annealed at a temperature a few degrees below the melting point. The shift of maximum of ε″–frequency curve to low frequency side was observed by annealing (Fig. 3). Such influence of the heat treatment of the sample upon the dielectric properties of *n*-alcohols suggests the correctness of co-operative orientation mechanism. According to this models, a chain of hydroxyl groups of alcohol molecules connected to each other by hydrogen bonds changes its direction by successive orientation of neighbouring molecules. Therefore, the relaxation time of dipole orientation of a chain depends upon the number *n* of hydrogen bonds included in the chain. For example, Sack[16] gave a result that the relaxation time is proprotional to n^2 and polarization is proportional to n^3. He did not give any estimation on the size of the region in which co-operative orientation occurred. However, the length of the hydroxyl chain would not exceed at most the distance between the neighbouring defects in the chain. Hence the relaxation time seems to be controlled by the distribution of the lattice imperfections in a crystal. Moreover, the effect of the size of crystallites in a sample might be taken into account. These factors will be affected appreciably by the condition of crystal formation, e.g., the cooling speed from the melt. So the dependency of the dielectric behaviour on the thermal history of a sample will be explained by the change of the relaxation time. Namely, the curves illustrated in Fig. 1 seems to correspond to the high frequency parts of the Debye-type dispersion curve with long relaxation time, and they shift to high frequency side in Fig. 2 corresponding to the shortening of relaxation time, as a result of the increase of defects in a hydroxyl chain.

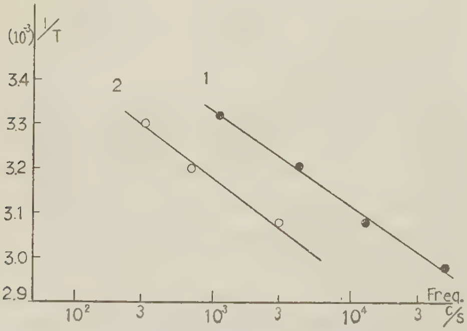

Fig. 3. Temperature dependency of f_m, the frequency of loss maximum, for $C_{34}H_{69}OH$. (1): Rapidly cooled sample. (2): Annealed sample.

In a word, the region of abnormal dispersion would exist at far below 50 c/s for slowly cooled sample, but it seems to come into the present measuring frequency region by rapid cooling. Some defects will be excluded by annealing. This in turn extends the O–H···O chain. The variation of relaxation times illustrated in Fig. 3 will be explained by such mechanism.

As a result of co-operative orientation, the distribution of the relaxation times will become broader than that in the case of single molecule orientation. The variation of Cole diagram is illustrated in Fig. 4 for quenched and annealed samples. Two remarkable effects brought by annealing are recognized in this figure. The first point is the increase of ϵ_s' and the second is the increase of α which expresses the distribution of relaxation times. For the slowly cooled samples ϵ_s' and α increased in more degree and $\epsilon'-\epsilon''$ diagram varied sometimes from Cole-Cole type to Davidson-Cole type. Namely, it is considered that the formation of a new group of relaxation times occurred.

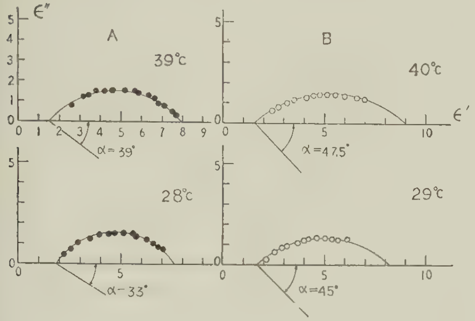

Fig. 4. Cole diagrams for $C_{34}H_{69}OH$. (A): rapidly cooled sample. (B): annealed sample.

The temperature dependencies of ϵ' and ϵ'' are also interesting. As an example, the curves for $C_{32}H_{65}OH$ are given in Fig. 5. The most remarkable feature is the rapid increase of dielectric constant with temperature, especially in the range above 60°C. Such temperature dependency might exist in the lower members of the series. But it was covered by the occurrence of the phase transformation from β or γ to α. As is seen in Table I, such phase transformation does not occur in heating stage for the higher members of even group than $C_{28}H_{57}OH$. So the above mentioned behaviour was fully developed without disturbance by phase transformation for such longer alcohols and it is recognized that such tendency is the characteristic to the low temperature forms of longer alcohols. Surely, the values of dielectric constant depend upon the frequency of the measurement corresponding to the Debye type dispersion mechanism explained previously. As is expressed in Fig. 4, a sample obtained by rather slow cooling from the melt gives a very wide distribution of relaxation times. Considering such fact, the temperature dependency of ϵ' may be expressed schematically as in Fig. 6. Namely the observed curve will be expressed by the superposition of different curves with different relaxation times. A comparison with two kinds of samples obtained by different cooling rates from the melt is also given in Fig. 7. This result supports the above explanation.

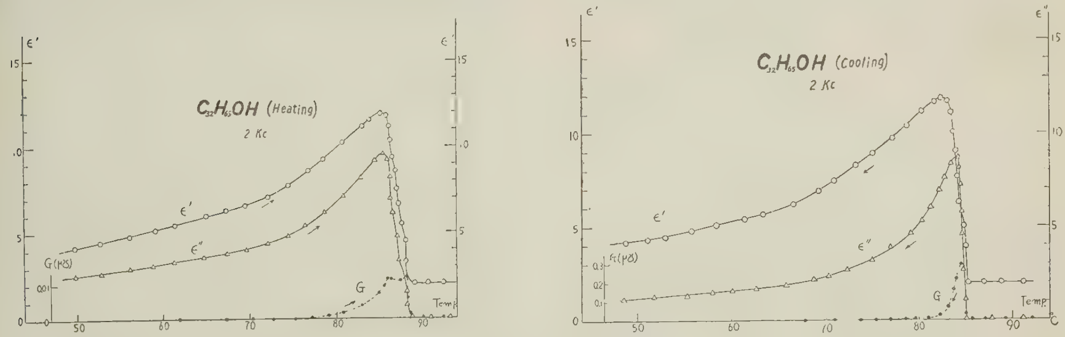

Fig. 5. Temperature dependencies of ϵ'' and ϵ'. Electric conductivity of the sample is also plotted in the figures by the notation G, but the scales are altered case by case, depending on the existence or non-existence of α-phase. The value of ϵ'' is A.C. value. (D.C. conductivity had been subtracted). (a): Heating stage, (b): Cooling stage.

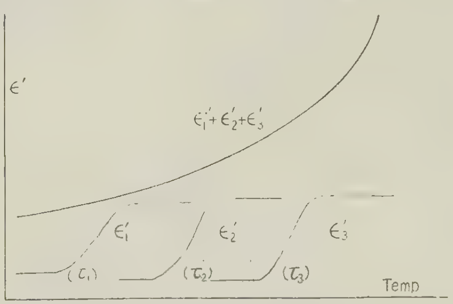

Fig. 6. Schematic diagram indicating the temperature dependency of dielectric constant of n-alcohols.

Namely, for rapidly cooled sample loss maximum shifts to low temperature side in temperature scale, corresponding to the shortening of τ, and therefore the rapid increase of ϵ' is not seen for this sample in contrast with the slowly cooled one.

As additional factors contributing to the increase of ϵ' with temperature rise, the partial break in hydroxyl chain and the usual thermal activation process may be considered. The former brings the shortening of relaxation time. In order to check the influence of such factors, the similar measurement was carried out at higher frequency of 1 Mc/s which is far away from the dispersion region (Fig. 8). The result for a single crystal of $C_{28}H_{57}OH$ also gives a similar curve (Fig. 9), though the accuracy of the measurement was not so good on account of the small size of the crystal (being about 30μ×0.5 mm×5 mm). Referring to these experimental results, the influence of the variation in the molecular freedom with the increase of temperature does not seem to play an important role at least up to the temperature close to the melting point.

The dielectric properties of n-primary alcohols have been noticed by previous investigators on account of the anomaly of α phase. But the high value of dielectric constant of this phase seems to be only apparent due to the high electric conductivity, and some discussion on this problem was made previously3). The high dielectric constant of the low temperature form is, however, the net value essential to n-higher alcohols. An interesting feature is shown in Fig. 10. The dielectric constant increases distinctly by the transformation to the low temperature form from the high temperature one, quite contrary

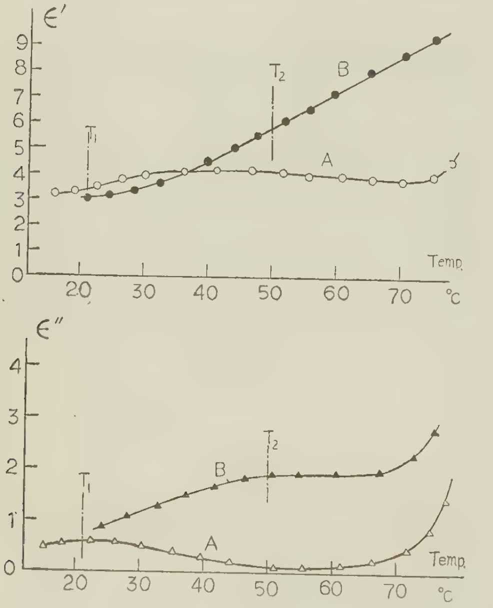

Fig. 7. Comparison of the dielectric properties between two different samples of $C_{35}H_{71}OH$. The temperature regions of low temperature form are only indicated. (A): Rapidly cooled sample. (B): Slowly cooled sample. T_1 and T_2 are the temperatures of loss maximum at this measuring frequency, 2 Kc/s, for (A) and (B) respectively, obtained by interpolation of f_m-1/T curves for each sample.

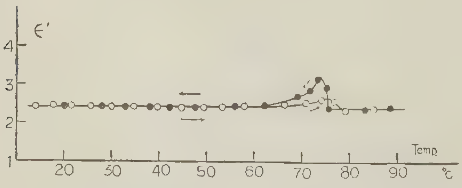

Fig. 8. Temperature dependency of ϵ' of $C_{34}H_{59}OH$ measured at 1 Mc/s.

● : Cooling ○ : Heating

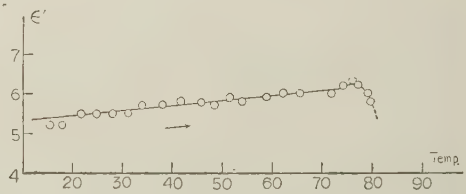

Fig. 9. Temperature dependency of a single crystal of $C_{23}H_{57}OH$ measured at 2 Kc/s. The direction of electric field is vertical to b–c plane of a crystal.

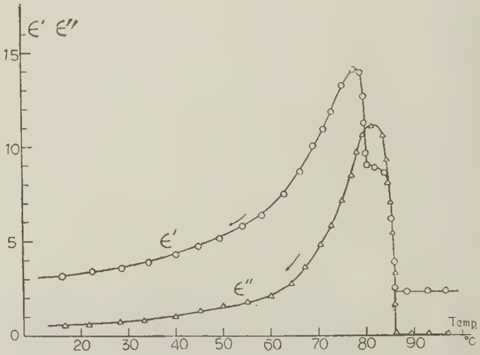

Fig. 10. Temperature dependencies of ϵ'' and ϵ' of $C_{31}H_{;}OH$ in cooling stage. The frequency of measurement is 2 Kc/s.

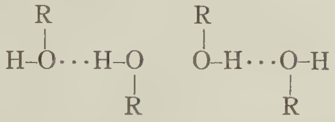
to the case of the lower members, for example, $C_{16}H_{33}OH$ (cetyl alcohol). O–H···O chain might be broken from place to place in α phase owing to the increased thermal motion of the individual molecules in more degree than in low temperature form. Hence the true dielectric constant must be smaller in α phase than in β or γ.

Lastly the detailed discussion should be made on the feature of co-operatively rotating dipoles. According to Sack[15), 16)] two models may be considered for it; one is such that each proton shifts co-operatively one potential minimum to another in a hydrogen bond connecting the neighbouring molecules. In this case molecules take successively the molecular state such as $\left(\begin{smallmatrix}\mathrm{O}\\ |\\ \mathrm{R}\end{smallmatrix}\right)^{-}$ and as a result of this process, a pair of positive and negative ions appear at each end of O–H···O chain. Another scheme given by Sack is the co-operative rotation of hydroxyl groups of alcohol molecules about their C–O bonds. In this case, there exists one pair of antiparallel neighbours of the type:



$$\begin{matrix}\mathrm{R} & & & \mathrm{R} & & \\ | & & & | & & \\ \mathrm{H{-}O\cdots H{-}O} & & & \mathrm{O{-}H\cdots O{-}H} & & \\ & | & & & | & \\ & \mathrm{R} & & & \mathrm{R} & \end{matrix}$$

and such a disorder can wander along the chain by means of reversals of individual dipoles. Thus the reversal of the whole chain can also be possible. But he did not give decisive conclusion in favour of any one of these two models.

In the high temperature form both mechanisms will be present together, giving the high electrical conductivity due to proton transfer. But the results on electrical conductivity show that this is not the case in the low temperature form. It may be inferred from the results of structure analysis[14)] that the chain of hydroxyl groups will run in the direction of a-axis in γ form, and b-axis in β form, respectively. And it is also known that the thermal motion of oxygen atoms is more remarkable than carbon atoms in the molecule. Hence there is a good reason to accept the model of rotation of hydroxyl group about C–O bond as true. But it is doubtful whether the dipole rotation occurs independently of the molecular motion as a whole, as explained by Meakins and others[7, 8, 15)]. As a foundation for it they stated that the relaxation time becomes short with increasing molecular weight. But the relaxation time is affected exceedingly by the number of hydroxyl groups in a chain as explained previously. So the relaxation time has not any important meanings in the discussion of molecular motion. It is not the relaxation time but the activation energy of dipole orientation that is important in the discussion of this problem. Dryden[8)] gave a value of 15 Kcal/mol commonly for three n-alcohols (C_{18}, C_{22} and C_{26}). But the dependency on the molecular weight of alcohol was observed in the present research for five odd alcohols and three even alcohols (Fig. 11). The activation energy increases with the molecular weight and the representative points for each alcohol in Fig. 11 seem to be classified into three groups according to the crystal structure. But it must be confirmed by a further study on more other kinds of n-alcohols.

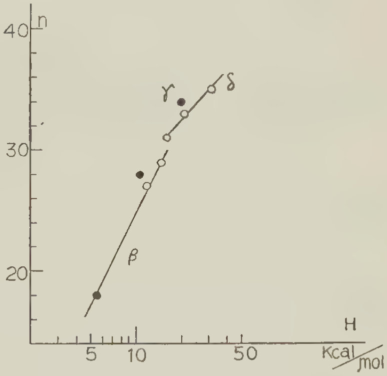


Fig. 11. The dependency of the activation energy of dipole orientation on the molecular size. n is the number of carbon atoms in an alcohol molecule.

The result is quite different from data by Dryden, but he also gave values dependent on the molecular weight for three symmetrical secondary alcohols in spite of considering the same orientation model. Moreover, the decisive information on the crystal structure was not obtained as a result of hard mechanical treatment of the sample material.

Anyhow, the activation of the dipole orientation of O–H···O chain must be considered at its ends. For example, the activation energy H may be the energy necessary for certain disorder such as described above to introduce into the chain. Here the molecular motion as a whole will play an important role. It is known by X-ray investigation[14] that the translational motion along the molecular long axis occurred in α phase so as to make impossible to decide the location of carbon atoms in the molecules. Indeed, the molecules are not so mobile in the low temperature forms, but the occasional possibility of such a motion will not be denied. It is difficult to propose a decisive model for the co-operative dipole orientation, but presumably it will be carried out by the successive elementary process which is a combination of small axial displacement of a molecule and the rotation of hydroxyl group about C–O bond.

The samples which was investigated by Takamatsu[10] seems to be a certain mixture of few neighbouring members, because even alcohols longer than $C_{28}H_{57}OH$ do not give a transformation point in heating process in spite of his result. Co-operative orientation would be disturbed in such a sample, so the results became different from others. In this case the hydroxyl chain would not be so developed as in the case of pure sample. But a value of 26.5 Kcal/mol is not so defferent from that of pure sample referring to Fig. 11, although τ is short consistent with the decrease of the number of dipoles in a chain.

Acknowledgement

The author wishes to express his sincere thanks to Professor K. Tanaka and Mr. T. Seto for their kind helps and fruitful discussions. He got much advantage by obtaining the detailed informations about the crystal structures of *n*-alcohols investigated by Seto. His thanks are also due to Professor R. Goto and Mr. A. Watanabe who gave him an opportunity of promoting the present work by synthesizing a series of pure *n*-alcohols.

Measurement of Ion Sheath Thickness using the Double Probe with Fixed Potential

By Minoru SUGAWARA and Yoshisuke HATTA

Faculty of Engineering, Tohoku University, Sendai, Japan

(Received February 10, 1959)

When a negative potential is given to the double probe usually used as floating condition for gaseous discharge, two ion sheaths formed around the two single probes may overlap. Application is made of this phenomenon in measuring the thickness of ion sheath in a dark plasma.

§ 1. Introduction

The present paper is concerned with the probe method in the plasma of gaseous discharge. When a negative potential with respect to the potential of surrounding plasma is applied to a double probe which consists of two single probes and which is usually used as floating condition[1),2)], ion sheaths are formed around two probes. And when the absolute value of the negative potential is sufficiently large, these two ion sheaths overlap each other, which can be seen by observing the decrease in ion current which flows to one of these two single probes compared with that when the other probe is floating and no overlap occurs. These phenomena are useful in measuring the ion sheath thickness in a dark plasma.

§ 2. Experiments and Consideration

Fig. 1 illustrates the circuit diagram of the authors' experiments. P_1 and P_2 are two single probes fixed in parallel. They are made of W rods and are of the same size (radius; $r_p=0.25$ mm, length; $l=5$ mm). Ip_1 and Ip_2 are the ion currents flowing to P_1 and P_2 respectively. In Fig. 2, Ip_1 and Ip_2 are plotted against Vp_1 by using Vp_2 as parameter. Among those curves, the character of Ip_1, when Vp_2 is floating potential, is the normal ion current characteristic of a single probe. Compared with it, we can see that Vp_2 is capable of decreasing Ip_1 when it is high negative. We can also see that Vp_1 affects Ip_2. These phenomena are thought to be the effects of the overlapping of the two ion sheaths.

Let Fig. 3 represent the perpendicular cross section of the ion sheaths when they overlap.

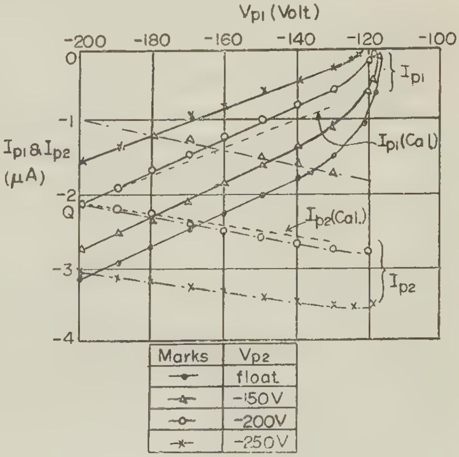

Fig. 2. Ip_1 and Ip_2 plotted against Vp_1. Anode current (I_a) is 2 ma.

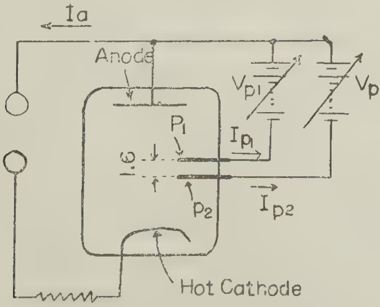

Fig. 1. The circuit diagram of the experiments. The test tube is filled with argon gas (21mmHg).

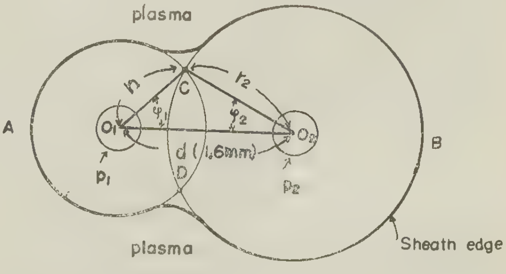

Fig. 3. The cross section of the overlapped ion sheaths.

In the figure, r_1 and r_2 are the radii of two ion sheaths when they are independent of each other, and C & D are the intersection of the two circles. The cross section of the overlapped ion sheaths is thought to be guitar-shaped, as shown by a solid line. Ions reaching the sheath edge by random motion flow to P_1 or P_2 according to boundary conditions. It is very difficult, however, to calculate the ratio Ip_2/Ip_1 accurately. Here, the authors assume the following as the first order approximation:

$$\frac{Ip_2}{Ip_1}=\frac{\text{length of arc } \overset{\frown}{\text{CBD}}}{\text{length of arc } \overset{\frown}{\text{CAD}}}=\frac{r_2(1-\varphi_2/\pi)}{r_1(1-\varphi_1/\pi)} \tag{1}$$

where

$$\left.\begin{aligned}\varphi_1&=\cos^{-1}\{(d^2+r_1^2-r_2^2)/(2dr_1)\}\\ \varphi_2&=\cos^{-1}\{(d^2+r_2^2-r_1^2)/(2dr_2)\}\end{aligned}\right\} \tag{2}$$

Now we shall check this assumption. The relation of r_1 to (Vp_1-V_s) where V_s is the space potential of the surrounding plasma in the case of a cylindrical probe and short mean free path was calculated by Kobayashi and Watanabe[3]. Using their results, we can calculate r_1 and r_2 as the function of Vp_1 and Vp_2 after determining V_s by the conventional single probe method. By putting these results in Eqs. (1) and (2), Ip_2/Ip_1 can be obtained. The broken lines shown in Fig. 2 are plotted by using the results of these calculations when Vp_2 is -200 Volts, the absolute value being adjusted so that both experimental and theoretical curves might agree at Q (where $Vp_1=Vp_2$). It can be said that the agreement is good in spite of rough approximation. The discrepancy is probably due to the potential difference between P_1 and P_2 which affects the path of ions and causes the drift current between them.

§ 3. Measurement of the Thickness of Ion Sheath

These results can be applied in measuring the thickness of an ion sheath. Owing to the above-mentioned considerations, the error of the calculation is considered to be minimum when $Vp_1=Vp_2$. So the authors made use of this case. First, P_1 and P_2 were directly connected and $Ip_1+Ip_2\,(=2Ip_1)$ was measured as $2Ip_1\,(\mathrm{D})$ at a certain negative value of Vp_1. Next, P_2 was put in the floating conditions. The sheath radius of the floating probe P_2 was so small as not to overlap with P_1. So P_1 behaved as a single probe. Vp_1 was kept unchanged. Under these conditions, Ip_1 was read as $Ip_1\,(\mathrm{S})$. Then, by the authors' assumption

$$M\equiv\frac{Ip_1(\mathrm{D})}{Ip_1(\mathrm{S})}=\frac{\pi-\varphi_1}{\pi}=1-\frac{1}{\pi}\cos^{-1}\left(\frac{d}{2r_1}\right) \tag{3}$$

or

$$r_1=\frac{d}{2\cos\{\pi(1-M)\}}\,. \tag{4}$$

By this method $r_1\,(=r_2)$ can be measured as the function of $Vp'\,(=Vp-V_s)$ as plotted in Fig. 4 in which it is stated that the following relation holds:

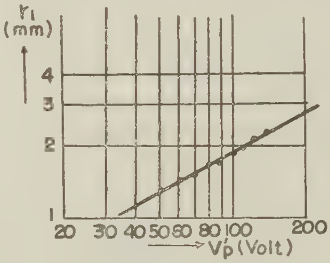

Fig. 4. Vp' vs. r_1.

$$r_1\propto(Vp')^{0.56}\,. \tag{5}$$

According to Kobayashi and Watanabe's calculation[3]

$$r_1\propto(Vp')^{0.6}\,. \tag{6}$$

The agreement is almost satisfactory.

Throughout these discussions, the authors assumed that the disturbance in the plasma condition by the ion sheath could be neglected.

§ 4. Conclusions and Acknowledgement

In the probe method, the measurement of the ion sheath thickness is an important mean to determine the ion density, because the sheath radius becomes an effective probe radius for ion collection. The shortcoming of this method is that it is practically useful only within the range of $0.5d<r_1<1.5d$, though the upper limit is not critical. So, we have to make use of the double probe whose d is adjustable when a previous estimation of r_1 is impossible. This may be troublesome, but it is the only mean to measure the thickness of the ion sheath in a dark plasma.

The authors wish to express their sincere thanks to Prof. Watanabe who directed the

work.

Excitation of Oscillations in a Plasma Layer

By Masao SUMI
Electrical Communication Laboratory
Musashino-shi, Tokyo, Japan

(Received April 30, 1959)

Theory of excitation of standing waves in a uniform plasma layer by an injected electron beam is presented. Various characteristics of excited waves are investigated; in particular, discontinuous jumps of frequency and mode can be expected with the variation of electron density, layer thickness and beam voltage. The consequences of the theory are compared with experimental results. It is seen that observed phenomena concerning standing plasma waves are satisfactorily illustrated in a quite natural way.

§1. Introduction

During the last thirty years a number of experiments on electron plasma oscillations have been performed in gaseous discharges. In recent years, particularly, various aspects of oscillation phenomena have been made clear in several observations.1)~5) These oscillations can be considered as arising from the interaction of an electron beam with a group of electrons in a medium plasma. The electron beam may be either emitted from a cathode in such a way as to create electrons in the medium by ionization or shot into the medium plasma from another source. Among observations quoted above, spatially growing plasma waves5) belong to a sort of double-stream amplification and have already been discussed in some detail by the author in a preceding paper.6) In the other works Wehner1) have successfully explained his results in terms of klystron-like mechanism. However, by means of this mechanism, it seems difficult to account for other experimental results as will be shown later. Therefore the range of validity of klystron-like mechanism remains still unestablished. In some observations there appeared standing plasma waves2)3) and in others much more complicated phenomena were observed3)4) probably in connection with the density gradient, for which reasonable explanations have not yet been given.

Recently the author has developed the more detailed theory of excited plasma waves,7) in which oscillations in a plasma layer bounded by thin sheaths have also been discussed.

The purpose of this paper is first to describe theoretical behaviours of standing plasma waves by use of a simple model of beam-excitation of oscillations in a uniform plasma layer and second to show that the consequences thus obtained are able to well-illustrate several phenomena characteristic of excited standing waves. Effects due to the non-uniformity of electron density will not be taken into account in this article.

§2. Theoretical Basis

As the details have been presented in the previous work,7) we shall describe here only the outline and the consequences of our theory. Basic equations are the Boltzmann equation for the distribution function of electron-velocity and the Poisson equation satisfied by an electric field in the plasma. The effect of short-range collisions for oscillating parts is neglected and that of long-range collisions is supposed to be included in the fluctuating electric field, as was earlier done by Vlasov.[8] These equations are linearized and solved by means of Fourier-Laplace transform method. Taking a Maxwellian velocity distribution function for the medium electrons and a single velocity one for the electron beam, we get the following dispersion relation

$$\left(\frac{\omega}{\omega_p}\right)^2=1+\frac{3}{2\beta^2}+\frac{15}{4\beta^4}\cdots+\sigma\frac{\beta^2}{(\xi-\beta)^2}, \quad (1)$$

where $\beta=\omega/ku_T$, $\xi=u_b/ku_T$, $\omega^2{}_p=n_pe^2/m\epsilon_0$ and $\sigma=n_b/n_p$. u_b and n_b denote the velocity and the number density of the beam respectively, while $u_T=(2\kappa T/m)^{1/2}$ and n_p are the thermal velocity and the number density of electrons in the plasma respectively. The relation (1) is obtained without any ambiguity by use of an approximation for $|\beta|\gg1$. Although similar dispersion relations have been derived and discussed to some extent by several authors,[9)-11)] more exact and detailed characteristics are needed for our purpose. Then Eq. (1) is solved for an excited wave, where $\mathrm{Im}(\omega)=\gamma>0$, a complex frequency being written as $\omega=\omega_0+i\gamma$. Each wave component builds up proportionally to $exp(\gamma t)\,exp[i(kx-\omega_0t)]$ from a ground level of initial disturbance, that is, a thermal fluctuating level. Except for very small values of σ ($\lesssim10^{-3}$), Eq. (1) cannot be solved analytically; hence it must be solved numerically for almost all practical cases. The typical case with the density ratio $\sigma=0.1$ is shown in Fig. 1, where the frequency ω_0 and the wave growth-rate γ, both normalized by plasma frequency ω_p, and the ratio of the plasma wave velocity $u_w=\omega_0/k$ to the beam velocity u_b are plotted against the wave number k. These characteristics are found to be not very sensitive to finite values of $\xi^2=(u_b/u_T)^2$, which implies that the effect of change of the beam velocity is not so great. Therefore, for simplicity, we shall consider only the case of $\xi^2\to\infty$ in later discussions. As is shown in Fig. 1, the phase velocity for an excited wave is always smaller than the beam velocity. Then the coupling between the beam and the wave is so strong that the kinetic energy of beam is transfered to the energy of excited wave. Both too fast and too slow waves cannot deprive the beam of enough energy to grow up. As a result, the excited wave has an upper limit of the wave number k, and the rate of wave growth becomes maximum at a value of k almost midway between zero and its critical limit, where the oscillation frequency is slightly lower than the plasma frequency in the medium.

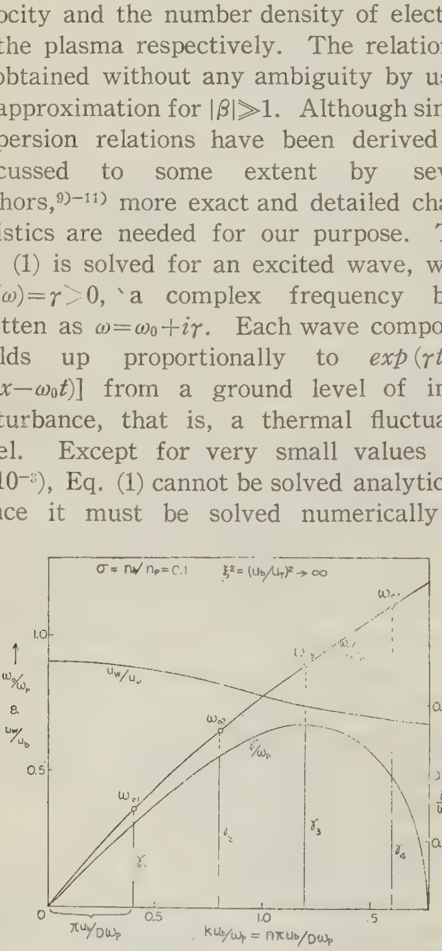

Fig. 1. Typical characteristics of excited waves in a plasma layer with a thickness *D*.

§ 3. Excitation of Standing Waves in a Uniform Plasma Layer[12]*

The theory described in the preceding section is applied to the excitation of a standing wave in a uniform plasma layer with a thickness D. Suppose that the layer is sharply bounded by extremely thin sheaths and that all the electrons in the medium plasma are reflected on both boundaries with negligible energy loss. There exist initially small density fluctuations due to thermal agitation in the layer. In such a disturbance there are wave-components which have wave-numbers and phase velocities appropriate for excitation as shown in the last section. They interact strongly with the beam which passes through the layer, and then receive energy from it. The waves thus excited are reflected on both boundaries, running back and forth. After a while only the waves which satisfy a condition for standing wave survive; Their wavelength λ must satisfy the relation

---

* A short note on this subject is seen in reference 12.

$D=n(\lambda/2)$, D being the layer thickness and n an integer. Then it is only to forward waves that the beam transfers its kinetic energy. On the other hand, backward waves play a role in the feedback of oscillatory energy to forward waves. Thus excited waves should have discrete wave numbers, $k_n=n\pi/D$, which must be less than the upper limit of k-value represented in Fig. 1. Corresponding to each value of k_n, it is possible to excite the wave with the frequency ω_{0n} and the growth rate γ_n as seen also in Fig. 1. Since the oscillatory energy W increases in proportion to $exp\,(2\gamma t)$, the rate of energy transfer from the beam to the plasma wave, $(1/W)\,(dW/dt)$, is proportional to γ. Therefore it may be right to consider γ_n as the relative intensity for each excited wave within the validity of linear approximation. If the transferred energy is not too large and the magnitude of parameter $\pi u_b/D\omega_p$ is not too small, it would be reasonable to suppose that the energy is concentrated exclusively in the mode corresponding to the maximum γ_n among possible modes. For example γ_3 is the maximum in Fig. 1; and therefore the wave with the mode of $n=3$ will be excited.

Now we consider the case when the parameter $\pi u_b/D\omega_p$ changes continuously. Letting it decrease, then in Fig. 1 γ_3 tends to be smaller, while γ_4 becomes larger; the frequency ω_{03} is gradually lowered, exhibiting a frequency-pulling phenomenon. As soon as γ_4 exceeds γ_3, the mode number of the excited plasma wave changes abruptly from $n=3$ to 4. At the same time, its frequency jumps from ω_{03} to ω_{04}. Further decrease of the parameter $\pi u_b/D\omega_p$ causes repeated jumps of wave-mode and frequency as shown in Fig. 2. Corresponding to the variation of magnitude of γ_n, the intensity of excited waves will become comparatively weak near the region where the mode-jumps occur and will attain its maximum almost midway between jumps. Since every combination of changes of the quantities u_b, D and ω_p brings about the variation of the parameter $\pi u_b/\mathrm{D}\omega_p$, yielding the frequency-pulling and the mode and frequency jumps, the pattern represented in Fig. 2 is of great importance for the prediction of various phenomena based on our theory. In the next section we will show how the observed phenomena can be explained on the basis of this pattern.

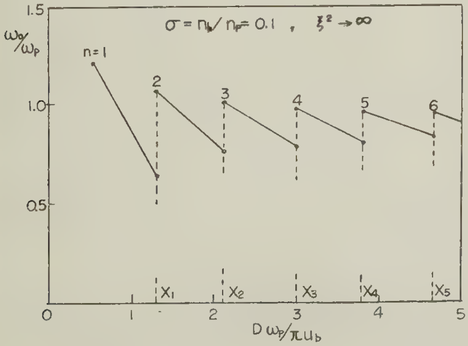

Fig. 2. The pattern of modes and normalized frequencies represented against the parameter $D\omega_p/\pi u_b$.

§ 4. Comparison between Theory and Experiments

In the theoretical pattern presented in Fig. 2, there are three simple cases in which the parameter $\pi u_b/\mathrm{D}\omega_p$ varies.

First is the case where ω_p and u_b hold constant and the thickness of the plasma layer D changes. It has been realized in experiments performed by Looney and Brown[2] and by Bailey and Emeleus[3] (abbreviated hereafter as L–B and B–E respectively). In the former, the existence and several features of a standing plasma wave were established; the successive jumps of frequency and mode were observed as the thickness of plasma sheath was varied. It corresponds to just what is shown in Fig. 2. In spite of the uncertain value of n_b/n_p, it is easy to see a good agreement in order of magnitude between theory and experiment. In the latter paper by B–E, similar phenomena of frequency jumps were displayed as a probe was moved away from the cathode. This can be well illustrated if we suppose that standing waves were excited in the region between the cathode and the probe. The intensity distribution in this case, too, is nicely checked by the theory. However we note that the measured intensity would not be picked up directly from the standing waves, but from the beam modulated proportionally to the intensity of standing waves.

A quantitative agreement will be found by comparing with their typical figure representing the frequency pulling. Denote observed distances from the cathode at which frequency jumps occur as D_n $(n=1, 2, \ldots)$. Assuming $\sigma=n_b/n_p=0.1$ and using the values of ω_p and u_b in their data, theoretical values of D_n are obtained from the relation $D_n\omega_p/\pi u_b=X_n$ where X_n is represented in Fig. 2. The calculated and observed values are listed in Table I, indicating a satisfactory agreement. The differences of them for n greater than 4 would be probably due to either the scattering of beam or the decrease in electron density with the distance away from the cathode.

Table I. The distances from the cathode where the successive mode-jump occurs.

	D_1	D_2	D_3	D_4	D_5
	mm				
cal.	2.0	3.2	4.5	5.7	7.1
obs.	2.1	3.2	5.0	6.4	9.2

Second case is that ω_p is varied, while u_b, D and σ are kept constant. It may be realized when the beam density is changed, the beam voltage being unchanged. Then D and σ may be practically regarded as constant. To see the variation of the frequency ω_0 with the plasma density, it is convenient to reform the pattern in Fig. 2 as that in Fig. 3. Likewise we can get Fig. 4 for $\sigma=1.0$. It is seen that discontinuous transitions of frequency and mode occur repeatedly as the plasma density increases. On each frequency plateau the intensity will become maximum nearly midway, since so behaves γ_n. Furthermore the inclination of frequency plateau is found to vary with the density ratio σ. For $\sigma=1.0$ it is entirely horizontal, but becomes inclined with the decrease of the value of σ.

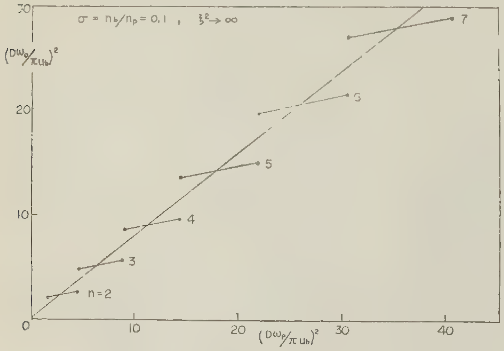

Fig. 3. The pattern of modes and frequencies for $n_b/n_p=0.1$ when the electron density in the medium is varied.

These behaviours of standing wave expected by the theory are qualitatively quite in accord with the results obtained by L–B. From Figs. 3 and 4 we can get calculated values of the centre frequency of each mode, using the observed values of D and u_b. They are compared with the observed centre frequencies in Table II. The calculated values are only slightly greater than the observed. It can be somewhat improved by taking into account of the velocity spread in the beam. Thus the quantitative agreement would also be almost satisfactory.

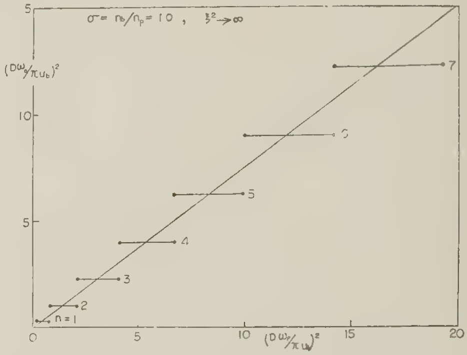

Fig. 4. The pattern of modes and frequencies for $n_b/n_p=1.0$ when the electron density in the medium is varied.

Table II. Centre frequency of each mode.

mode-number n	f_0 (cal.)		f_0 (obs.)
	$\sigma=0.1$	$\sigma=1.0$	
	Gc/s		
2	0.6	0.4	—
3	0.9	0.6	0.6
4	1.2	0.8	0.7
5	1.5	1.0	0.8
6	1.8	1.2	0.9
7	2.1	1.4	1.0

Third is the case where u_b is altered, whereas ω_p and D are unaltered. This can be also expected to give rise to the same phenomena as the first case. However no corresponding experiment has yet been known.

Looney and Brown applied the klystron-like mechanism in order to illustrate their experimental results. In fact Wehner has given an almost satisfactory explanation of his data by the use of this mechanism, in which the beam is velocity-modulated near the sheath-edge of injection side and the energy of this modulation is extracted at the sheath of opposite side, thus yielding the feedback mechanism to the uniformly oscillating medium plasma. Accordingly, the analogy to the klystron is very direct. Here it is to be noted that, for the medium plasma, oscillations do not exist in the intermediate region between sheaths, but only exist at both sheath-edges. In the case by L–B, on the contrary, the situation is somewhat different from Wehner's. It appears that the extraction point by L–B is not always in the region where the energy is actually extracted from the beam. For, the extraction planes calculated by them lie sometimes nearly midway between both sheaths, thus being unable to provide the oscillating energy to the medium plasma.

It was moreover shown by L–B that there was a relation such as $X_s+X_t=$constant, where X_s is the sheath thickness and X_t is the transit distance from the modulation point at the sheath edge to the extraction point. However it is easy to see that this relation can be interpreted in terms of our theory as $X_s+(D/2)=$constant, which has really a definite physical meaning of a half distance between two electrodes.

As a consequence, it may be concluded that the mechanism proposed by the author would be more reasonable for the excitation of standing plasma waves.

§ 5. Discussions

At first we assumed a model of a plasma layer with infinitely thin sheaths. Then it was verified that consequences derived from our theory based on this model could quite naturally explain observed phenomena concerning standing plasma waves. This indicates that the model adopted is very adequate for the present case. In actual cases, however, the sheath thickness is finite, so that electrons in the medium impinging on it are reflected after different penetrations into the sheath according to different electron energies. Hence reflected waves will be more or less distorted. But the distortion would be small if the sheath thickness is much thinner than the wavelength of excited plasma wave. Therefore in most practical cases the sheath thickness may be neglected, enabling the above model to be valid.

It will be interesting for some investigators to discuss a condition for the excitation of millimeter waves. For this, it is first necessary to realize a thin plasma layer with electron density higher than about 10^{13} per cubic centimeter. For the layer thickness of about 1 mm the theory predicts that an injected electron beam of nearly one thousand volts will excite a suitable mode of standing wave. For instance, the beam with 1600 volts will give the mode number of 4 or 5 for the layer of 1 mm in thickness and of 10^{13} in density. The intensity obtainable will increase with the current density of the beam, but is difficult to estimate by the present theory.

It will be the next problems to evaluate the intensity of oscillations as well as the effects due to inhomogeneity in plasmas.

The author is indebted to Professor S. Kojima and Dr. K. Takayama for illuminating discussions, in particular, concerning the comparison with experiments. He is also grateful to Professor T. Kihara for helpful remarks on this manuscript.

High Subsonic Flow past a Wedge in a Two-Dimensional Wind Tunnel at its choked State

By Shigeki MORIOKA

Department of Aeronautics, Faculty of Engineering,
Kyoto University

(Received April 21, 1959)

The two-dimensional high subsonic flow at the choked state past a symmetrical double-wedge profile placed midway between two parallel walls is investigated. The subsonic flow field over the front half of the profile is given by the relaxation solution for a Tricomi's boundary value problem in the hodograph plane. The supersonic flow over the rear half is calculated by the method of characteristics. The results for the pressure distribution and the choking Mach number are found to agree well with Marschner's analytical results over fairly wide range of the transonic parameter.

§ 1. Introduction

The two-dimensional high subsonic flow at the choked state past a symmetrical double-wedge profile placed midway between two parallel walls has been studied analytically by B. W. Marschner1) and Z. Hasimoto.2) Though the problem is rather simple as a boundary value problem for Tricomi's equation, the analyses developed by these writers are fairly complicated and seem to contain some questions. The problem may also be solved numerically by the relaxation method formulated by W. G. Vincenti.3) This method is free from any restriction except for the transonic approximation and gives the data for the whole flow field. Therefore, it may be worth while to reconsider the problem by this method and to check the existing analytical results. The calculation is accomplished for three values of the transonic parameter; –0.703. –0.921, and –1.116. These correspond to the values of the choking Mach number: 0.869, 0.829, and 0.795, respectively, for a special wedge of thickness ratio 0.1. Marschner's parameter ρ_0/ρ_c takes the values 0.159, 0.353, and 0.608 for respective cases. This parameter measures the wall effect and is assumed to be small in Marschner's analysis. In the Appendix, the case of sonic unbounded flow is also treated by the numerical method.

§ 2. Boundary Value Problem and its Reduction to Finite Difference Equation

The flow in the physical plane and its image in the hodograph plane are shown in Figs. 2, 3 and Fig. 1, respectively. (In the following description only the flow in the upper half-plane will be described, since the flow is symmetrical about the chord line.) In this paper are used the same notations as in Ref. 3 except for the definition of the pressure coefficient. As for detailed formulation of the boundary value problem in the hodograph plane, its reduction to finite difference equations, and the transformation to the physical plane, reference may be made also to the cited paper. Here are listed only the relations necessary in the following discussion.

Notations

a^*	critical velocity
c	airfoil chord
H	width of the tunnel
M_0	choking Mach number
p	local pressure
p^*	pressure at the critical speed
t	airfoil thickness
V	local speed of the flow
x, y	Cartesian coordinates in the physical plane
γ	ratio of the specific heats (1.4 for air)
θ	local inclination of the flow relative to the x-axis
θ_w	half vortex-angle of the wedge, $=t/c$
ρ^*	fluid density at critical speed
ψ	stream function
ψ_w	value of ψ on the tunnel wall

Boundary value problem

Fundamental equation:

$$\psi_{\tilde{\eta}\tilde{\eta}}-2\tilde{\eta}\psi_{\tilde{\theta}\tilde{\theta}}=0 \qquad (1)$$

where $\tilde{\eta}=\eta/\eta_0$, $\tilde{\theta}=2^{\frac{1}{2}}\theta/\eta_0^{\frac{3}{2}}$, and

$$\eta=(\gamma+1)^{\frac{1}{3}}(V-a^{*})/a^{*}$$

Boundary conditions:

On basic streamline:

$$\begin{aligned}&\psi=0 \quad \text{for} \quad \tilde{\eta}<-1, \quad \tilde{\theta}=0\\ &\psi=0 \quad \text{for} \quad \tilde{\eta}\leqq 0, \quad \tilde{\theta}=\tilde{\theta}_w \qquad (2)\\ &\psi=0 \quad \text{for} \quad \tilde{\eta}\to-\infty, \quad 0\leqq\tilde{\theta}\leqq\tilde{\theta}_w\end{aligned}$$

On sonic line:

$$\eta_{\tilde{\eta}}(0,\theta)+\frac{2^{\frac{4}{3}}\pi}{3^{\frac{1}{6}}\Gamma^3(\frac{1}{3})}\int_{\tilde{\theta}_w}^{\tilde{\theta}}\frac{\psi_{\tilde{\theta}}(0,\tilde{\theta}')}{(\tilde{\theta}'-\tilde{\theta})^{\frac{3}{2}}}d\tilde{\theta}'=0$$

$$\text{for} \quad \tilde{\eta}=0, \quad 0\leqq\tilde{\theta}\leqq\tilde{\theta}_w \qquad (3)$$

On solid wall:

$$\psi=\psi_w(=1) \quad \text{for} \quad -1<\tilde{\eta}\leqq 0, \quad \tilde{\theta}=0 \qquad (4)$$

Transformation to the physical plane

$$d\left(\frac{x}{c}\right)=\frac{1}{4I_w}(2\tilde{\eta}\psi_{\tilde{\theta}}\,d\tilde{\eta}+\psi_{\tilde{\eta}}\,d\tilde{\theta})$$

$$d\left(\frac{y}{c}\right)=\frac{1}{4I_w}\left\{2\tilde{\theta}_w/(\gamma+1)\left(\frac{t}{c}\right)\right\}^{\frac{1}{3}}d\psi \qquad (5)$$

where

$$I_w=\int_{-\infty}^{0}\tilde{\eta}\psi_{\tilde{\theta}}(\tilde{\eta},\tilde{\theta}_w)d\tilde{\eta}$$

Pressure coefficient and its relation to Marschner's and Vincenti's ones:

$$\begin{aligned}\tilde{c}_p&=(\gamma+1)^{\frac{1}{3}}\left(\frac{t}{c}\right)^{-\frac{2}{3}}(p-p^*)\Big/\frac{1}{2}\rho^*a^{*2}\\ &=[c_p]_{\text{Vincenti}}-2\xi_0 \qquad (6)\\ &=(\gamma+1)^{\frac{1}{3}}[\theta_0{}^{-\frac{2}{3}}c_p]_{\text{Marschner}}\end{aligned}$$

Singular point

In the vicinity of the singular point $\tilde{\eta}=-1$, $\tilde{\theta}=0$ (source type for the present problem) corresponding to the uniform flow, Tricomi's equation can be approximated by Laplace's equation. This gives an approximate solution

$$\psi=\psi_w\left\{1-\frac{1}{\pi}\tan^{-1}\frac{\tilde{\theta}}{2^{\frac{1}{2}}(\tilde{\eta}+1)}\right\} \qquad (7)$$

Then, $d\left(\frac{x}{c}\right)=-\frac{\psi_w}{2^{\frac{1}{2}}\pi I_w}d\left\{\tilde{\eta}-\log(\tilde{\eta}+1)\right\}$ (8)

But, in the present method, the singularity may be represented simply by taking $\psi=\frac{\psi_w}{2}$ at the lattice point $\tilde{\eta}=-1$, $\tilde{\theta}=0$.

§ 3. Hodograph Solution and Flow in the Physical Plane

Fig. 1 shows the hodograph pattern for $\xi_0=-0.921$. Figs. 2 and 3 show the flow in the physical plane for $\xi_0=-0.921$ and -1.116. It may be seen that the patterns of the equi-speed line for both cases are very similar.

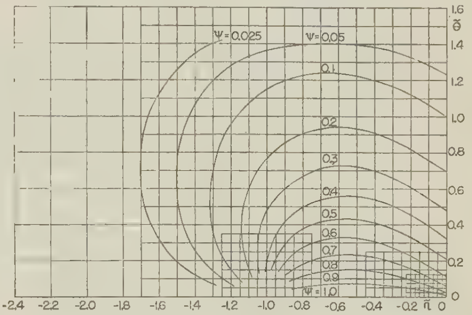

Fig. 1. Distribution of lattice points and stream-lines pattern in $\tilde{\eta}-\tilde{\theta}$ plane ($\xi_0=-0.921$)

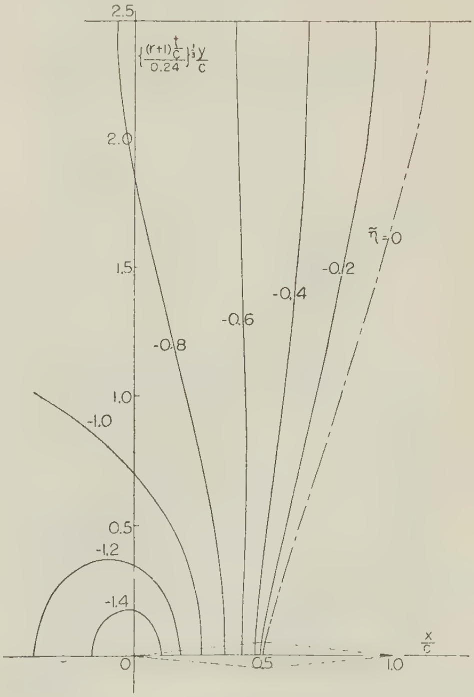

Fig. 2. Equi-speed line and sonic line relative to wedge profile and tunnel wall ($\xi_0=-0.921$)

The change of $\psi_{\tilde{\eta}}$ along the sonic line and the streamline pattern near the origin of the hodograph plane suggest that the shape of the sonic line near the wall is similar to that near the axis of a Laval nozzle, where[2] $\psi\propto\tilde{\theta}^{\frac{1}{3}}$, $\psi_{\tilde{\eta}}\propto\tilde{\theta}^{-\frac{1}{3}}$ along $\tilde{\eta}=0$, and hence $x\propto y^2$, i.e. it is parabolic.

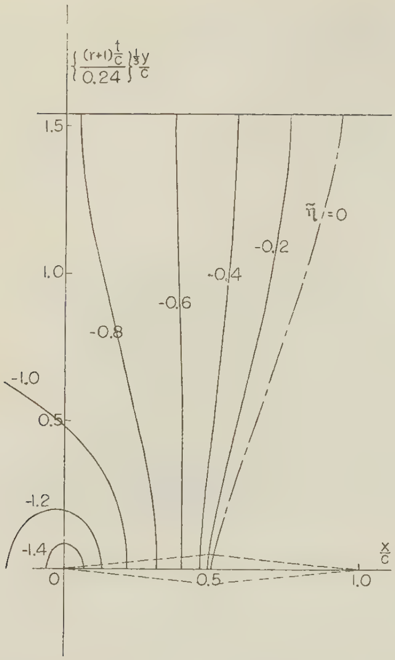

Fig. 3. Equi-speed line and sonic line relative to wedge profile and tunnel wall ($\xi_0=-1.116$)

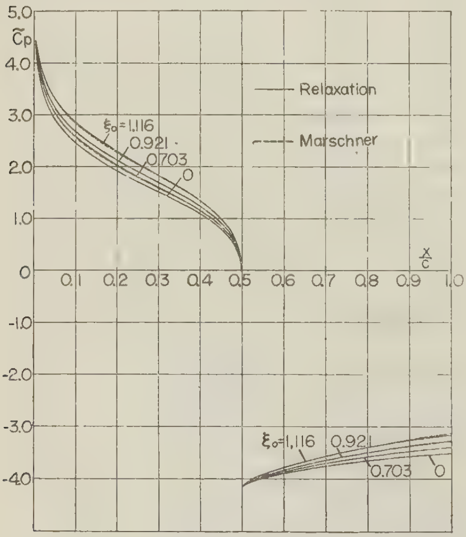

Fig. 4. Chordwise distribution of pressure coefficient.

§ 4. Pressure Coefficient

Fig. 4 shows the distribution of the pressure coefficient on the profile. The dotted line in the figure represents for comparison the result calculated by Marschner's formula. It will be seen that the agreement of the present and analytical results is fairly good even for $\xi_0=-1.116$. In this connection it should be mentioned that Marschner's formula predicts only the difference from the resul for the unbounded sonic flow. As to th latter there exists well known study due t Guderley and Yoshihara.[5] The presen writer has, however, recalculated the sai case also by the relaxation technique. Th details are given in the Appendix of th present paper. The curve for $\xi_0=0$ in Fig 4 shows the result of calculation. As is see in the Appendix, the curve has small bu systematic deviation from Guderley an Yoshihara's one. The cause of discrepanc is not clear to the present writer. In th present paper, however, the numerical one is used as the basis of Marschner's correctio formula, since it gives better agreemen Also it seems preferable in view of the so-called sonic freeze.

§ 5. Choking Mach Number

The values of choking Mach number are plotted in Fig. 5 against the ratio t/H of the airfoil thickness to the width of the tunnel, for the said three values of ξ_0 assuming $t/c=0.1$. The results due to Marschner and to the one-dimensional theory are also plotted for the sake of comparison.

Now, the transonic parameter is usually defined as

$$\xi_0=(\gamma+1)^{\frac13}\left(\frac{V_0}{a^*}-1\right)\left(\frac{t}{c}\right)^{\frac23} \tag{9}$$

where $\frac{V_0}{a^*}=(\gamma+1)^{\frac12}M_0/\{2+(\gamma-1)M_0^2\}^{\frac12}$

Since (M_0-1) is small, this can be approximated by.

$$\xi_0=(M_0^2-1)\Big/\left\{(\gamma+1)\frac{t}{c}\right\}^{\frac23} \tag{10}$$

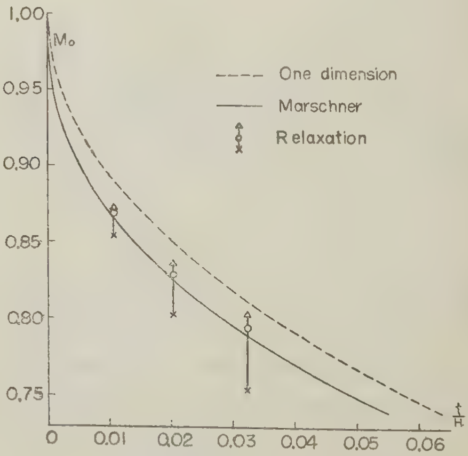

Fig. 5. t/H vs. choking Mach number for $t/c=0.1$

Eqs. (9) and (10) are equivalent within the transonic approximation. There occur, however, numerical difference when we calculate M_0 from these formulas with given γ, ξ_0 and t/c. Small circles in Fig. 5 represent the values as computed by Eq. (9). These are seen to lie near to Marschner's curve. While, Eq. (10) gives the values indicated by crosses in the figure, which suggest fairly lower choking Mach numbers than Marschner's values. On the other hand, the present flow may also be regarded as produced by a normal shock at infinity upstream from a supersonic uniform flow with the transonic parameter $-\xi_0$. Then, evaluating the Mach number of the supersonic flow by Eq. (10), and applying the transonic normal shock condition (symmetric jump in Mach number), we get the values denoted by small deltas in Fig. 5. These values indicate higher values of the choking Mach number. From these results it seems that the determination of the choking Mach number for a given configuration is a delicate problem to the transonic approximation theory.

The writer wishes to express his hearty thanks to Prof. K. Tamada and to Prof. Z. Hasimoto for their encouragement and valuable discussion.

Appendix. *Sonic flow past a wedge profile at zero angle of attack.*

The equations (1) to (6) have been derived by the transformation $\tilde{\eta}=\eta/\eta_0$, $\tilde{\theta}=2^{\frac{1}{3}}\theta/\eta_0^{\frac{3}{2}}$. For the sonic flow, the transformation cannot be used because the upper boundary in the hodograph plane runs away to infinity. In this case, we take the transformation

$$\tilde{\eta}=\tilde{\theta}_w^{\frac{2}{3}}\eta/2^{\frac{1}{3}}\theta_w^{\frac{2}{3}}$$
$$\tilde{\theta}=\tilde{\theta}_w\theta/\theta_w$$

By this transformation, the equations (1) to (6) are invariant in their forms. But, the singular point corresponding to the uniform flow is shifted on the sonic line, i.e. $\tilde{\eta}=0$, $\tilde{\theta}=0$, and the upper boundary in the hodograph plane remains at $\tilde{\theta}=\tilde{\theta}_w$.

As the values of ψ at the lattice points facing the singular point, we take the following

$$\psi=\sum_{m=-\infty}^{\infty}\psi_w$$

where $\psi_m=-f_m/(2f_m^2-\tilde{\eta})^3$

$$f_m^3-\frac{3}{2}\tilde{\eta}f_m+\frac{3}{4}(\tilde{\theta}-2m\tilde{\theta}_w)=0$$

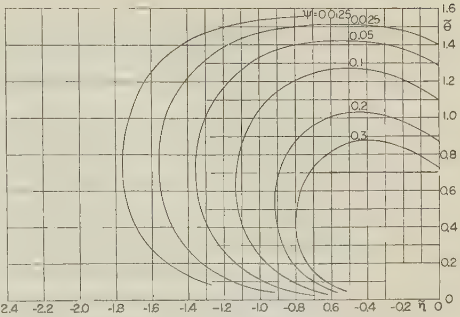

Fig. 6. Distribution of lattice points and streamlines pattern in $\tilde{\eta}-\tilde{\theta}$ plane (sonic unbounded flow).

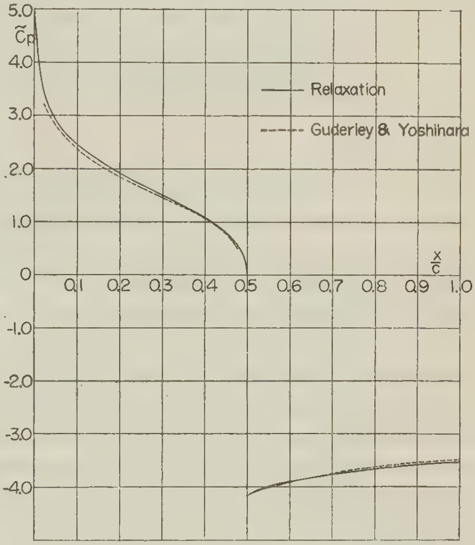

Fig. 7. Distribution of pressure coefficient on wedge profile at sonic unbounded flow.

It can easily be shown that $\psi_m(\tilde{\eta}, \tilde{\theta})$ is a fundamental solution of Eq. (1) representing the sonic uniform flow at infinity in the physical plane. Further, it is obvious that $\psi(\tilde{\eta}, \pm\tilde{\theta}_w)=0$.

Fig. 6 shows the calculated hodograph pattern. In Fig. 7 is given a comparison of the present result and Guderley's one for the distribution of pressure coefficient on the profile.

Rheological Equation of Voigtian Material

By Wataru Segawa

Faculty of Literature and Science, Nihon University, Tokyo

(Received April 11, 1959)

In this paper, the well-known classical one-dimentional rheological equation of Voigtian material having a single retardation time is extended so as to be applicable to three-dimentional and large deformation, and Lagrange's and Euler's representations are explicitly used.

Our rheological equation in Euler's representation is reduced to the most general stress-strain relation which was described by Rivlin and is derived by general procedure using the elastic theory of finite deformation, when its terms relating to viscosity are eliminated, and is reduced to the most general stress-strain rate relation which was derived by Reiner and Rivlin, when its terms relating to elasticity are omitted.

Then, the above equation is applied to simple elongation and simple shear, with satisfactory results.

§ 1. Introduction

It is well known that the theory of hydrodynamics is well expressed by two representations, Lagrange's and Euler's, which are, whether explicitly or not, used also in the theory of finite elastic deformation[1]. But, we can seldom find the theory of viscoelasticity or elastico-viscosity, where the above two representations are explicitly used. In this paper, we will use the two representations explicitly and effectively to derive three-dimentional rheological equation of a Voigtian material.

The most general stress-strain relation in finite elastic deformation can be derived by a general procedure in the elastic theory of finite deformation, and its Euler's representation was described by Rivlin[2], and the most general stress-strain rate relation of isotropic viscous liquid was derived by Reiner[3] and Rivlin[4]. As it is well known, the classical Voigt model[5] having a single retardation time is a parallel combination of a Hookian spring and a Newtonian dashpot. Thus, if we want to seek the three-dimentional extention of the one-dimentional model, we should replace the Hookian spring and the Newtonian dashpot by the spring whose behavior is ruled by the most general stress-strain law and the dashpot whose behavior is ruled by the most general stress-strain rate law, respectively. In other words, the general equation of Voigtian material in Euler's representation should be reduced to Rivlin's equation of the finite elastic deformation if its viscous terms are omitted, and to Reiner-Rivlin's equation if its elastic terms are eliminated. In this article, we will derive such general equations of Voigtian material.

For the simplicity of mathematical description, we will use Einstein's convention throughout this article. We will denote the quantities relating to Lagrange's and Euler's representations by the suffixes of Latin letters (i, j, k etc.) and of Greek letters (λ, μ, ν etc.) respectively.

§ 2. Strain, Strain Rate and Stress

Let us regard a Voigtian material as a system of particles. Let the position of a material point be P for $t=0$ (undeformed state) and P^* for time t (deformed state), and let the coordinates of P and P^* be x^i and x^{*i} ($i=1, 2, 3$), respectively, on a rectangular coordinate system X^i ($i=1, 2, 3$) fixed in space. Then, we have

$$x^{*i}=x^{*i}(x^1, x^2, x^3, t)\,, \quad x^{*i}(x^1, x^2, x^3, 0)=x^i \tag{2.1}$$

or

$$x^i=x^i(x^{*1}, x^{*2}, x^{*3}, t)\,, \quad x^i(x^{*1}, x^{*2}, x^{*3}, 0)=x^{*i} \tag{2.1$'$}$$

where we assume that the function x^{*i} and x^i are one valued and continuous functions and are differentiable by the respective independent variables as many times as necessary. The Lagrange's representation of the strain in P^* is given by

$$\varepsilon_{ij}=\tfrac{1}{2}(g_{ij}-\delta_{ij}) \tag{2.2}$$

where

$$g_{ij}=x^{*k}_{,i}x^{*k}_{,j} \quad (x^{*k}_{,j}=\partial x^{*k}/\partial x^i) \tag{2.2$'$}$$

and δ_{ij} is Kronecker's δ. Then, we have

$$\varepsilon_{ij}=\varepsilon_{ij}(x^1, x^2, x^3, t)\ , \quad \varepsilon_{ij}(x^1, x^2, x^3, 0)=0 \qquad (2.3)$$

The displacement u^k ($k=1, 2, 3$) is defined by

$$x^{*k}-x^k=u^k \qquad (2.4)$$

If we substitute Eq. (2.4) into Eq. (2.2) and Eq. (2.2′), we have

$$\begin{aligned}\varepsilon_{ij}&=\tfrac{1}{2}\{(x^k+u^k)_{,i}(x^k+u^k)_{,j}-\delta_{ij}\}\\ &=\tfrac{1}{2}\{(\delta_{ki}+u^k_{,i})(\delta_{kj}+u^k_{,j})-\delta_{ij}\}\\ &=\tfrac{1}{2}\{\delta_{ij}+u^i_{,j}+u^j_{,i}+u^k_{,i}u^k_{,j}-\delta_{ij}\}\\ &=\tfrac{1}{2}(u^i_{,j}+u^j_{,i}+u^k_{,i}u^k_{,j}) \qquad (2.5)\end{aligned}$$

From Eq. (2.5), we can see that the values of the shearing components of the strain in this paper are one half of the values of the corresponding shearing components of the strain ordinarily used.[1)]

From Eq. (2.3), we can define the strain rate in Lagrange's representation $d\varepsilon_{ij}/dt$. Denoting the strain rate in Euler's representation by $f_{\lambda\mu}$, we have the following relation between $\dot{\varepsilon}_{ij}$ and $f_{\lambda\mu}$:

$$f_{\lambda\mu}=x^i_{,\lambda}\,x^j_{,\mu}\,\dot{\varepsilon}_{ij} \qquad (x^i_{,\lambda}=\partial x^i/\partial x^{*\lambda}) \qquad (2.6)$$

or

$$\dot{\varepsilon}_{ij}=x^{*\lambda}_{,i}\,x^{*\mu}_{,j}\,f_{\lambda\mu} \qquad (2.6')$$

Let the X^λ-component of the velocity $\boldsymbol{v}$ of a material particle in time t be v^λ, then $f_{\lambda\mu}$ is also defined by

$$f_{\lambda\mu}=\tfrac{1}{2}(v^\lambda_{,\mu}+v^\mu_{,\lambda}) \qquad (2.7)$$

as ordinarily done. We can prove that the right hand side of Eq. (2.6) is equivalent to that of Eq. (2.7), as follows:

$$\begin{aligned}&x^i_{,\lambda}\,x^j_{,\mu}d/dt\tfrac{1}{2}(g_{ij}-\delta_{ij})\\ &=x^i_{,\lambda}\,x^j_{,\mu}d/dt\tfrac{1}{2}(x^{*k}_{,i}\,x^{*k}_{,j})\\ &=\tfrac{1}{2}x^i_{,\lambda}\,x^j_{,\mu}(\dot{x}^{*k}_{,j}\,x^{*k}_{,i}+\dot{x}^{*k}_{,i}\,x^{*k}_{,j})\\ &=\tfrac{1}{2}(\dot{x}^{*k}_{,\mu}\,\delta_{k\lambda}+\dot{x}^{*k}_{,\lambda}\,\delta_{k\mu})\\ &=\tfrac{1}{2}(\dot{x}^{*\lambda}_{,\mu}+\dot{x}^{*\mu}_{,\lambda})=\tfrac{1}{2}(v^\lambda_{,\mu}+v^\mu_{,\lambda}) \qquad (2.8)\end{aligned}$$

where we have used following relations:

$$x^{*k}_{,i}\,x^i_{,\lambda}=\frac{\partial x^{*k}}{\partial x^1}\frac{\partial x^1}{\partial x^{*\lambda}}+\frac{\partial x^{*k}}{\partial x^2}\frac{\partial x^2}{\partial x^{*\lambda}}+\frac{\partial x^{*k}}{\partial x^3}\frac{\partial x^3}{\partial x^{*\lambda}}=\delta_{k\lambda}\ , \quad \text{etc.}$$

$$\frac{dx^{*\lambda}}{dt}=v^\lambda\ , \quad \text{etc.}$$

Let the Lagrange's and Euler's representation of stress be σ^{ij} and $T^{\lambda\mu}$ respectively, then we have

$$DT^{\lambda\mu}=x^{*\lambda}_{,i}\,x^{*\mu}_{,j}\,\sigma^{ij} \qquad (2.9)$$

or

$$\sigma^{ij}=D\,x^i_{,\lambda}\,x^j_{,\mu}\,T^{\lambda\mu} \qquad (2.9')$$

where D is the volume magnification ratio. In the sequel, we assume that the above relations can be hold relating to elastic stress and viscous stress, separately. $T^{\lambda\mu}$ is the stress relating to the unit area in deformed state and often called *actual stress*. So-called *conventional stress*, that is, the stress relating to the unit area in undeformed state is not σ^{ij}, but σ^{ij} multiplied by extention ratio in x^i-direction or x^j-direction[1)].

We can define many sets of invariant quantities of strain, strain rate and stress in Lagrange's and Euler's representation, but the followings will be used in this article:

$$I_1^*=\varepsilon_{ii}\ , \quad I_2^*=\tfrac{1}{2}\varepsilon_{ij}\,\varepsilon_{ij}\ , \quad I_3^*=\tfrac{1}{3}\varepsilon_{ij}\,\varepsilon_{jk}\,\varepsilon_{ki} \qquad (2.10)$$

$$I_1=g_{ii}\ , \quad I_2=D^2g^{ii}=D^2g_{\lambda\lambda}'\ ,$$
$$I_3=D^2=\det|g_{ij}|=\det|g'^{\lambda\mu}| \qquad (2.11)$$

where

$$\left\{\begin{aligned}g^{ij}&=x^i_{,\lambda}\,x^j_{,\lambda} &&(2.12)\\ g'_{\lambda\mu}&=x^i_{,\lambda}\,x^i_{,\mu} &&(2.13)\\ g'^{\lambda\mu}&=x^{*\lambda}_{,i}\,x^{*\mu}_{,i} &&(2.14)\end{aligned}\right.$$

$$K_1^*=f_{\lambda\lambda}\ , \quad K_2^*=\tfrac{1}{2}f_{\lambda\mu}f_{\lambda\mu}\ , \quad K_3^*=\tfrac{1}{3}f_{\lambda\mu}f_{\mu\nu}f_{\nu\lambda} \qquad (2.15)$$

§ 3. Derivation of Rheological Equation

Let the free energy of Helmholtz and the dissipation function per unit volume in undeformed state be A and W', respectively, then we have, from the first law of thermodynamics, for isothermal rheological process,

$$\frac{dA}{dt}+W'=\sigma^{ij}\frac{d\varepsilon_{ij}}{dt} \qquad (3.1)$$

Denote the quantities relating to elasticity (spring) and viscosity (dashpot) by the suffixes e and v respectively. Extending the assumptions which hold in one-dimentional Voigt model, we assume that next relations can hold in three-dimentional Voigt model:

$$\sigma^{ij}=\sigma_e^{ij}+\sigma_v^{ij} \qquad (3.2)$$

$$\dot{\varepsilon}_{ij}=\dot{\varepsilon}_{eij}=\dot{\varepsilon}_{vij} \qquad (3.3)$$

Substituting Eq. (3.2) into Eq. (3.1) and taking Eq. (3.3) into account, we obtain

$$dA/dt=\sigma_e^{ij}\,\dot{\varepsilon}_{ij} \qquad (3.4)$$

$$W'=\sigma_v^{ij}\,\dot{\varepsilon}_{ij} \qquad (3.5)$$

i) *elastic stress*

From (3.4), we have

$$\sigma_e^{ij}=\partial A/\partial\varepsilon_{ij} \qquad (3.6)$$

If the body is isotropic in undeformed state ($t=0$), we have

$$A=A(I_1^*, I_2^*, I_3^*) \qquad (3.7)$$

then, we obtain

$$\sigma_e^{ij}=\frac{\partial A}{\partial I_1^*}\delta_{ij}+\frac{\partial A}{\partial I_2^*}\varepsilon_{ij}+\frac{\partial A}{\partial I_3^*}\varepsilon_{ik}\,\varepsilon_{kj} \tag{3.8}$$

Further, if the body is incompressible, we have

$$D=1$$

then, we have

$$\partial D/\partial\varepsilon_{ij}=D^2g^{ij}=g^{ij} \tag{3.9}$$

where g^{ij} is defined by (2.12). Let the undetermined multiplier be φ', then we have, using Eq. (3.8) and Eq. (3.9), and taking $\partial A/\partial I_3^*=1$ into account,

$$\sigma_e^{ij}=\varphi' g^{ij}+\frac{\partial A}{\partial I_1^*}\delta_{ij}+\frac{\partial A}{\partial I_2^*}\varepsilon_{ij} \tag{3.10}$$

Then, if we put as follows:

$$\begin{aligned}\varphi'&=\varphi+\frac{1}{2}(2I_1^*-4I_2^*+4I_1^*+3)\frac{\partial A}{\partial I_1^*}\\&=\varphi+\frac{1}{2}I_2\frac{\partial A}{\partial I_1^*}\end{aligned}$$

where I_2 is defined by (2.11), Eq. (3.10) can be rewritten as follows:

$$\sigma_e^{ij}=\left(\varphi+\frac{1}{2}I_2\frac{\partial A}{\partial I_1^*}\right)g^{ij}+\frac{\partial A}{\partial I_1^*}\delta_{ij}+\frac{\partial A}{\partial I_2^*}\varepsilon_{ij} \tag{3.11}$$

If we apply Eq. (2.9) to elastic stress, we have

$$DT_e^{\lambda\mu}=x^{*\lambda}{}_{,i}\,x^{*\mu}{}_{,j}\,\sigma_e^{ij} \tag{3.12}$$

Substituting Eq. (3.8) and Eq. (3.11) into Eq. (3.12), we have following equations.[7]

$$\begin{aligned}T_e^{\lambda\mu}=\frac{2}{D}\Big\{&g'^{\lambda\mu}\frac{\partial A}{\partial I_1}(g'^{\nu\nu}g'^{\lambda\mu}-g'^{\nu\lambda}g'^{\nu\mu}-I_2\delta_{\lambda\mu})\\&\cdot\frac{\partial A}{\partial I_2}+I_2\delta_{\lambda\mu}\frac{\partial A}{\partial I_2}+I_3\delta_{\lambda\mu}\frac{\partial A}{\partial I_3}\Big\}\end{aligned} \tag{3.13}$$

and

$$\begin{aligned}T_e^{\lambda\mu}=2\Big\{&g'^{\lambda\mu}\frac{\partial A}{\partial I_1}+(g'^{\nu\nu}g'^{\lambda\mu}-g'^{\nu\lambda}g'^{\nu\mu}-I_2\,\delta_{\lambda\mu})\\&\cdot\frac{\partial A}{\partial I_2}+\varphi\,\delta_{\lambda\mu}\Big\}\end{aligned} \tag{3.14}$$

respectively, where I_1, I_2, and I_3 are defined by (2.11) and $g'^{\lambda\mu}$ is defined by Eq. (2.14).

ii) *viscous stress*

If we apply Eq. (2.9′) for viscous stress, we have

$$\sigma_v^{ij}=D\,x^i{}_{,\lambda}\,x^j{}_{,\mu}\,T_v^{\lambda\mu} \tag{3.15}$$

substituting Eq. (2.6′) and Eq. (3.15) into Eq. (3.5), we have

$$W'=D\,T_v^{\lambda\mu}f_{\lambda\mu} \tag{3.16}$$

Let the dissipation function relating to deformed state be W, then we have

$$DW=W' \tag{3.17}$$

From Eq. (3.16) and Eq. (3.17), we have

$$W=T_v^{\lambda\mu}f_{\lambda\mu} \tag{3.18}$$

If we assume that the process of viscous flow does not yield anisotropy, then we have

$$W=W(K_1^*,K_2^*,K_3^*) \tag{3.19}$$

moreover, if we assume that W can be expanded as the power series of K_1^*, K_2^* and K_3^*, we have (using Einstein's notation)

$$\begin{aligned}W&=a_i\,K_i^*+b_{ij}\,K_i^*\,K_j^*+c_{ijk}\,K_i^*\,K_j^*\,K_k^*+\cdots\\&=a_1\,K_1^*+b_{1j}K_1^*\,K_j^*+c_{1jk}\,K_1^*\,K_j^*\,K_k^*+\cdots\\&\quad+a_2\,K_2^*+b_{2j}\,K_2^*\,K_j^*+c_{2jk}\,K_2^*\,K_j^*K_k^*+\cdots\\&\quad+a_3\,K_3^*+b_{3j}\,K_3^*\,K_j^*+c_{3jk}\,K_3^*\,K_j^*K_k^*+\cdots\\&=(a_1+b_{1j}\,K_j^*+c_{1jk}\,K_j^*\,K_k^*+\cdots\cdot)K_1^*\\&\quad+(a_2+b_{2j}\,K_j^*+c_{2jk}\,K_j^*\,K_k^*+\cdots\cdot)K_2^*\\&\quad+(a_3+b_{3j}\,K_j^*+c_{3jk}\,K_j^*\,K_k^*+\cdots\cdot)K_3^*\end{aligned}$$

Putting as follows:

$$\begin{aligned}\eta_1&=a_1+b_{1j}\,K_j^*+c_{1jk}\,K_j^*\,K_k^*+\cdots\cdot\\2\eta_2&=a_2+b_{2j}\,K_j^*+c_{2jk}\,K_j^*\,K_k^*+\cdots\cdot\\3\eta_3&=a_3+b_{3j}\,K_j^*+c_{3jk}\,K_j^*\,K_k^*+\cdots\cdot\end{aligned}$$

we have

$$W=\eta_1\,K_1^*+2\eta_2\,K_2^*+3\eta_3\,K_3^* \tag{3.20}$$

(As $W\geqq 0$ always, some of the coefficients $a_i, b_{ij}, c_{ijk}, \cdots$, $(i, j, k=1, 2, 3)$ will become zero.) From Eq. (3.18) and Eq. (3.20), taking Eq. (2.15) into account, we have

$$T_v^{\lambda\mu}=\eta_1\,\delta_{\lambda\mu}+\eta_2\,f_{\lambda\mu}+\eta_3\,f_{\lambda\nu}f_{\nu\mu} \tag{3.21}$$

where η_1, η_2, and η_3 are functions of K_1^*, K_2^*, and K_3^*. If incompressible, $K_1^*=\operatorname{div}\boldsymbol{v}=0$, then η_2 and η_3 will become the function of K_2^* and K_3^*, and η_1 will become arbitrary hydrostatic pressure. Then, if we rewrite K_2^* and K_3^* by K_2 and K_3 which are strain rate invariants ordinarily used, we can obtain the equation of Reiner and Rivlin.

The Euler's representation of Eq. (3.2) is expressed by

$$T^{\lambda\mu}=T_e^{\lambda\mu}+T_v^{\lambda\mu} \tag{3.22}$$

From Eq. (3.13), Eq. (3.14), Eq. (3.21) and Eq. (3.22), we can obtain the rheological equations of Voigtian material which is isotropic in undeformed state as follows (filing $\eta_1\,\delta_{\lambda\mu}$ into $\varphi\delta_{\lambda\mu}$ in Eq. (3.24)):

$$\begin{aligned}T^{\lambda\mu}=\frac{2}{D}\Big\{&g'^{\lambda\mu}\frac{\partial A}{\partial I_1}+(g'^{\nu\nu}g'^{\lambda\mu}-g'^{\nu\lambda}g'^{\nu\mu}-I_2\,\delta_{\lambda\mu})\\&\cdot\frac{\partial A}{\partial I_2}+I_2\,\delta_{\lambda\mu}\frac{\partial A}{\partial I_2}+I_3\,\delta_{\lambda\mu}\frac{\partial A}{\partial I_3}\Big\}\\&+\eta_1\,\delta_{\lambda\mu}+\eta_2\,f_{\lambda\mu}+\eta_3\,f_{\lambda\nu}f_{\nu\mu}\end{aligned} \tag{3.23}$$

for a compressible material, and

$$T^{\lambda\mu}=2\left\{g'^{\lambda\mu}\frac{\partial A}{\partial I_1}+(g'^{\nu\nu}\,g'^{\lambda\mu}-g'^{\nu\lambda}\,g'^{\nu\mu}\right.$$
$$\left.-I_2\,\delta_{\lambda\mu})\frac{\partial A}{\partial I_2}\right\}+\varphi\,\delta_{\lambda\mu}+\eta_2 f_{\lambda\mu}+\eta_3 f_{\lambda\nu}f_{\nu\mu} \quad (3.24)$$

for an incompressible material.

§ 4. Simple Elongation

Let us consider uniform elongation of incompressible rod-like material which is homogeneous and initially isotropic, in the direction of its length, which we select as the direction of X^1-axis. This deformation is specified by

$$x^{*1}=\alpha x^1\,,\quad x^{*2}=\frac{1}{\sqrt{\alpha}}x^2\,,\quad x^{*3}=\frac{1}{\sqrt{\alpha}}x^3\,,\qquad \alpha=\alpha(t) \quad (4.1)$$

or

$$x^1=\frac{1}{\alpha}x^{*1}\,,\quad x^2=\sqrt{\alpha}\,x^{*2}\,,\quad x^3=\sqrt{\alpha}\,x^{*3}\,,\qquad \alpha=\alpha(t) \quad (4.2)$$

where α is an extention ratio, and

$$T^{22}=T^{33}\,,\quad T^{12}=T^{23}=T^{31}=0 \quad (4.3)$$

Substituting (4.1) into (2.14), we have

$$g'^{11}=\alpha^2\,,\quad g'^{22}=g'^{33}=1/\alpha\,,\quad \text{all others}=0 \quad (4.4)$$

From the second equation of (2.11), (2.12) and (4.2), we have

$$I_2=g^{11}+g^{22}+g^{33}=\frac{1}{\alpha^2}+2\alpha \quad (4.5)$$

From (4.1) and (4.2), we have

$$\left.\begin{aligned} v^1&=\frac{dx^{*1}}{dt}=\dot\alpha\,x^1=\frac{\dot\alpha}{\alpha}x^{*1}\\ v^2&=\frac{dx^{*2}}{dt}=-\frac{1}{2}\alpha^{-3/2}\dot\alpha\,x^2=-\frac{1}{2}\frac{\dot\alpha}{\alpha}x^{*2}\\ v^3&=-\frac{1}{2}\frac{\dot\alpha}{\alpha}x^{*3}\end{aligned}\right\} \quad (4.6)$$

Then, if we substitute (4.6) into (2.7), we have

$$f_{11}=\frac{\dot\alpha}{\alpha}\,,\quad f_{22}=f_{33}=-\frac{1}{2}\frac{\dot\alpha}{\alpha}\,,\quad \text{all others}=0 \quad (4.7)$$

If we substitute (4.3), (4.4), (4.5) and (4.7) into (3.24), we have

$$\left.\begin{aligned} T^{11}&=2\left\{\alpha^2\frac{\partial A}{\partial I_1}+\left(-\frac{1}{\alpha^2}\right)\frac{\partial A}{\partial I_2}\right\}\\ &\qquad+\varphi+\eta_2\frac{\dot\alpha}{\alpha}+\eta_3\left(\frac{\dot\alpha}{\alpha}\right)^2\\ 0\;&=2\left\{\frac{1}{\alpha}\frac{\partial A}{\partial I_1}+(-\alpha)\frac{\partial A}{\partial I_2}\right\}\\ &\qquad+\varphi+\eta_2\left(-\frac{1}{2}\frac{\dot\alpha}{\alpha}\right)+\eta_3\left(-\frac{1}{2}\frac{\dot\alpha}{\alpha}\right)^2\end{aligned}\right\} \quad (4.8)$$

From (4.8), we have

$$T^{11}=2\left(\alpha^2-\frac{1}{\alpha}\right)\left(\frac{\partial A}{\partial I_1}+\frac{1}{2}\frac{\partial A}{\partial I_2}\right)+\frac{3}{2}\eta_2\frac{\dot\alpha}{\alpha}+\frac{5}{4}\eta_3\frac{\dot\alpha^2}{\alpha^2} \quad (4.9)$$

According to Neo-Hookian theory of rubber elasticity,

$$A=\frac{1}{2}\mu(I_1-3)$$

then, we have

$$\frac{\partial A}{\partial I_1}=\frac{1}{2}\mu\,,\qquad \frac{\partial A}{\partial I_2}=0$$

Corresponding to the above relations, if we assume as follows:

$$\tfrac{1}{2}\eta_2=\eta=\text{const}\,,\quad \eta_3=0$$

then (4.9) becomes

$$T^{11}=\mu\left(\alpha^2-\frac{1}{\alpha}\right)+3\eta\frac{\dot\alpha}{\alpha} \quad (4.10)$$

If we put as follows:

$$\alpha=1+\varepsilon$$

then (4.10) becomes

$$T^{11}=\mu\{(1+\varepsilon)^2-(1+\varepsilon)^{-1}\}+3\eta\frac{\dot\varepsilon}{1+\varepsilon}$$
$$=3\mu\,\varepsilon\left(1+\frac{\varepsilon^2}{3}-\frac{\varepsilon^4}{3}+\cdots\cdots\right)+3\eta\frac{\dot\varepsilon}{1+\varepsilon}$$

If $\varepsilon\ll 1$ and terms of higher orders of ε can be neglected, the above equation becomes

$$T^{11}=3\mu\,\varepsilon+3\eta\,\dot\varepsilon \quad (4.11)$$

which is equivalent to the classical equation of Voigt model.

§ 5. Simple Shear

Let us consider incompressible simple shearing flow parallel to the X^1X^3-plane. This motion is specified by

$$x^{*1}=x^1+kx^2\,,\quad x^{*2}=x^2\,,\quad x^{*3}=x^3\,,\quad k=k(t) \quad (5.1)$$

or

$$x^1=x^{*1}-kx^{*2}\,,\quad x^2=x^{*2}\,,\quad x^3=x^{*3}\,,\quad k=k(t) \tag{5.2}$$

where $\frac{1}{2}\dot{k}$ is the shear velocity.

Substituting (5.1) into (2.14), we have

$$\left.\begin{aligned} &g'^{11}=1+k^2\,,\quad g'^{22}=1\,,\quad g'^{33}=1\\ &g'^{12}=k\,,\qquad g'^{23}=g'^{31}=0 \end{aligned}\right\} \tag{5.3}$$

and from the second equation of (2.11), (2.12) and (5.2) we have

$$I_2=g^{11}+g^{22}+g^{33}=k^2+3 \tag{5.4}$$

Differentiating (5.1) with respect to time t and taking (5.2) into account, we obtain

$$v^1=\dot{k}\,x^{*2}\,,\quad v^2=v^3=0 \tag{5.5}$$

Substituting (5.5) into (2.7), we have

$$f_{12}=\tfrac{1}{2}\dot{k}\,,\quad \text{all others}=0 \tag{5.6}$$

And substituting (5.3), (5.4) and (5.6) into (3.24), we can obtain

$$\left.\begin{aligned} &T^{11}=2\left\{(1+k^2)\frac{\partial A}{\partial I_1}-\frac{\partial A}{\partial I_2}\right\}+\varphi+\eta_3\left(\frac{1}{2}\dot{k}\right)^2\\ &T^{22}=2\left\{\frac{\partial A}{\partial I_1}-(k^2+1)\frac{\partial A}{\partial I_2}\right\}+\varphi+\eta_3\left(\frac{1}{2}\dot{k}\right)^2\\ &T^{33}=2\left(\frac{\partial A}{\partial I_1}-\frac{\partial A}{\partial I_2}\right)+\varphi\\ &T^{12}=2\left(k\frac{\partial A}{\partial I_1}+k\,\frac{\partial A}{\partial I_2}\right)+\eta_2\left(\frac{1}{2}\dot{k}\right)\\ &T^{23}=T^{31}=0 \end{aligned}\right\} \tag{5.7}$$

Then, if we assume that $T^{33}=0$, we obtain

$$\left.\begin{aligned} &T^{11}=2k^2\frac{\partial A}{\partial I_1}+\eta_3\left(\frac{1}{2}\dot{k}\right)^2\\ &T^{22}=-2k^2\frac{\partial A}{\partial I_2}+\eta_3\left(\frac{1}{2}\dot{k}\right)^2\\ &T^{12}=2k\left(\frac{\partial A}{\partial I_1}+\frac{\partial A}{\partial I_2}\right)+\eta_2\left(\frac{1}{2}\dot{k}\right)\\ &\text{all others}=0 \end{aligned}\right\} \tag{5.8}$$

We can see, from (5.8) that there appears so-called second-order effects (Poynting effect and cross viscosity,) and the third equation of (5.8) will be reduced to the corresponding classical equation if appropriate approximations similar as in § 4 are done.

§ 6. Discussions

We have assumed isotropy of the material in undeformed state, when we derive elastic stress-strain relation in § 3. This assumption does not mean that the material must be isotropic always, in other words, the material may become anisotropic in the process of elastic large deformation even if it is isotropic in its initial state. (Such material may be called *quasi-isotropic material.*[6]) At the same time, we have assumed that the process of viscous flow will not yield any anisotropy. Moreover, we assume that the above-mentioned two assumptions are not inconsistent with each other. In the actual process of deformation of our Voigtian material, both elastic and viscous process take place at the same time, and the material which is isotropic in initial state will become anisotropic as the deformation proceeds.

As far as we stay in the Voigt model having single retardation time, our rheological equations, Eq. (3.23) and Eq. (3.24), seem to be the most general possible equations under the assumptions of isotropy as above and the others mentioned in § 3. As we have already mentioned, their elastic terms are equivalent to the corresponding terms in Rivlin's equation of large elastic deformation, and their viscous terms to those in Reiner-Rivlin's equation. The results of application of Eq. (3.24) to simple deformations are reasonable and satisfactory, as we have seen in § 4 and § 5. Eq. (3.23) and Eq. (3.24) are given in Euler's representation but, if necessary, we can derive their Lagrange's representation by virtue of Eq. (2.9′).

Surface Cracks of Sheet Glass Produced by Sodium Vapor Treatment

By Junn NAKAYAMA

Ceramic Division,
Research Laboratory of Asahi Glass Co., Yokohama

(Received April 28, 1959)

Observation was made on the surface cracks of soda-lime-silica sheet glass produced by sodium vapor treatment in vacuum at 350°C. It was suggested first by Andrade and Tsien and recently concluded by Gordon *et al* that these surface cracks are developed from latent Griffith cracks through some etching action (the so-called decoration by Gordon *et al*) of sodium vapor. According to the present experiment, there are several phenomena on the surface cracks which are difficult to explain by the latent crack theory. The correlations of surface cracks to the drawing mark or to the direction of the periphery of the specimen, for instance, can be more reasonably explained by the cracking mechanism due to the shrinkage of transmuted surface layers after the sodium vapor attack. In this connection, it should rather be prefered that the surface cracks are newly originated by the treatment.

§1. Introduction

It has been known that the treatment of a piece of glass by sodium vapor in vacuum at high temperatures produces visible cracks on the surface. This was first reported by Andrade and Tsien¹⁾, who considered that the cracks were developed from the latent cracks, the so-called Griffith cracks²⁾, through the *etching* action of sodium vapor. Levengood and Butler³⁾ also seem to insist the presence of the latent cracks in their experiment on the adhesive strength of glue to glass surface and show the surface cracks produced by the sodium treatment. Recently Gordon *et al*⁴⁾ have published a work with conclusion similar to that made by Andrade and Tsien.

We have reached, however, to the conclusion different with the previous workers'. According to the present experiment, it is believed that the cracks are mostly not developed from latent cracks but newly created by the sodium treatment. The mechanism of the formation of these cracks might be attributed to the contraction of sodium treated surface layer against mother glass in the process of cooling after heating at 350°C.

§2. Experimental Procedures

The method for making the surface cracks is similar to that of Levengood and Butler, with some small modifications. Specimen container in which the reaction takes place is an ordinary glass tube, 2 to 3 cm in diameter and about 20 cm in length, with a "neck" as shown in Fig. 1. The specimens are cut from soda-lime-silica sheet glass of 2, 3 and 5 mm thicknesses, and a rod of 5 mm diameter of fused quartz is added for com-

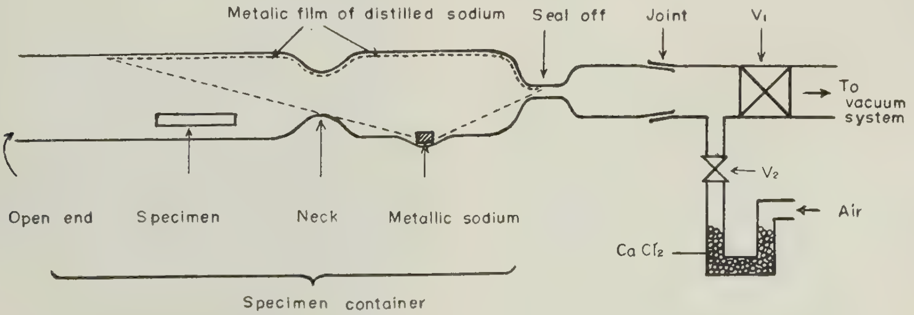

Fig. 1. Schematic diagram of the apparatus.

parison. Details of the procedure are as follows:

1) The specimen (*ca.* $1\times2\,\mathrm{cm}^2$) is cleaned by soaking with soap and distilled water.
2) The container is attached to the vacuum system with the valve V_1 closed and V_2 opened.
3) The dried air is kept to pass through the container from V_2 to the "open end" while the whole container is heated by a hand burner for about one minute to remove the adsorbed water from the inner surface.
4) After the container has been cooled down to the room temperature, a metallic sodium cube with edges of 5 to 10 mm length is inserted into the hollow of the tube from the "open end" without wiping off the kerosene which has protected the metallic sodium during storation.
5) The "open end" is sealed after the specimen is set in the container.
6) The valve V_2 is closed and V_1 is opened to evacuate the container to 1×10^{-3} mm Hg. In this process the kerosene vaporizes and is removed from the surface of sodium.
7) By heating the hollow in which the sodium block is located whole sodium melts and gradually evaporates to make a mirror of metallic sodium on the inner surface of the container. The neck in the tube protects the specimen from a direct deposition of metallic sodium on it.
8) When the vacuum reaches to 1×10^{-4}mm Hg, the container is sealed off from the the vacuum system.
9) The container is heated in an electric furnace and kept at 350°C for one hour or more. In this process, the specimen and the container wall get colored yellow or brown.
10) After the container has been cooled to the room temperature, it is broken and the surface of the specimen is observed.

§ 3. Experimental Results

1) *Surface cracks*

(*a*) Fig. 2 shows typical cracks produced. Cracks have a tendency to run perpendicularly to the edges of the specimen, in spite of the fact that the edges can have arbitrary directions relative to the drawing direction of the sheet glass.

(*b*) Cracks appear not only on the origina glass surface but also on the surfac newly produced by cutting or breaking (See Figs. 3 and 4.)

(*c*) A contaminated spot due to incomplete cleaning often becomes a starting poin of surface cracks. (See Fig. 5.)

(*d*) Cracks can appear even when the specimen is fire-polished just before the

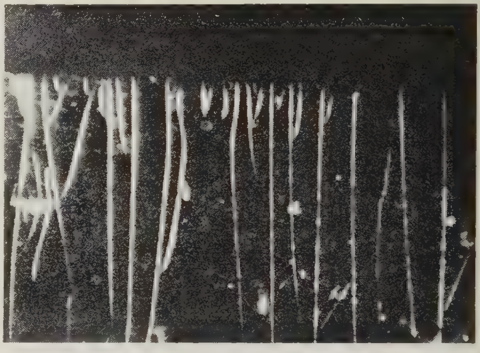

Fig. 2. Typical surface cracks developed perpendicularly to the edge of the specimen. (40×).

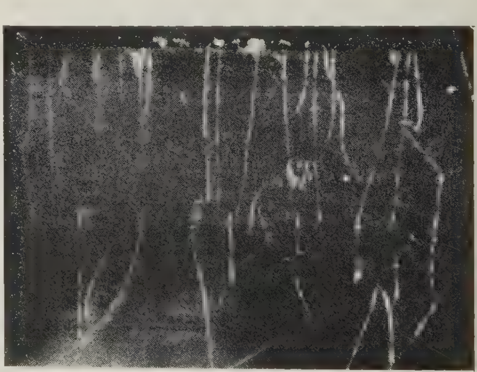

Fig. 3. Surface cracks on the cut side. (40×).

sodium treatment.

(*e*) By the sodium treatment, the surface crack which had disappeared with the lapse of time after its appearance by chilling could not be reproduced.

(*f*) The number of cracks increases with the treating time approaching to some ultimate value which probably depends on the quantity of sodium used.

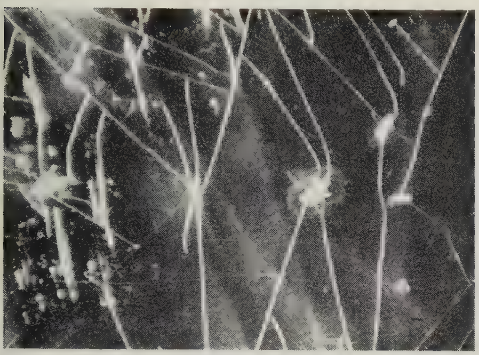

Fig. 5. Surface cracks observed when cleaning is incomplete. Cracks start from the contamination spots. (40×).

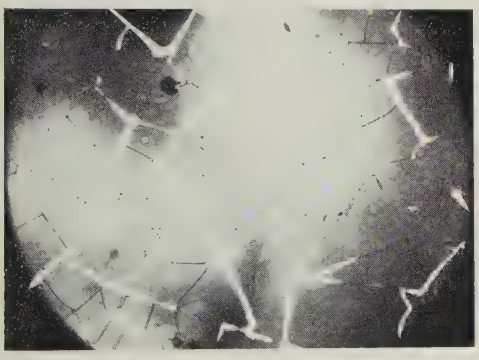

Fig. 6. Surface cracks produced by prolonged treatment. Each domain surrounded by the cracks shows Newton's rings. (30×)

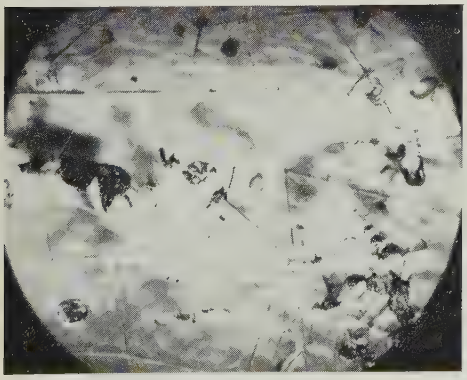

Fig. 7. The surface of specimen after the original surface layer has been flaked off. (30×)

(*g*) Treating with 0.3 g of sodium for 14 hours produces many cracks which are visible with the naked eyes. In Fig. 6, each domain surrounded by the cracks shows Newton's rings indicating that the surface is going to flake off. In this photograph, some cracks look like white lines showing that the light from the source comes directly through the cracks which are to some extent widely opened. The surface layer which is going to flake off can easily be removed by rubbing mechanically, and the new surface shows a roughened structure as is illustrated in Fig. 7.

(*h*) In a rod of fused quartz, cracks are more easily produced with less sodium and less treating time than in the ordinary soda-lime-silica glass. When pieces of soda-lime-silica glass and of fused quartz are treated at the same time in one container, the latter shows definitely darker color and more numerous cracks than the former.

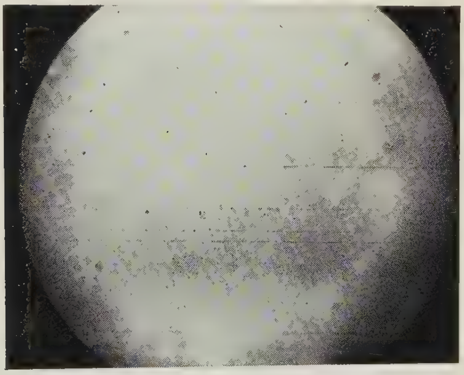

Fig. 8. Drawing marks (parallel straight lines) produced by sodium treatment. (30×)

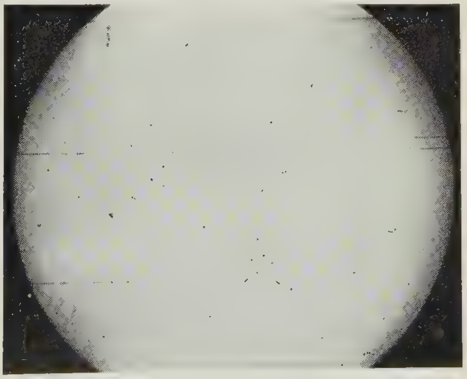

Fig. 9. Drawing marks after the water soaking of the specimen in Fig. 8. (30×)

2) *Drawing marks*

If a large quantity of sodium, say 1 g, is used, there frequently appears a group of lines with low contrast resembling to the so-called "drawing marks" which usually are observed by etching with hydrofluoric acid. (See Fig. 8.)

These lines, however, are made very clear by soaking the treated specimen in water above *ca.* 70°C (Fig. 9). In this photograph, a drawing mark forms a hair-curled shape. This indicates that these lines are not the "etched" parts but rather the "unetched" parts. The cross sectional view of the surface layer before and after the soaking would be as illustrated in Fig. 10.

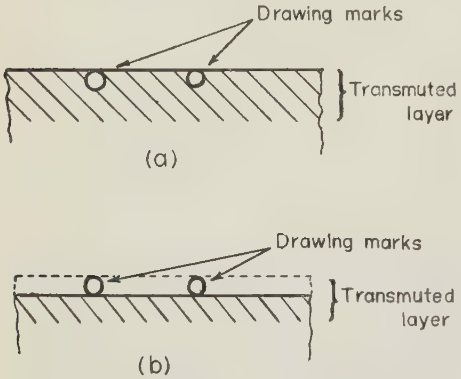

Fig. 10. Cross-sectional view of sodium treated surface layer with drawing marks. (a) Before, and (b) after soaking in water.

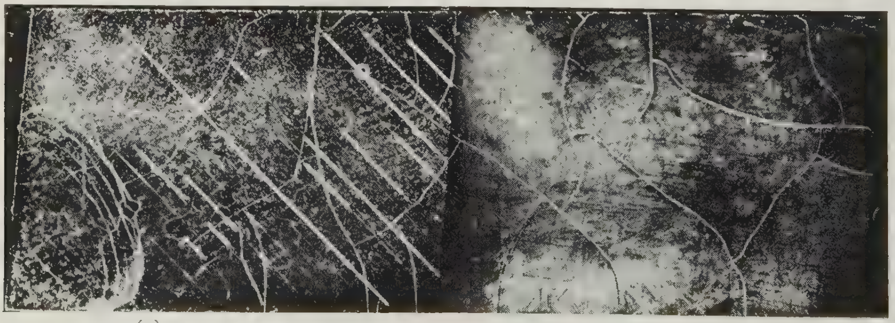
The difference in composition between mother glass and the drawing marks may result in the difference in reaction with sodium vapor and causes a difference in refractivity between the drawing marks and the rest of the surface film which makes these lines visible. Before soaking in water, these lines are fairly faint, as was the case in hydrofluoric acid etching, probably due to the small difference in refractivity. By soaking in water, however, surface layer except the portion of drawing marks seems to be carried away. The thread-like drawing marks are left on the new surface, which of course are more easily observed.

3) *Relation between the surface cracks and the drawing marks*

The surface of the specimen treated with a large amount of sodium (*ca.* 1.5 g) for about 15 hours looks dark brown or almost black and the observation by transmitted light is impossible. By reflected light, however, one can easily find out many drawing marks and very rough cracks as shown in Fig. 11. The parallel straight lines running obliquely in the left-half of the photograph are the drawing marks, and the other irregular lines are the surface cracks. The circular cracks which are seen left below are due to the contamination in the cleaning process. By soaking in water of *ca.* 70°C, both the surface layer and the drawing marks which have been especially developed by the "black" treatment can be thoroughly removed as flaked small pieces, but the surface cracks remain unchanged as seen in the right half of Fig. 11.

The flakes of the surface layer precipitated in this case were examined by X-ray and spectral analysis. The X-ray diffraction pattern was very complicated, and it was difficult to determine the structure. The result of the spectral analysis is given in Table I. It is interesting that the quantity of sodium is unexpectedly small. From this it is considered that the sodium atoms enter



(a) (b)

Fig. 11. Surface cracks and drawing marks produced by prolonged treatment with a large amount of sodium. (4×) (a) Before, and (b) after soaking in water.

into the network of glass, and destroy the glass structure. The sodium ions are then easy to move and dissolve into water exhaustedly.

The observation of the intersecting point of a drawing mark and a surface crack (circle mark in the left half of Fig. 11) reveals that the drawing mark is shifted aside when it crosses the surface crack as in Fig. 12. The width of the crack is measured, in this case, directly on the photograph to be about 30μ. From these results a geometric model is proposed as illustrated in Fig. 13. The drawing marks lie exclusively in the surface layer, whereas the cracks reach a further depth.

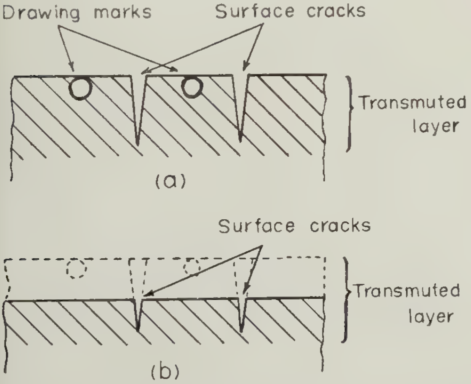

Fig. 13. Cross-sectional view of sodium treated surface layer with surface cracks and drawing marks. (a) Before, and (b) after soaking in water.

4) *Other natures of surface layer*

The color of the surface of the specimen changes from yellow through brown to black depending on the degree of treatment, especially on the quantity of the sodium used. Being soaked in water of about 50°C, or warmer, the color faids out producing bubbles, and the wet surface at this state shows alkalinity and the color of interference probably due to the flowing out of sodium ions from the surface layer.

The volume of the surface layer treated by sodium increases in contrast to the hydrofluoric acid etching. According to the measurement by the interference microscope, the treated layer is higher than the original surface by 5000Å in the extreme case, but it gets lower than the latter by 1000Å after soaking in water. The increment of height might be due to the sodium atoms entering into the network of glass structure and destroying the Si–O structure as was mentioned before. As the result of the destruction of the glass structure, the surface layer becomes very fragile, and is easily flaked off by rubbing. When soaked in water, the sodium flows out from the destroyed network into the water, resulting in the decrement of volume or level.

§ 4. Discussion

It would not be useless to elucidate the conclusions and discussions of the previous workers before discussing the present experiment. Andrade and Tsien, who first reported the detailed behaviour of the surface cracks produced by sodium treatment, tried the experiments on several sorts of glasses with different compositions. They concluded that the surface cracks produced by the sodium treatment are the *latent Griffith cracks* from the following experimental results.

1) The cracks are well developed in the situations where systematic scratching is improbable.
2) The cracks (latent cracks) develop with age which are almost completely absent on fresh glass immediately after drawing, and get frequent on the same glass some hours after drawing.

3) They are well developed in hard glasses, and hardly found in soft soda glasses.

4) A piece of plate glass exposed to sodium vapor showed no typical Griffith cracks. A fine diamond scratch was then made on another specimen from the same piece. Etching (sodium treatment) revealed typical cracks running out on both sides from the scratch in directions approximately normal to its length.

5) Other surface markings, such as scratches and drawing marks, can be developed by the attack of hydrofluoric acid; the Griffith cracks cannot be so brought to light.

6) The nature of the attack by the sodium vapor is not studied.

Gordon *et al* are led to the same conclusion as to the intrinsic nature of the surface cracks in the meaning that the cracks which are made visible by the sodium treatment are the *pre-existent* cracks. They derived the conclusion from the following results.

1) There is a relationship between the frequency of surface cracks and the mechanical weakness of the glasses from the same test rods; and it may be supposed that the more numerous the cracks, the greater the chance of a lethal defect.

2) Two Pyrex rods were twisted in opposite senses and were then clamped together at the ends so that they maintained mutually opposing torsional strains when decorated (*i.e.* sodium treated). For both rods the primary cracks run nearly normal to the tensional component of the shear, and many of the secondary cracks have been opened against the compressive stress. The same result was obtained with a silica rod subjected to bending, with the normal and parallel cracks to the axis of the piece on the tensile and compressive side, respectively.

3) In the accidental scrape, the pattern of cracks produced by the scrape is entirely contained by the pre-existent crack pattern. In the artificial scrape, there appear the primary cracks intersecting the scrape line, and the secondary cracks which run from the scrape normal to it are stopped by the pre-existent primary cracks.

4) In many cases cracks start from the surface devitrifications. If such a process were to take place on a smaller scale in the surface of glass, it might account for some of the observed behavior of glass surfaces. That is to say, it would explain both the origin of the cracks and perhaps the existence of surface tension.

Apart from the discussion about the existence of Griffith cracks, there no doubt are weak points on the glass surface. The weak points might be of various kinds, such as mechanical scratches, devitrifications around which the stress concentration is inevitable, and corrosion of glass surface by the so-called weathering in which the glass structure at the surface layer gets changed mainly due to dissolution of metallic ions into the adsorbed moisture. We consider, however, that the cracks produced by sodium treatment are mostly not the latent cracks but are newly originated or grown from the weak points mentioned above.

It is clear, first, from Fig. 12 that the nature of the attack by sodium vapor of which previous workers have not given any explanation, is not a simple etching. If it were the etching, the drawing mark which intersects the surface crack would have to lie on a straight line however wide the gap of the crack may be after the crack is made. Actually, however, as shown in Fig. 12, the drawing mark is shifted aside to each other by the surface crack. This shows that the mechanism might be attributed to the shrinkage of surface layer against mother glass. In the case of hydrofluoric acid etching the surface crack except the scratches cannot be developed, as was also already pointed out by the previous workers.

Observations on the surface cracks in the present experiment show the validity of the assumption that the cracking takes place after the treatment. If the surface cracks did pre-exist, the crack pattern would be independent of the direction of the periphery of the specimen, and to the contaminated spot which could be cleaned up by soaking process. Moreover, if the surface cracks appeared on the new surface of shell-shaped fracture, the cracks would have to be independent to the cracks on the original surface. However, these demands which arise from the assumption of the pre-existent racks are not realized as have been stated n the previous section. These results show hat the surface cracks are mostly produced y the sodium treatment. The mechanism f cracking after the treatment has not yet een made clear strictly, but a possibility is roposed that the difference in shrinkage etween the surface layer and the mother lass is responsible for this.

Almost all the experimental results of the revious workers can well be understood by he "subsequent cracking" mechanism. With he hard glasses the cracks are easy to appear ecause of a large difference in shrinkage. The statement made by Andrade and Tsien that the cracks are hardly found in soft soda glass would probably be due to the short duration of treating time: they treated the specimen for half an hour at most. The results that the cracks develop with age and that a diamond scratch makes many cracks may be attributed to the increase of weak points with age and to the presence of fine cracks which are usually observed in the friction of glass on hard substance, respectively. The selective appearance of primary cracks on the specimens subjected to the torsional or bending stress, as was found by Gordon *et al*, is naturally understood by the present mechanism. In this case, the surface layer which is made fragile by the attack of sodium vapor may easily be broken by the applied stress in a direction normal to the maximum tension. They showed a photograph of intersection of a surface crack (primary crack) and a scratch made by steel needle in which the primary crack preceded the surface cracks grown from the scratch, and this fact seems to be a key-point of the "pre-existent" crack theory of Gordon *et al*. In this case, it is supposed by the subsequent cracking theory that the originating point of the primary crack was weaker than the fine cracks which existed at the scratch. It is often experienced that an artificially made scratch does not become the starting point of fracture in the breaking tests of glass, and it is possible for the primary crack to precede the cracks which grow from the fine cracks at the scratches.

§ 5. Conclusions

It is concluded that the surface cracks produced by the sodium treatment are mostly not the latent cracks but the newly originated or grown ones by the treatment from the flaws of various kinds. The difference in shrinkage between the surface layer and the mother glass is proposed to be a possible assumption as to the cracking mechanism.

The nature of the attack by the sodium vapor is not yet clear, but it has been proved that the structure of glass in the surface layer is destroyed and is made very fragile by the sodium treatment.

Acknowledgements

The author should like to express his sincere thanks to President Dr. S. Suetoshi, Vice President Dr. T. Uekawa, and Chief Researcher Dr. E. Kanai of the Res. Lab. of Asahi Glass Co., and President Dr. M. Funaoka of the Iho Factory of Asahi Glass Co. for their kind advices. He is also indebted to Prof. K. Kinosita of Gakushuin University for his kind discussion and recommendation to publish this work.

Note added 30 June 1959. An interesting paper was reported by A. S. Argon (Proc. Roy. Soc. **A**, **250** (1959) 472), which dealt with the surface cracks developed by sodium treatment on flat chemical Pyrex glass. He used the ball indentation method to distinguish the "real" (pre-existent) cracks from the artificial ones. That is, he made the Hertz fracture on the specimen before the sodium treatment. After the treatment, if a crack intersects the Hertz fracture at two points, it can be considered to have existed originally as a real crack; but, if not, it is artificial. He found a few "real" long cracks in this way on one single specimen, but vast majority of cracks were found to be artificial.

Thermal Stability of the R, N and M Centres and the Oscillator Strength of the M Band of KCl Crystal

By Tetsuhiko TOMIKI

Department of Physics, The Faculty of Science, Tohoku University, Sendai, Japan

(Received June 4, 1959)

Okura[1)] measured the oscillator strength of the *M* band f_M of KCl crystal and obtained the relation $f_M=0.42f_F$, where $f_F=0.83$ is the oscillator strength of the ***F*** band of KCl. In this experiment, the assumption was made that only the transformation in the form of $\boldsymbol{F}\rightarrow\boldsymbol{M}$ occurred by irradiation with ***F*** light at beginning. Unfortunately, this basic assumption is not valid strictly: Firstly, the ***A*** band comes out at first on the red tail of the ***F*** band during the course of illumination with ***F*** light, as pointed out by Petroff[2)]; secondly, the ***R*** and ***N*** centres are also created simultaneously as the ***M*** band is developed; furthermore, in general, the half-width of the ***F*** band varies as the illumination with ***F*** light proceeds, and the ***K*** band is enhanced. Therefore, it is conceivable that $f_M=0.42f_F$ was underestimated.

In order to determine the oscillator strength of the ***M*** band experimentally, it is necessary to exclude these complexities. It is confirmed that this necessary condition is satisfactorily fulfilled when the additively coloured KCl crystal, which was exposed to ***F*** light so as to produce the ***M*** centre (together with the undesired ***A*** and ***R*** centres) a room temperature, is heated slowly up to 115°C followed by a slow cooling to room temperatur (see the curve (2) in Fig. 1 (b)), because the photochemical products except for the ***M*** centre ar thermally unstable and decompose according t the next forms: $\boldsymbol{R}\rightarrow\boldsymbol{N}$ and ***F*** (above 50°C), an $\boldsymbol{N}\rightarrow\boldsymbol{F}$ and ***M*** (above 100°C). The ***M*** centre is the most stable and decomposes thermally into the ***F*** centre above 130°C according to the equatio $1/\tau=2\cdot10^{12}\exp(-1.31\,(\text{ev})/kT)\,(\text{sec}^{-1})$. Thus, it is possible to realize the necessary condition that the crystal contains only ***F*** and ***M*** centres (see, Fig. 1 (a) and (b)). This fact enables us to determin the oscillator strength of the ***M*** band with high precision.

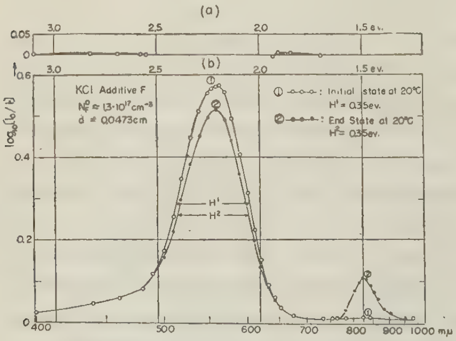

Fig. 1 (a): The increment of the absorption in the spectral region except the ***M*** band.

Fig. 1 (b): Curve (1) is the initial state, curve (2) shows the absorption spectra when the specimen was cooled to room temperature after the ***M*** band was developed at room temperature following by the temperature elevation to 115°C.

When the density of the ***F*** centres are determined with Kleinschrod-Smakula equation[3)] $1.31\cdot10^{16}\,K_FH_F$ and that of the ***M*** centres with Smakula equation[4)] $1.06\cdot10^{16}\,K_MH_M$, it is found that 2***F*** centres are required to creat one ***M*** centre. This indicates that the oscillator strength of the ***M*** band is formally equal to 0.5. In this case, it is *assumed* that the second absorption of the ***M*** centre does not exist in the region of the ***F*** band, because the bleaching curve of the ***F*** band caused by illumination with ***F*** light does not exhibit any anomaly even when the ***M*** band decreases at later stage. Furthermore, that the ***M*** centre carries only one electron is also assumed. To test this assumption, the quantum yield η_F defined by (Number of created ***F*** centres)/(Quanta absorbed by ***M*** band) was studied as a function of temperature. The result shows that η_F reaches a maximum value 0.56 above 130°C where the photochemical reaction occurred in the pure form $\boldsymbol{M}+(\text{photon})_M\rightarrow\boldsymbol{F}$, *i.e.*, $\eta_F=2\eta_M$. On the other hand, η_M was an order of 10^{-2} at room temperature.

The detailed description of this experiment will be reported in this journal. To Prof. M. Ueta, the author is very grateful for his kind interest and stimulating discussions.

Antiferromagnetism in $KMnF_3$

By Shinji Ogawa

Research Institute of Applied Electricity,
Hokkaido University

(Received May 28, 1959)

The magnetic susceptibility of $KMnF_3$ has been easured from room temperature down to 77°K ıd an antiferromagnetic behavior has been found. Martin *et al.*1) have reported on the antiferromagnetm in compounds of the type KMF_3 (where M=Mn, e, Co, Ni and Cu), in which the investigations of MnF_3 and $KCuF_3$ were not complete, however.

Specimens were prepared in two different ways; ne from the aqueous solutions of KF and $MnCl_2$ ollowing Nuka's method2), and the other by preipitating $KMnF_3$ in KCl from the melts of $MnCl_2$ nd 3KF at about 900°C in a platiumm crucible. he former specimen (A) was a fine powder of hite color with a dash of pink, and the latter pecimen (B) was transparent pale brown cubic rystals. An X-ray analysis revealed that both pecimens crystalize in the cubic perovskite strucures with lattice parameters a_0=4.190Å and 4.186Å or A and B respectively.

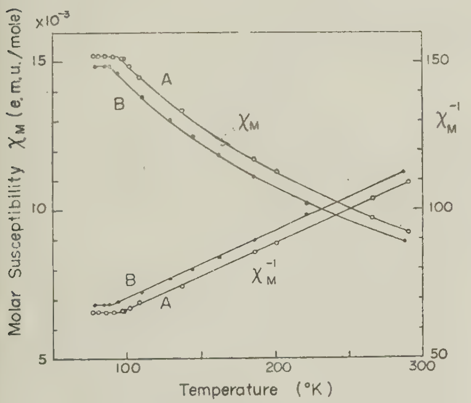

Fig. 1. Molar susceptibilities of specimens A and B of $KMnF_3$ versus temperature. (Inverse susceptibilities were also plotted.) These curves were corrected for the diamagnetism of -0.03×10^{-3} e.m.u./mole.

The temperature dependence of the susceptibility s shown in Fig. 1, and the magnetic data are summarized in Table I together with the X-ray data.

The measured susceptibilities obey fairly well to he Curie-Weiss law above about 100°K, and become onstant below 95° and 89°K for specimens A and B respectively, showing the presence of an antierromagnetic order in these temperature ranges. The antiferromagnetism should be mainly caused by an superexchange interaction through an intermediate fluorine ion, and this will be suggested by the fluorine hyperfine structure in the paramagnetic resonance of Mn^{2+} in a $KMgF_3$ single crystal3).

In the NMR of F^{19} in $KMnF_3$, Shulman *et* al.4) have recently observed a shift of resonance line by which the presence of a fairly large superexchange interaction is suggested, and have found a transition temperature 88.3°K which is in good agreement with T_N of our specimen B within the experimental error.

Table I. Lattice parameter a_0, Néel temperature T_N, asymptotic Curie temperature Θ, Curie constant C_M, effective number of Bohr magnetons p and molar susceptibility at Néel temperature $\chi_M(T_N)$ of $KMnF_3$.

	Specimen A	Specimen B
a_0	4.190±0.001Å	4.186±0.001Å
T_N	95±3°K	89±1°K
Θ	202±2°	204±2°
C_M	4.52±0.04	4.38±0.04
p	6.04±0.03	5.94±0.03
$\chi_M(T_N)$	15.2×10^{-3}	14.9×10^{-3}

Paramagnetic Resonance of Manganese in $KMgF_3$

By Shinji OGAWA and Yasaburo YOKOZAWA

Research Institute of Applied Electricity, Hokkaido University

(Received May 28, 1959)

In connection with the antiferromagnetism in $KMnF_3$ [1], a paramagnetic resonance of Mn^{2+} ions has been observed in a single crystal of $KMgF_3$ containing about a few hundred parts per million manganese ions, at room temperature and 3.2 cm wave length.

As to the crystal structure of $KMgF_3$, there have been reported two types; a cubic perovskite[2),3)] and a monoclinic[4),5)]. The sample used in the resonance experiment had a cubic perovskite structure with a lattice parameter $a_0=3.987\pm0.002$Å.

The observed paramagnetic resonance spectrum consisted of many extra lines in addition to the usual fs and hfs lines of a Mn^{2+} ion. These extra lines may be due to the hyperfine interaction between manganese electrons and surrounding fluorine nuclei as in the case of Mn^{2+} in ZnF_2[6)] and CaF_2[7)]. Thus the observed spectra at various crystal orientations are all described by the spin Hamiltonian;

$$\mathscr{H}=g\beta\boldsymbol{H}\cdot\boldsymbol{S}+(1/6)a[S_x{}^4+S_y{}^4+S_z{}^4 -(1/5)S(S+1)(3S^2+3S-1)]+A\boldsymbol{S}\cdot\boldsymbol{I}+\mathscr{H}'$$

and

$$\mathscr{H}'=\sum_N \boldsymbol{S}\cdot A^N\cdot\boldsymbol{I}^N\ ,$$

where N runs over the six nearest neighbor fluorine ions, $\boldsymbol{I}^N$ is the nuclear spin of the Nth nearest neighbor fluorine ion and A^N the hyperfine interaction tensor between the manganese electronic spin and the fluorine nuclear spin. In our case of cubic symmetry, $\mathscr{H}'$ produces a shift δH of the resonance field;

$$\delta H=A_s\sum_N I_z{}^N+A_p\sum_N I_z{}^N(3\cos^2\theta^N-1)\ ,$$

where A_s is the isotropic part of A^N, A_p the anisotropic part and θ^N is the angle between the external magnetic field and the σ-bonding axis to the Nth fluorine ion. If use is made of Tinkham's notation[6)], our A_p is equal to his $(A_{p\sigma}-A_{p\pi})$. That is, one can know only a difference between cont butions from σ- and π-bondings of p electron.

Parameters determined from the observed spect are summarized in Table I.

From the above value of A_s, one can estimat in the same way as Tinkham[6)] and Baker *et al* have done, the amount of time the magnetic electrons spend in s orbitals on the fluorine ion, a suming that they are all in $2s$ orbitals. We co clude that the magnetic electrons have 0.58 ± 0.03 $2s$ character at each fluorine nucleus and 1.74 0.09% in each two $d\gamma$ orbitals. To estimate th amount of time in p orbitals, the contribution from direct dipole-dipole interaction, 3.6×10^{-4} cm must be subtructed from the observed A_p. Afte this has been done, we conclude that the $2p$ character is more than 1.2 ± 1.0% at each fluorin nucleus and more than 3.7 ± 3.0% in each $d\gamma$ orbita

Recently, Shulman *et al.*[8)] have observed a nuclea magnetic resonance of F^{19} in $KMnF_3$. From th shifts of resonance lines, they estimated A_s an A_p (A_σ in their notation) to be 15.5 ± 0.5 and 1.2 $\pm0.13\times10^{-4}$ cm^{-1} respectively. If the differenc of Mn^{2+}–F^- distances in $KMgF_3$ and $KMnF_3$ i taken into account, the results of electron para magnetic and nuclear magnetic resonances are ra ther in good agreement. This point will be dis cussed in a future paper.

Similar resonances of Mn^{2+} ions have been ob served in $KCdF_3$ and K_2MgF_4. Details will be published in this journal.

Table I. g-factor, cubic crystal field splitting parameter a and hfs parameter A of Mn^{2+} ion, and hf interaction parameters between manganese electrons and surrounding fluorine nuclei, A_s and A_p, in $KMgF_3$.

g	1.999 ± 0.002
a	$(+)\ 8.5\pm1.0\times10^{-4}$ cm^{-1}
A	$(-)\ 91.2\pm1.0\times10^{-4}$ cm^{-1}
$\lvert A_s\rvert$	$18.2\pm0.9\times10^{-4}$ cm^{-1}
$\lvert A_p\rvert$	$4.7\pm0.9\times10^{-4}$ cm^{-1}

Fine Structure in the Giant Resonance for Cu^{63} and $Ag^{107}(\gamma, n)$ Reactions

By Teruo NAKAMURA, Kiyoji FUKUNAGA,
Kunio TAKAMATSU, Minoru YATA
and Shinjiro YASUMI

Department of Physics, Faculty of Science,
Kyoto University

(Received June 6, 1959)

Hitherto the investigations on the fine structure ı the giant resonance for the nuclear photoreaction ave been carried out by many authors. For medi- m weight nuclei, any fine levels were not detected y Saskatchewan group1) although they found many vels for several light nuclei, but Phillips2) de- cted more than ten breaks in the $Cu^{63}(\gamma, n)$ acti- ation curve in the energy range from 13.5 Mev 17.5 Mev with a 20 Mev betatron.

By the experiments with capture γ rays also, the xistence of fine structures in the Cu and $Zn(\gamma, n)$ xcitation curves has been reported by Bunbury3) nd Campbell4). We have investigated for medium veight nuclei such as Cu and Ag whether there xist fine structures or not, utilizing the energy ariation of Li-*p* γ rays by the Doppler effect.

The Li-*p* γ rays emitted from a thick lithium nethal bombarded with 500 kev protons consist of 17.6 Mev line with 10.7 kev half-width (in C.M. ystem) and a broad spectrum of 14.8 Mev com- onent. In the laboratory system, the energy of γ ays varies depending on the "Doppler angle" that s defined as the angle between proton beams and rays, since the excited nuclei of Be^8 have some elocities ranging from 1.23 to 1.28×10^8 cm/sec vithin the resonance width and can be considered o maintain those velocity vectors until they emit rays. (For the life-time of Be^{8*} to ground state ransition is estimated as 4×10^{-17} sec from $\Gamma_\gamma=$ 6.7 ev, and so the running distance of Be^{8*} nuclei vithin this life-time is about 5×10^{-9} cm). The ange of energy variation due to the Doppler effect is ±65 kev for 17.6 Mev line, while the photons of 14.8 Mev component could not contribute to produce fine structures because those energy spread is very broad (~2 Mev) compared to the width of fine structures as far reported.

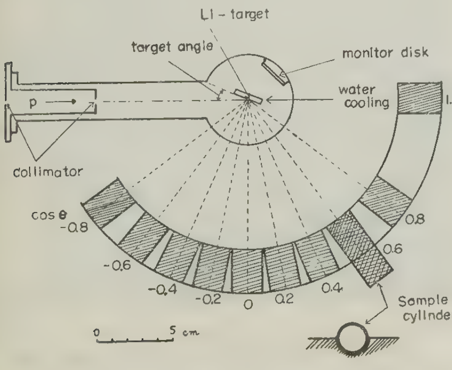

Fig. 1. Irradiation system of γ rays.

The target assembly is shown schematically in Fig. 1. The distance between a sample and γ-ray source was 10 cm. The form of a sample was a hollow cylinder with 5 cm length, 1.64 cm inner diameter and 1 mm thick. Eighteen cylinders made of copper and two cylinders made of silver were used, and the dimension of each sample was equal within 0.3% error.

The energy distribution of γ-rays irradiated on a sample is determined by the resonance formula with 10.7 kev half-width (in C.M. system) and the Doppler spread of photon energy due to the finite angle subtended by the sample cylinder at the γ-source. In our experimental arrangement it can be shown by calculations that a half of the total activities produced in a sample was produced by the γ-rays with about ±7 kev energy spread.

The samples were irradiated for about 20 minutes for copper and for about 25 minutes for silver at nine Doppler angles in front of a lithium target. β activities of irradiated samples were measured with two cylindrical G.M. counters of thin brass wall (0.125 mm thick). The counting efficiencies of both counters were mutually checked by Ra γ-source placed at the fixed position. In addition, in order to avoid the systematic errors due to the lack of uniformity of sample dimensions and slight inequality on the counting efficiencies of two counters, the combination of sample and counter at a given angle was interchanged. γ-ray intensities were

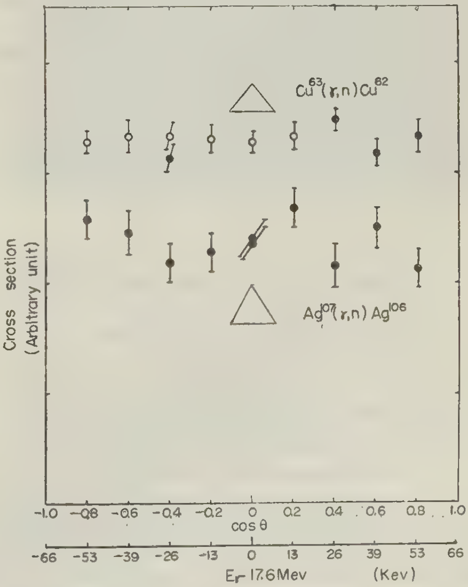

Fig. 2. Excitation curves of $Cu^{63}(\gamma, n)Cu^{62}$ and $Ag^{107}(\gamma, n)Ag^{106}$ reactions.

monitored with the β activities of a copper or silver disk irradiated simultaneously with sample cylinders.

The relative cross sections for Cu^{63} and $Ag^{107}(\gamma, n)$ reactions are plotted as a function of Doppler angles in Fig. 2. (The contributions from activities of Ag^{108} were eliminated by using the decay curve.) For copper the data of target angle 60° and 25° are shown with open and closed circles respectively, and for silver only the data of target angle 25° are plotted. The errors indicated in the figures are only statistical, and other errors are negligibly small.

In the present experiment, the lower limits of detectable magnitude of a fine level were considered as roughly three times of statistical errors, and they were evaluated as about 0.2 Mev-mb for copper and 0.7 Mev-mb for silver using the cross section values recently determined by us5) and so it was concluded from Fig. 2 that in $Cu^{63}(\gamma, n)$ reaction there was no fine level larger than 0.2 Mev-mb, while in $Ag^{107}(\gamma, n)$ reaction there was no fine level larger than 0.7 Mev-mb but some fine levels less than 0.7 Mev-mb seem to exist in the energy region of 17.6 Mev ± 65 kev. These conclusions do not agree with Bunbury's results3), but for the case of copper they agree with the result reported by Foster6) that there was no fine level for Cu by the method of Li-p γ-rays and neutron detection.

Hot Holes in Tellurium

By Yasuo KANAI

Electrical Communication Laboratory,
Musashinoshi, Tokyo

(Received June 16, 1959)

Current-voltage character and Hall coefficient of Te single crystals were measured in the pulsive high electric field at 77°K. Typical result of our samples is shown in Fig. 1. The direction of current flow was parallel to the c-axis, and the sample had the following character at 77°K; resistivity $\rho = 1.04 \times 10^{-1}$ ohm-cm and Hall coefficien $R = +412$ cm³/coul., hence the hole density $p = 3\pi/8Re = 1.78 \times 10^{16}$/cc and the hole mobility $\mu_0 = 8R/3\pi\rho = 3.37 \times 10^3$ cm²/V sec. As shown in Fig. 1 in the high electric field the current density was not proportional to the electric field but proportional approximately to the square root of it. In the same region of electric field, there was no change in the value of Hall coefficient. Hence we might believe that the decrease of current density of Te in high electric field was caused by the reduction of hole mobility.

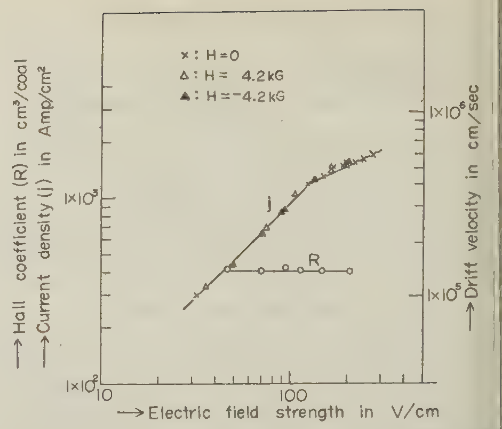

Fig. 1. Current-voltage character with and without transverse magnetic field and Hall coefficien at 4.2 kG of Te crystal at 77°K.

Following the Shockley's calculation1), E_c, the critical value of the electric field, where the Ohm's law ceases to be valid, is given approximately by the formula

$$\mu_0 E_c \equiv v_{dc} = 1.51\, v_s$$

where

μ_0: low field mobility
v_{dc}: critical value of drift velocity
v_s: sound velocity in crystal.

If we assume2) 0.5×10^{12} c.g.s. for the value of c_{ii}, the elastic constant, in Te, we get 2.83×10^5 cm/sec for the value of v_s in Te. So we can estimate 1.27×10^2 V/cm as the theoretical value of E_c. This value is in good agreement with the experimental value, i.e. 1.2×10^2 V/cm. Hence, if it is allowed to neglect the anisotropy of Te crystal, we may conclude that the main part of the energy loss of holes in Te is acoustic-phonon scattering, and the contribution from optical-phonon scattering seems to be negligible.

Anomalous Transmission of Electrons in a Film of Molybdenite

By Kazutake Kohra
Institute of Physics, College of General Education, University of Tokyo, Komaba, Meguro, Tokyo
and
Hiroshi Watanabe
Hitachi Central Research Laboratory, Kokubunji, Tokyo

(Received June 13, 1959)

It is known from pretty long ago that the transmission of X-rays abnormally increases when the diffraction takes place in a nearly perfect crystal with sufficient thickness[1]. This phenomenon was explained with the dynamical theory taking account of absorption[2].

The present note reports that the similar effect has been observed also in case of electrons. The Hillier patterns from a film of molybdenite crystal were taken at several regions with various thickness, the accelerating voltage being 75 kv.

From relatively thin parts of the film, usual net patterns were obtained, where many diffraction streaks form diffraction images (Fig. 1). Corresponding to most of the diffraction streaks the extinction (dark) streaks were ascertained in the incident image, as usually expected. (In practice, such correspondence could not be ascertained for all diffraction streaks probably because of the complicated nature of the pattern. However, any bright, not dark, streaks in the incident image were not found corresponding to the diffraction streaks).

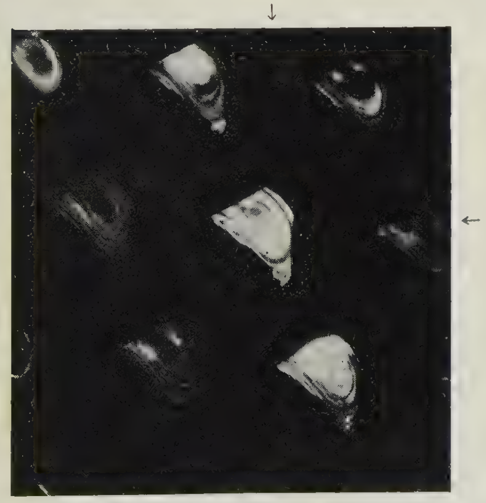

Fig. 1. Hiller pattern from a thin part of molybdenite film.
(The incident pattern is indicated by the arrows.)

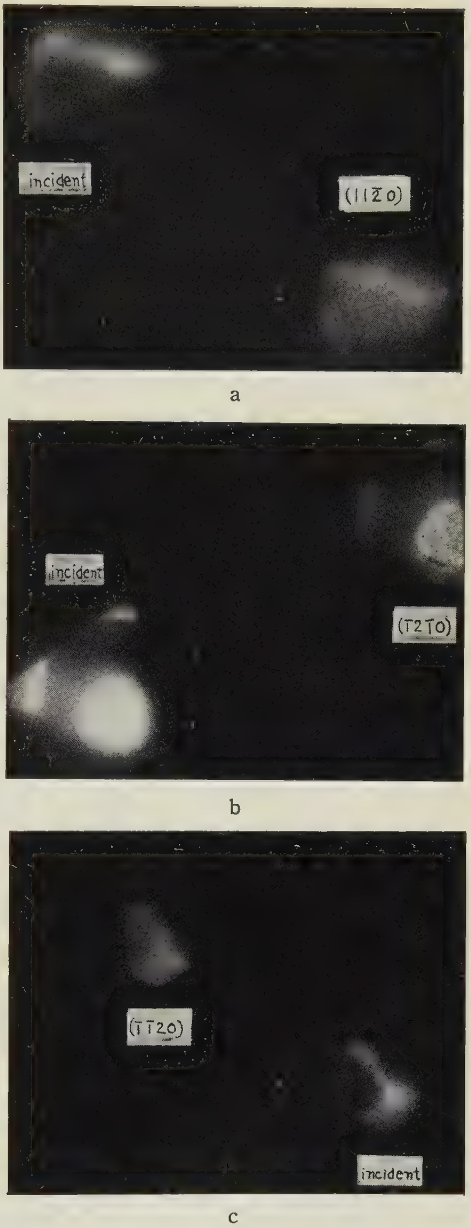

Fig. 2. Hillier patterns from thickparts of molybdenite film.

When the irradiated part is appropriately thick, the patterns as shown in Fig. 2 were obtained. Besides the incident image, only one diffraction image is remarkable, the index of which is (11$\bar{2}$0) or equivalent to it for all cases*. Although the pattern is not sharply defined and of weak contrast because of the strong backgrornd, it can be clearly seen that the *bright*, *not dark*, streak in the incident image corresponds to some bright streak in the diffraction image. They are almost same to each other in shape and intensity. This phenomenon means that the transmitted intensity does not decrease, but increases when the diffraction takes place, being no more than that of anomalous transmission which is known for X-rays.

---

* In the original photographic plate, another diffraction (10$\bar{1}$0) and the Kikuchi band, although faint, were sometimes observed.

The phenomenon of anomalous transmission for electrons can be explained analogously to for X-rays. According to the theory, this phenomenon is observed only when the crystal is sufficiently thick. This is consistent with our observation that the anomalous transmission appears only when the film is so thick that the net pattern disappears and the Kikuchi band appears.

It is also to be noted that the streaks are not straight, but curved. This is probably caused by that the film is curved. Then it might be said that the anomalous transmission is observed even if the crystal is not so perfect.

On the Magnetic Property of Iron Telluride

By Ichiro TSUBOKAWA and Shoko CHIBA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai, Japan

(Received May 15, 1959)

Magnetic properties and the phase diagram of the system of iron and tellurium in the range of the vicinity of stoichiometric composition (fifty atomic percent) were investigated by one of the present authors[1] as well as by Kondoh and Uchida[2]. The former author showed that there exists a single phase domain of iron telluride (α-phase) extending from 46 to 49 atomic percent of tellurium ($FeTe_{0.85}$~$FeTe_{0.96}$) in this binary system. Grϕnvold, Haraldsen and Vihovde[3] reported also that this phase has a cyrstal structure intermediate between PbO and Fe_2As structures. Recently, Westrum, Chou and Crϕnvold[4] reported a lumda-shaped anomalous heat absorption at 63°K for the compound with the composition $FeTe_{0.90}$. From the specific heat vs. temperature curve obtained by them, the excess heat absorption and the total entropy change were estimated to be afout 60 cal per mol of iron atom and 0.57 cal/mol°K respectively.

In order to clarify the origin of the heat absorption above mentioned, the magnetic susceptibility for an α-phase compound, $FeTe_{0.95}$ was measured by the present authors from the boiling point of of helium to room temperature. The measuremen was made by means of a magnetic balance in the magnetic field of 3.0 kOe. The result obtained is shown in Fig. 1. As seen from the figure, the susceptibility reaches its maximum at about 63°K, which coincides with the lumda point in the specific heat vs. temperature curve. On the higher temperature side of this maximum point (200°~750°K), the susceptibility is represented quite well by an equation $\chi=(0.0042)/(T+130)$*. From this Curie constant, the corresponding effective Bohr magneto nnumber is found to be 2.44. Assuming $\mu_{eff}=\sqrt{g^2S(S+1)}$ and $g=2$, $S=1.64/2$ is obtained. (S is the average spin quantum number and g the Landé factor). If the change at 63°K is antiferro → paramagnetic transition, the total entropy change and excess heat absorption are estimated to be $\Delta s=R\log(2S+1)=1.94$ cal/mol°K and $\Delta Q=103$ cal/mol. Although these figures are slightly greater than the results from the measurement of the specific heat mentioned above, the lumda point of susceptibility may be considered to be the antiferromagnetic Néel point.

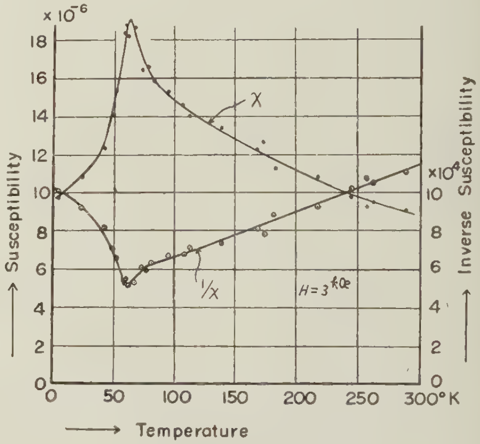

Fig. 1. The susceptibility or the inverse susceptibility versus temperature curves for $FeTe_{0.95}$.

The authors wish to express their hearty thanks to Profs. T. Hirone, S. Maeda and N. Tsuya for their encouragement and valuable discussion.

---

* The Curie constant differs from the value in the previous paper[1]. It has been found for the chech by Chiba that the absolute values of the susceptibility in the preveous measurements were not correct and they were smaller than the correct value by about 20%.

Thomas-Fermi Model of Compressed Positive Ion

By Shigehiro Kobayashi

Department of Physics, Kagawa University, Takamatsu

(Received June 8, 1959)

For the following three cases 1 to 3, the TF nethod was established previously by the corresponding investigators.

	neutral atom	positive ion
free state	1. Thomas-Fermi[1)	2. Guth-Peierls[2)
compressed state	3. Slater-Krutter[3)	3.

We have made a calculation of the remaining (most general) case 4, namely the TF method for positive ons in compressed state. We wish to report about ts method briefly in the following short note.

The TF equation of a compressed positive ion akes also the ordinary form

$$\phi''=\phi^{3/2}/x^{1/2}\,. \tag{1}$$

ts solution, so-called the TF function denoted by $\phi_{q,X}(x)$ for the case of ionization degree $q\equiv$ $Z-N)/Z$ (Z=atomic number, N=electron number) nd boundary radius X (in TF unit μ), is subject o the conditions at the nucleus ($x=0$)

$$\phi_{q,X}(0)=1 \quad : \quad \text{nucleus predominates} \tag{2}$$

nd at the boundary ($x=X$)

$$\phi_{q,X}(X)\neq 0 \quad : \quad \text{finite pressure} \tag{3}$$

nd

$$\phi_{q,X}(X)-X\phi'_{q,X}(X)=q \quad : \quad \text{net charge}=(Z-N)e\,. \tag{3a}$$

n the case of free state (boundary radius $x_0>X$), he last conditions are replaced by the following onditions

$$\phi_{q,x_0}(x_0)=0 \quad : \quad \text{zero pressure} \tag{4}$$

nd

$$-x_0\phi'_{q,x_0}(x_0)=q \quad : \quad \text{net charge}=(Z-N)e\,. \tag{4a}$$

These circumstances can be seen from Fig. 1, where four tangent lines [1] to [4] correspond to the boundary conditions of the above four cases 1 to 4, respectively.

Then, it has been established that for a definite value of q the decreasing boundary radius (the increasing compression) takes the TF curve with the decreasing initial slope (shifted more upwards), the relations of which are shown in Fig. 2.

In our case characterized by (q, X), also, the electron density and the potential distribution are given by

$$\rho=\frac{Z}{4\pi\mu^3}\left[\frac{\phi_{q,X}(x)}{x}\right]^{3/2} \tag{5}$$

and

$$V=V_0+\frac{Ze}{\mu}\,\frac{\phi_{q,X}(x)}{x} \tag{6}$$

respectively, as functions of x. Here, V_0 is the maximum potential for the electrons in the ion and can be determined, following Slater and Krutter, in such a way that the potential V in the immediate neighborhood of the nucleus has a value independent

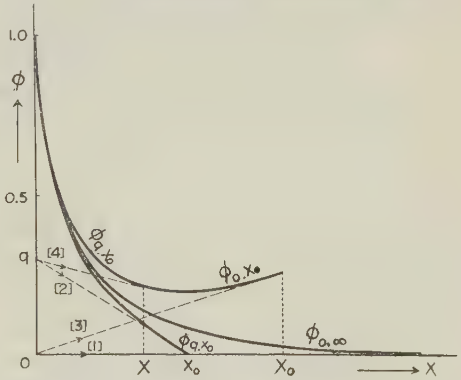

Fig. 1. The boundary conditions of the TF function $\phi(x)$.

$\phi_{o,\infty}$: free } neutral atom
ϕ_{o,x_0}: compressed } neutral atom

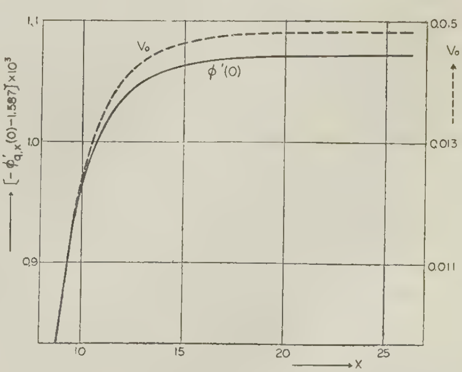

Fig. 2. The initial slope of the associated TF curve $\phi'_{q,X}(0)$ and maximum potential V_0 as functions of the boundary radius X for Cs ion.

of the boundary radius as

$$V_0=\left[\frac{q}{x_0}+\phi'_{q,x_0}(0)-\phi'_{q,X}(0)\right]\frac{Ze}{\mu} \tag{7}$$

dependent on q and X. (Cf. Fig. 2)

As our case is most general, this expression (7) is reduced for the three cases naturally to the familiar ones[4];

$$\begin{aligned} V_0&=0 && \text{for free neutral atoms}\\ &=(Z-N)e/\mu x_0 && \text{for free ions}\\ &=[\phi'_{0,\infty}(0)-\phi'_{0,X_0}(0)]\frac{Ze}{\mu} && \text{for compressed atoms.} \end{aligned}$$

These expressions (5) to (7) have enabled us to calculate various physical quantities for positive ions in compressed state, for example, equation of state, compressibility and so on.

The details of the calculation and the evaluated values of these quantities for Cs ion will be soon published in a separate paper[5].

The author wishes to express his sincere thank to professor K. Umeda of Okayama University fo his continued guidance and kind encouragemen throughout this work.

Electroluminescence of ZnS Phosphors Excited by Short Field Pulses

By Shoji TANAKA

Department of Applied Physics, University of Tokyo,
Tokyo, Japan

(Received February 7, 1959)

The electroluminescence in ZnS:Cu, Pb phosphors excited by short field pulses are investigated and excitation and recombination mechanisms of luminescent centers are discussed. The exciting pulse fields used in these experiments are rectangular pulses having durations of 1 to 40 microseconds. From the experimental results about emission spectra, brightness waveforms, dependences of light outputs on the applied voltages and pulse durations, decay times, build-up characteristics and their temperature dependences, the following considerations are made: the local intense field generated at the cathode region of phosphor particle accerelates the primary electrons and the luminescent centers are impact-ionized by these electrons. The field strength may be smaller than in the case of sinusoidal field excitation and then the excitation efficiency of primary electron greatly decreases compared with the latter case. The primary electrons are partly generated thermally and partly by the direct field-ionization. The decay of electroluminescence obeys the bimolecular law and is affected by the electron traps in the region of long pulse durations. The build-up characteristics are also affected by the deeply lying electron traps.

§ 1. Introduction

The electroluminescence phenomena in ZnS phosphors have been greatly investigated recently. Voltage dependences, brightness waveforms, frequency and temperature dependences and other associated characteristics have been reported. Above all, the intrinsic electroluminescence, which is obtained with the powder phosphor dispersed in dielectric medium, has been exclusively studied.

The mechanism of electroluminescence, however, is not clear enough even now, since the phenomena generated in phosphors are very complicated and can hardly be separated into elementary processes experimentally. Curie1), Piper and Williams2), Zalm3) and others proposed the fundamental considerations based on the impact ionization mechanism. The impact ionization of luminescent centers by primary electrons which are accerelated in the intense field is the most reasonable excitation mechanism, but the source of the primary electrons, effects of electron traps and donors, and the reason of formation of local intense field have been discussed from the several points of view.

The aim of this paper reported here is the study of the excitation and recombination mechanisms of the luminescent centers in ZnS powder phosphors by means of high speed pulse fields. As explained in a previous report4), the excitation by the short field pulse is more useful than usual sinusoidal field excitation for the study of the electroluminescence phenomena, since the waveforms are very simple, and the processes of the excitation and recombination can be separated and moreover the troublesome trapping of electrons may greatly decrease compared with the sinusoidal field excitations. Matossi and Nudelman5), Zalm3), and Hahn and Seemann6) investigated the electroluminescence by using the pulse fields. Matossi and Nudelman used relatively slow pulses and other nonsinusoidal fields, and discussed the effects of the inner polarization fields from the electroluminescence waveforms. Zalm studied the brightness waveforms and analysed them under the assumption of the recombination process of the excited luminescent centers and free electrons. These studies, however, seem to have payed little care on the waveform of exciting pulse. On the other hand, Hahn and Seemann used high speed pulses and discussed the effects of boundary layers between phosphors and electrodes, and polarization charges qualitatively.

According to our studies, it is evident that the brightness waveforms of electroluminescence are greatly affected by the waveforms of exciting fields, and so the rise and fall times of the exciting pulse fields must have as small values as possible. In the following sections, the emission spectra, brightness waveforms, voltage dependences and other associated characteristics of the electroluminescence of ZnS:Cu, Pb phosphors excited by short field pulses will be mentioned, and discussed with the excitation and recombination mechanisms.

§ 2. Experimental Procedure

The samples used in this experiment are ZnS:Cu, Pb powder phosphors being especially made for the electroluminescence, and are prepared as follows: ZnS powder is mixed with Cu and Pb of about 0.1% and baked at 900°C (with NaCl as flux material), 1 hour in air, and after baking washed in NaCN solution.

These samples are dispersed in silicone oil and pressed between metal plate and conducting glass. They are, however, separated from the both electrodes by Mylar sheets of 12μ thick. These Mylar sheets are used to avoid the contact effects between the samples and the electrodes, because the contact phenomena influence the electroluminescence brightness waveforms as indicated by Hahn and Seemann. Therefore, the cell is completely symmetric in its construction. The dimension of the cells are $5\times5\times0.025\ \text{mm}^3$ and their electric capacities are about 30 PF (for the pulse method, the smaller the cell capacity is the better).

The exciting electric pulse fields obtained from the pulse generator are always negative DC pulses and their rise and fall times are 0.2 and 0.3 microseconds respectively. The heights of the electric pulses are 1500 volts at maximum and repeating frequencies are 25 c/s to 1 kc/s, and pulse durations are 1 to 40 microseconds.

The luminescence generated by the exciting pulse field in the sample is detected by RCA 931–A multiplier phototube which is shielded by metal case from the disturbance of outer electric fields. The output signal from the multiplier phototube is observed by a synchroscope which can resolve the transient phenomena shorter than 0.1 microsecond. On the other hand, in the case of measuring the integrated light output the direct current amplifier is used to measure the integrated output current of multiplier phototube.

§ 3. Experimental Results

(a) *Emission spectra*

ZnS:Cu, Pb phosphors used in this experiment have two emission bands in green and

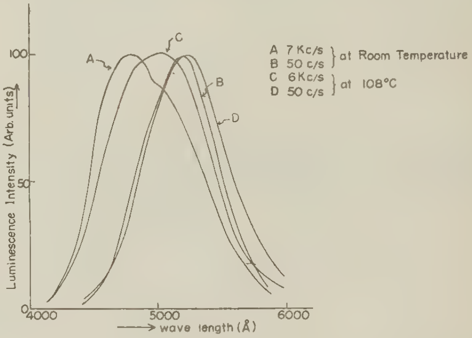

Fig. 1. Emission spectra of electroluminescence excited by sinusoidal fields.

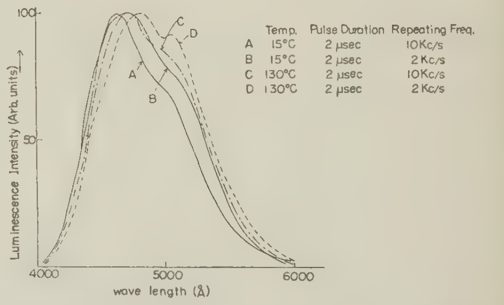

Fig. 2 (a). Emission spectra of electroluminescence excited by short field pulses.

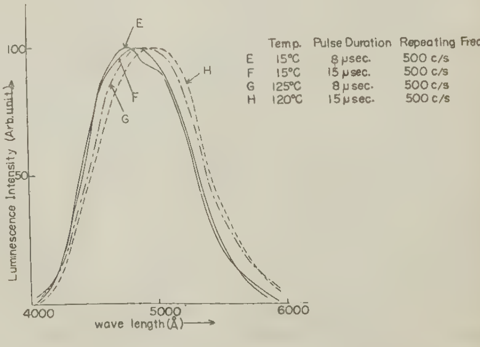

Fig. 2 (b). Emission spectra of electroluminescence excited by short field pulses.

blue regions. The green band is observed by excitation with ultraviolet irradiation or low frequency sinusoidal field at room temperature and seem to have a peak output at 520 mμ in wavelength. The blue band, on the other hand, is observed by excitation with high frequency sinusoidal field and seems to have a peak at 460 mμ. (Fig. 1)

When these samples are excited by short field pulses used in this experiment, the blue band emissions are predominantly observed even at low repeating frequencies, though the emission peaks tend to shift to longer wavelength slightly at high temperatures or long pulse durations, as indicated in Fig. 2. Considering that the decay time of luminescence is short enough—a few microseconds—in the case of short field pulse excitation as indicated in the following section, it may be expected that the hole migrations from blue to green centers hardly affect the emission spectra contrary to the case of sinusoidal field excitation.

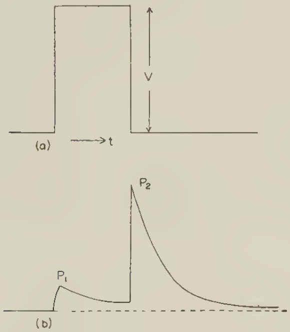

Fig. 3. Brightness waveform of electroluminescence.
(a) Waveform of exciting pulse field.
(b) Brightness waveform.

(b) *Brightness waveforms*

The brightness waveforms of electroluminescence excited by short field pulses have two peaks, and the first and the second peaks are in phase with the rise and fall of the rectangular exciting pulse. The typical one is shown in Fig. 3, but the ratio of heights of two peaks and luminescent decay following these peaks depend on the kinds of phosphors considerably (three kinds of phosphors other than that reported here are observed by the same experimental apparatus).

In our samples, the first peaks are much smaller than the second peaks (Fig. 4), though the former tend to increase compared with the latter at high repeating frequencies or long pulse durations.

Furthermore, the polarity of the emission of electroluminescent cell is observed, because the DC pulses are used for the excitation. The multiplier phototube faces to the transparent conducting glass of the cell, and when the conducting glass electrode is negative to the metal electrode, the obtained brightness is 1.25 times larger than the reverse case (Table I). Since the construction of the cell is symmetric as above mentioned, this polarity of the emission is caused from the absorption or scattering of the emitted light by the sample material itself.

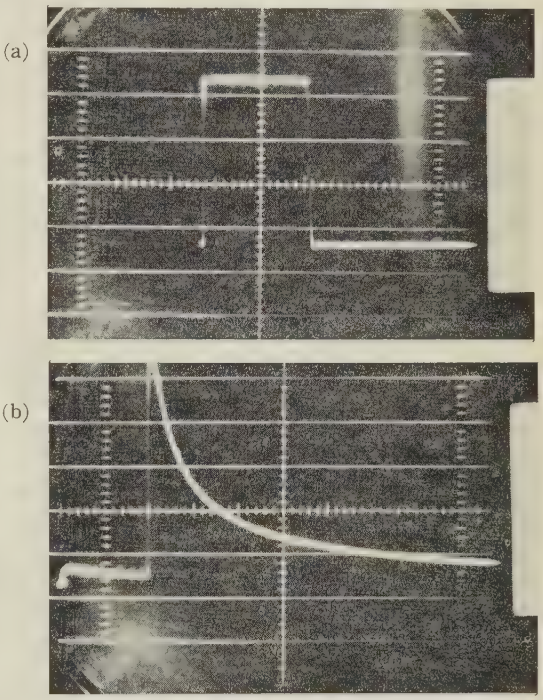

Fig. 4. Brightness waveform of electroluminescence.
(a) Waveform of applied field pulse, duration 10 microseconds.
(b) Waveform of electroluminescence excited by the pulse field indicated by (a). Time mark is 1 microsecond.

These results indicate that the excitation of electroluminescence in the phosphor by electric field is generated in the cathode region of phosphor particles, in accordance with results obtained by several other workers.

P_2': Second peak height when conducting glass is negative.

P_2'': Second peak height when conducting glass is positive.

(c) *Decay of electroluminescence*

It is very interesting to analyse the decay character of electroluminescence, for the initial decay which is difficult to be observed in usual photoluminescence, can be observed. In this experiment the decay of the electroluminescence is measured only in the one which follow the second peak, because the first peak is very small and hence it is difficult to analyse it accurately.

The luminescent decay of ZnS type phosphors should obey the bimolecular law in principle: that is

$$I=\frac{I_0}{(1+An_0t)^2}\,, \tag{1}$$

or

$$\frac{\sqrt{I_0}}{\sqrt{I}}=(1+An_0t)\,, \tag{2}$$

where I is the brightness of phosphorescence during the decay, I_0 is the initial value of I at $t=0$, A is a recombination constant of the excited centers and free electrons, n_0 is the initial value of the density of the excited centers, and

$$A=\sigma v\,, \tag{3}$$

where σ is the recombination cross section of luminescent centers and v is the thermal velocity of free electrons.

One of our results is illustrated in Fig. 5 and 6 according to the equations (1) and (2) respectively. From these figures it is evident that the bimolecular law is valid in the beginning of decay up to 20% of the initial value, that is, the slope of log-log plot in Fig. 5 is equal to 2, and in Fig. 6 the curve of inverse square root values of I is nearly straight line at the beginning of decay. Furthermore semi-log plot of decay is shown

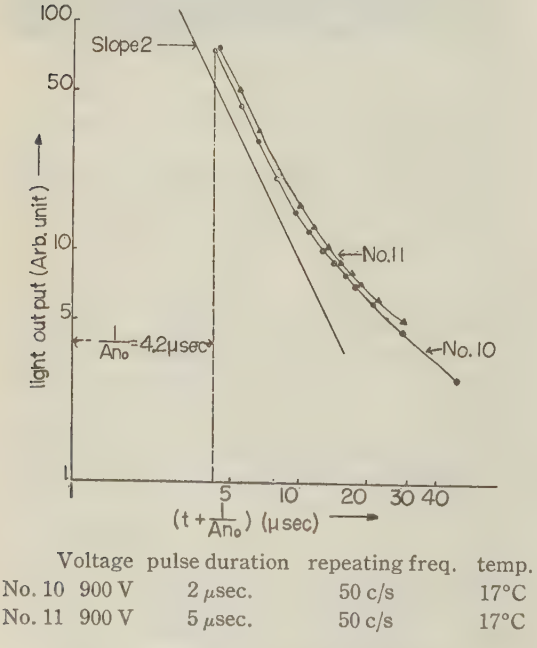

Fig. 5. Decay of electroluminescence.

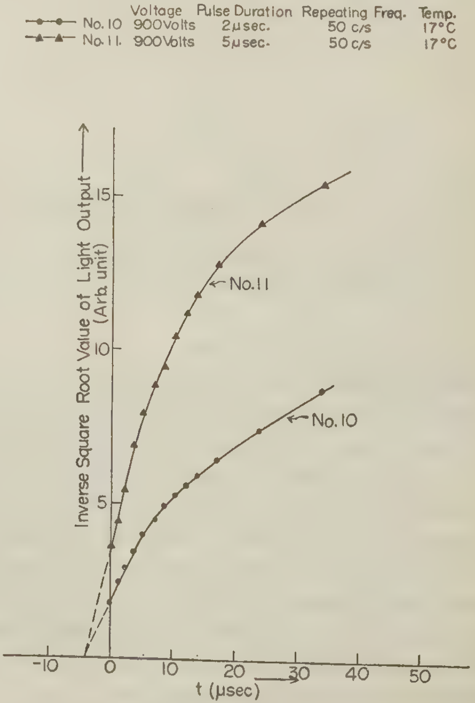

Fig. 6. Decay of electroluminescence.

in Fig. 7 to compare the experimental result with the monomolecular law, and this plot does not coincide with the straight line. The value of An_0 is obtained from the intersection of extrapolated straight line of $\sqrt{I_0}/\sqrt{I}$ on the horizontal time scale line in Fig. 6 or the time necessary to decay to 0.25 I_0 in Fig. 7. The obtained values of An_0 and the corresponding excitation conditions are shown in Table II. From Table II we can find that the decay times (in this paper it is defined as the time which is necessary for decay to one quater of initial value i.e. $1/An_0$) of these electroluminescence are in the region of 4 to 10 microseconds. The nature of the decay is very interesting especially at high tempera-

ture, that is, the values of An_0 in these data are almost equal even in various exciting voltages. The two curves illustrated in Fig. 8 indicate this feature: that is, although the peak values of the brightness of case (B) is about six times larger than the case (A) as explained in a later section, the values of An_0 are nearly equal in two cases. Moreover, at high temperature the decay times tend to increase with the pulse durations as shown in Fig. 9. On the contrary, the decay times at room temperature fluctuate considerably even for same exciting conditions: this might be due to the effects of electron traps as discussed later.

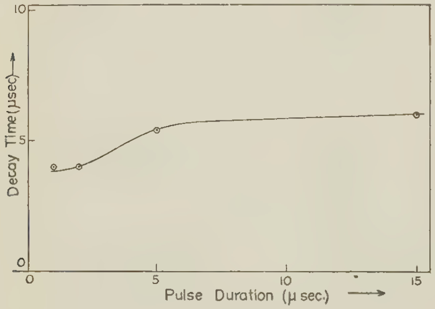

Fig. 9. Dependence of electroluminescent decay on pulse duration at 140°C.

These decay characters seem to be important to understand not only the electroluminescent mechanism, but also the nature of the luminescent centers, as will be discussed later.

(d) *Voltage dependences of brightness*

The voltage dependences of the electroluminescent brightness can be measured by the peak value of the brightness waveforms because of the invariance of the wave forms with the applied voltages. The integrated light outputs are also measured by DC amplifier, when it is necessary to compare two cases, i.e. pulse and sinusoidal field excitations. The typical results are illustrated in Fig. 10, and these voltage dependences seem to obey the law which is proposed by Taylor and Alfrey[7], and Zalm[3], at least under 1000 volts, that is

$$B=B_0 \exp\left(-\frac{c}{\sqrt{V}}\right), \tag{4}$$

where B is the brightness, V is the applied voltage to the cell, B_0 and c are constants. The values of c are obtained from the slope of Fig. 10, and the results obtained in the same cell under various exciting conditions are listed in Table III. These results illustrate that the c-values are nearly independent of exciting conditions except for the case of high repeating frequency and are about $2.6\times 100\ (\text{volts})^{1/2}$. In the region of voltages higher than 1000 volts, however, the dependences become slightly steeper than in the low vol-

tage region.

The comparison of exciting efficiencies in two cases of sinusoidal and pulse field excitations (in the same cell) are made by measuring the integrated light outputs by DC amplifier in low voltage region and the results are shown in Fig. 11. In this figure the applied voltage V of sinusoidal field means the peak voltage of the field. The interesting features in this results are as follows: first, the integrated light output is much smaller in the pulse field excitation than in the case of sinusoidal field excitation, and second, the voltage dependence is steeper in the case of pulse field excitation and the c-value is nearly twice as much as in the case of sinusoidal field excitation. (The slight difference of c-value between in Fig. 10 and 11 might be due to the using of different cells in each case.)

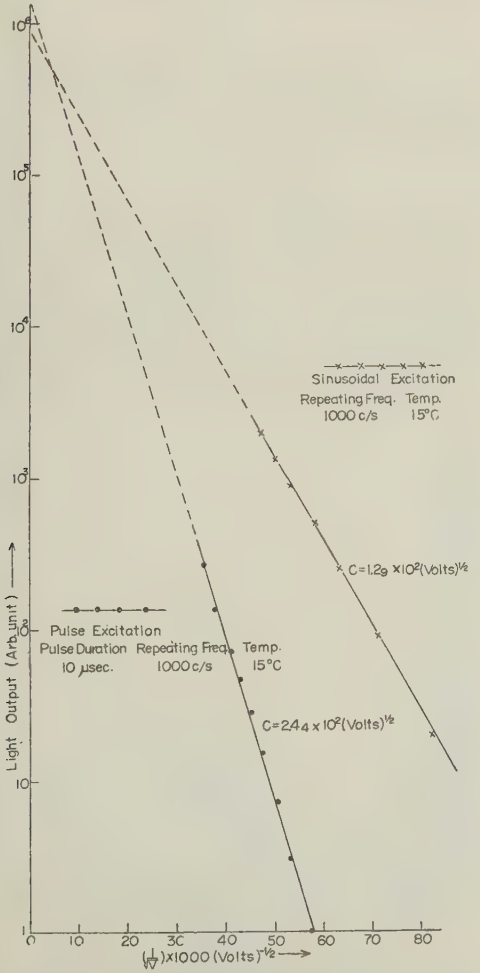

Fig. 11. Voltage dependences of electroluminescence.

The constant factor B_0 in Eq. 4, which is determined from the intersection point of the extrapolated straight line with the light output scale in Fig. 11, is about three times larger in the case of pulse field excitation than in the sinusoidal case. (The light outputs indicated in this figure must be divided by two in the case of sinusoidal excitations to compare with the ones in the case of pulse excitation, because in the former case the excitation raises up twice in each cycle.) The emission bands of luminescence in each case, however, are considerably different, *i.e.*, the blue band in pulse case and the green band in sinusoidal case are predominant respectively as indicated in Sect. 3 (a). Therefore, speaking of the number of photons emitted from the phosphors, the difference of the constant factor B_0 between two cases may become smaller, because the photosensitivity of multiplier phototube is smaller in the green band than in the blue band. These facts indicate that the excitation efficiency is almost completely determined in both cases by the exponential factor in Eq. 4, which involves the inner field generation, and not the constant factor B_0, which may involve the primary electron generation, at least over the room temperature.

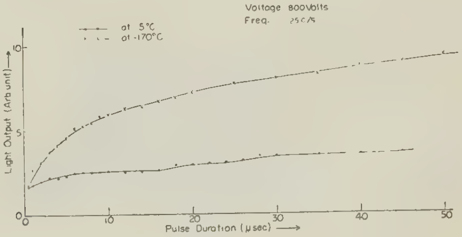

Fig. 12. Dependence of electroluminescence on pulse duration.

(e) *Dependences on the pulse durations*

The light output of electroluminescence tends to increase with the pulse duration of exciting field, and this feature is larger at room temperature than at higher or lower temperatures. Fig. 12 shows this character, where the light outputs are measured with DC amplifier as mentioned in the previous section. In the region up to 20 microseconds, the approximately exponential increases are observed, and in the region longer than 20 microseconds the slower increases are observ-

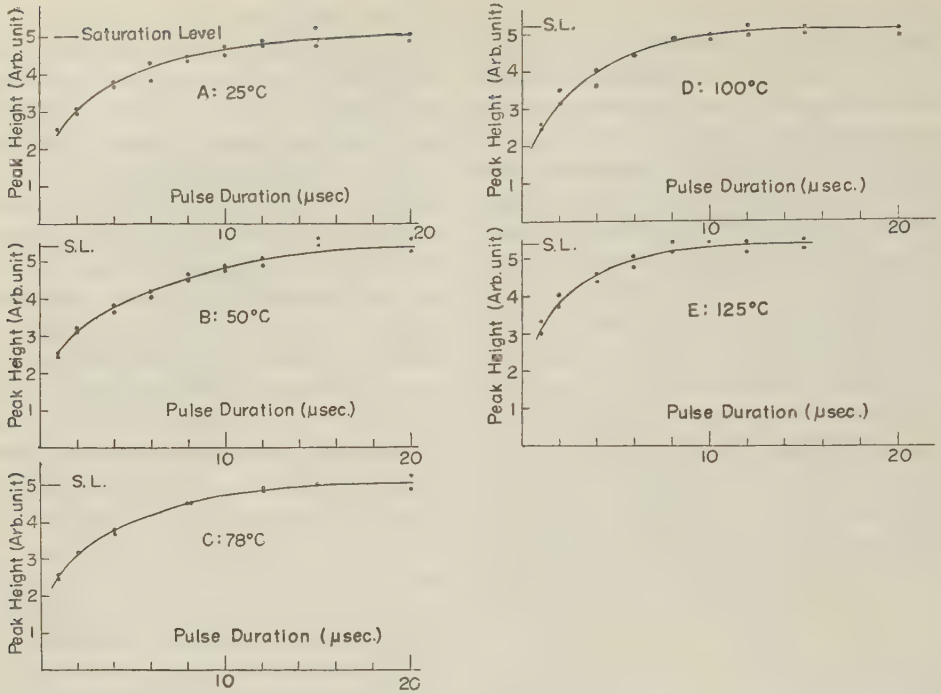

Fig. 13. Dependences of electroluminescence on pulse duration at different temperatures.

Voltage	Repeating freq.
900 Volts	50 c/s

ed at room temperature. At liquid air temperature, on the other hand, the sharp rise of light output with the pulse duration is hardly observed and the output increases slowly up to over 40 microseconds. The sharp rise at temperature higher than room temperature is measured up to 170°C in the region of 1 to 15 microseconds (to keep the constancy of temperature, longer pulse durations are not used). The results are shown in Fig. 13 and if we assume the suitable saturation values of light outputs with the pulse durations (this assumption means that the sharp and slow rises may be due to different mechanisms), these curves are all expressed by exponential form as shown in Fig.

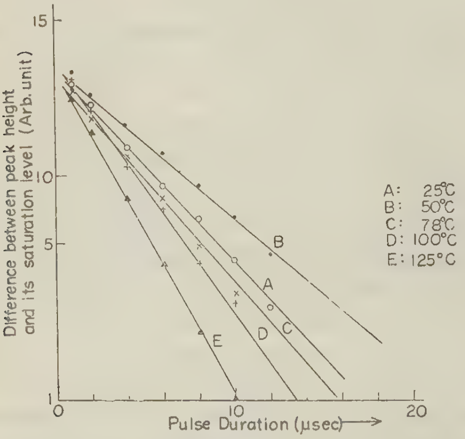

Fig. 14. Semi-log plot of curves in Fig. 13 for each temperature.

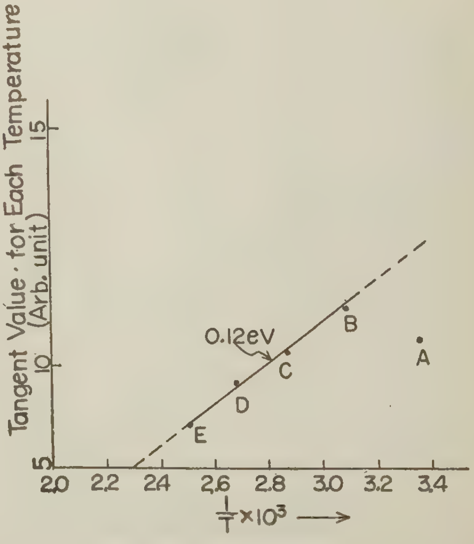

Fig. 15. Temperature dependence of slope in Fig. 14.

14. The logarithmic values of slopes of these curves in Fig. 14 are plotted in Fig. 15 against temperature and we obtain the activation energy of about 0.12 eV except only one point corresponding to room temperature. The variation of this activation energy with the applied voltage can not be observed between 600 to 900 volts.

Comparing with the results of the voltage dependences of the intensity mentioned above, these results are very interesting and will be discussed later.

(f) *Dependences on the repeating frequencies of exciting pulse*

The luminescent brightness are nearly independent of the repeating frequencies of exciting pulse up to 1 kc/s, therefore the repeating frequencies under 1 kc/s are used throughout in this experiment except that of the build-up characteristics mentioned in the next section.

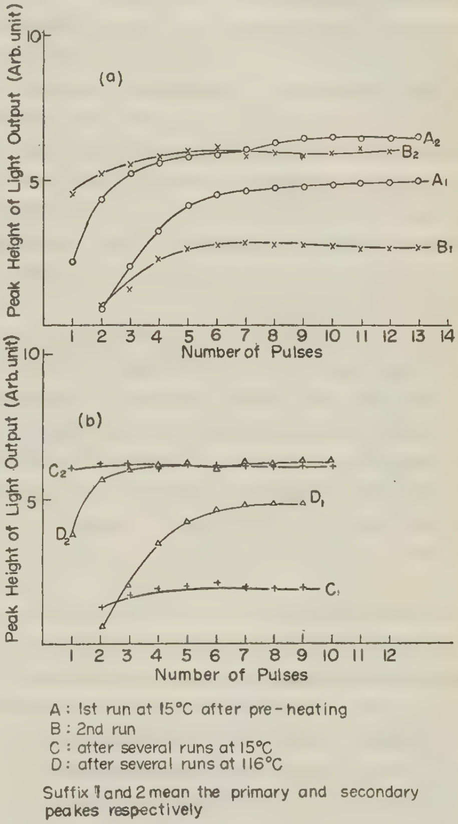
(g) *Build-up characteristics*

The build-up phenomena is important to understand the mechanism of electroluminescence. That is, the processes of the formation of local intense field in the phosphor powder, and the trapping of excited electrons in the anode region, take parts in this phenomenon as mentioned by Zalm. The electrons trapped elesewhere may not be able to escape for considerably long time after electric excitations at room temperature, and so the preheating of the sample up to high temperature is necessary to obtain the precise results of the build-up characteristics. In our experiment, these phenomena are observed by the single sweep method using a synchroscope and the considerably high repeating frequencies of the exciting pulse are used, since the precise observations are obtained only at high frequencies by this method.

The samples are heated at about 120°C for half an hour and cooled to room temperature in the dark, and then the measurements are made at room temperature. The first and the second runs of the measurements after preheating give clearly different results as shown in Fig. 16. The measurements are made at 116°C and 25°C, and when the exciting pulse of duration of 2 microseconds and of 50 kc/s frequency is used, the obtained results are as follows:

(1) In all cases the first peaks are smaller than the second ones, and at first application of the exciting pulse the first peaks are too small to be measured accurately.

(2) At 116°C the second peaks saturate at fifth pulse, and the first peaks grow more slowly and saturate at eighth pulse. The saturated values of the first peaks are about 80% of those of the second peaks. On the other hand, the first peaks are only few percent of the second ones in the case of low repeating frequencies as explained in the preceding sections. These differences of the brightness waveforms with the repeating frequencies may be interesting problem, though the detailed discussions are not made in this paper.



Voltage	Pulse duration	Repeating freq.
900 Volts	2 μsec.	50 Kc/s

Fig. 16. Build-up of electroluminescence excited by pulse field.

(3) At room temperature the results from the preheated samples are similar with the former case, at least in the first run, except the slower build-up than at 116°C, but in the second run of the measurement the results

are considerably different. In the second run, the first peaks are smaller by a factor of two than the first run, and the second peaks grow faster, although the values of the saturated peaks are almost equal to the ones in the first runs. Thus the saturated first peaks are becoming smaller with the measurement runs, while the saturated secondary peaks are almost constant.

In the case of another exciting condition, (duration of 10 microseconds and repeating frequency of 5 kc/s), the general features are similar to the former case, but the ratio of the saturated values of the first and the second peaks is smaller than the former case even in the first run, and this might be due to the exciting conditions which are similar to the continuous excitations mentioned in the preceding sections.

From the above results, we can conclude that the build-up characteristics of electroluminescence are greatly affected by the trapping of excited electrons, and the brightness waveforms are also considerably sensible to this electron trapping (or the space charges formed by the positively charged excited centers).

§ 4. Discussions

The experimental results described in the previous sections are closely connected one another and therefore the unified discussions about these results are necessary to clarify the mechanism of electroluminescence. The mechanism of the electroluminescence has been discussed by many workers from different points of view, and the favourable theories are proposed at least in the basic points. Piper and Williams[2] compared theoretically the possible cases of the excitation mechanism and concluded that the impact ionization of luminescent centers by fast electrons is the most acceptable.

We are going to settle the mechanism of the excitation and recombination processes in electroluminescence as follows and will discuss the experimental results in later sections.

To obtain the electroluminescence, the primary electrons have to be accerelated by the externally applied electric field until they get enough optical energy i.e. the energy corresponding to the forbidden gap or the one from the ground state to the conduction band. We assume that the local intense field is generated just near the surface of phosphor particle dispersed in dielectric medium as proposed by Piper, Williams[2], Curie[1] and Zalm[3], and the excitation processes are raised up only in this region. Moreover an extensive low field region in series with this high field region permits operation over a broader range of applied voltages without creation of unstable breakdown condition. Schematic diagram of this situation is shown in Fig. 17. In the first region (cathode side of the particle) the primary electrons are generated from the donors or traps by the field- or thermal-ionization processes, and these electrons risen in the condition band are accerelated in the second region, in which the local intense field stronger than mean field about by a factor of ten is generated. The electrons in the ground states of the centers or in the filled band are excited up to the conduction band by inelastic collisions with the fast primary electrons. It may be possible that the 1st and 2nd regions overlap each other in some phosphors. The secondary electrons ejected up to the conduction band flow with the primary electrons by the external field to the third, low field region, and stay there during the application of the external field. When the applied field is off, the electrons in the 3rd region begin to come back to the 2nd region, and recombine with the ionized centers to emit the light. As the ionized centers left in the 2nd region are positively charged, the positive space charge layer grows in the second region and therefore the inner field is strengthened, until the steady state is established.

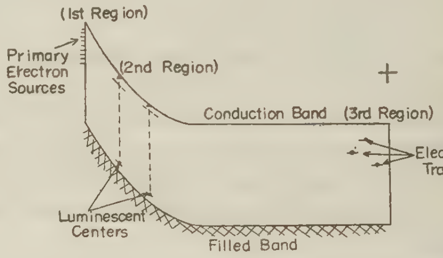


Fig. 17. Band model of electroluminescence in ZnS:Cu, Pb phosphor.

The excitation probability (multipication factor) in the 2nd region is roughly estimated as follows: the probability that an electron in electric field is accerelated to ionization energy without a collision with the crystal lattice is given by Seitz[8)] as

$$p=\exp\left(-\frac{c'}{F}\right), \tag{5}$$

where c' is a constant, and this factor is estimated by Callen[9)] as about 2.3×10^6 volts/cm at room temperature. Therefore the number of secondary electrons produced while n primary electrons move dx, is given by

$$dn=\frac{n}{\mu\tau F}\exp\left(\frac{-c'}{F}\right) \tag{6}$$

where μ is the electron mobility and τ is the collision time of electron with the lattice and F is the field strength.

Therefore the total number of centers excited during the excitation process is

$$n-n_0=n_0\left\{\exp\left(a\int_0^{F_{\max}}\frac{\exp(c'/F)}{F}dF\right)-1\right\} \tag{7}$$

where a is dx/dF, n_0 is the number of primary electrons, and $F_{\max}$ is the maximum field strength in the barrier.

Zalm indicated that the multiplication factor is smaller than 1 and then the Eq. 7 is approximately expressed by

$$n-n_0\sim\exp\left(\frac{-c'}{F_{\max}}\right) \tag{8}$$

in the case of ZnS single crystal, in which the primary electrons penetrate through the potential barrier between crystal and metal electrode and the inner field is calculated simply under assumption of Mott-Schottky type exhaustion layer as discussed by Piper and Williams.

In the case of intrinsic electroluminescence, on the other hand, the source of primary electrons and the situation of the inner field are not clear enough. But according to Zalm the strength of the inner field in the 2nd region is nearly expressed as follows:

$$F=A\sqrt{V}, \tag{9}$$

where A is a constant, and this expression is the same as in the case of single crystal above mentioned. Therefore the voltage dependence of electroluminescent brightness is

$$B=B_0\exp\left(-\frac{c}{\sqrt{V}}\right) \tag{10}$$

from Eqs. 8 and 9 where B_0 and c are constants. This equation is the same as Eq. 4 and is the suitable expression for experimental results in the wide range of applied voltages as reported by many investigators.

The problem of the primary electron source seems to be fairly critical, as the electroluminescence is the field-dominated phenomenon. Piper and Williams[2)] proposed a model in which the deep lying donors are the source of them, and calculated the voltage dependences under the assumption of the field ionization of these donors. On the other hand, Taylor and Alfrey[7)] assumed that the primary electrons are generated thermally from the electron traps and analysed their experimental data of frequency dependences of electroluminescence. Moreover Zalm assumed that the donors in the interface layer between ZnS and Cu_2S which exists on the surface of the phosphor particle, are the primary electron sources, and the variation of the distribution of these donors hardly affects the voltage dependences of electroluminescence mentioned in Eq. 10. It seems, however, that the effects of electron traps and donors on the excitation of electroluminescence are considerably complex. Actually Johnson, Piper and Williams[10)] explained the temperature dependences of electroluminescence under the assumption that the traps may supply the primary electrons by field ionization at low temperature and on the other hand they are thermally emptied, enhancing the field strength in the 2nd region at high temperature.

In this paper we compare these mechanisms of the primary electron generation in detail in Sect. 4 (d).

The processes of the excitation and recombination above mentioned are only outlines of the electroluminescent phenomena, which are very complex and give diverse results in various samples. In the following sections, the detailed considerations about the experimental results in our samples will be made and some mechanisms will be proposed.

(a) *Emission spectra and luminescent centers*

In our experimental results described in Sect. 3 (a) the spectral distributions of electroluminescence excited by short field pulses shift considerably to the shorter wavelength compared with the case of sinusoidal field excitations even at very low repeating frequencies. As the emission peak of the electroluminescence excited by sinusoidal field shifts to the shorter wavelength with frequency as shown in Fig. 1, the pulse excitation might be considered corresponding to the sinusoidal excitation of considerably high frequency. Phenomenologically speaking, the pulse excitation used in this experiment might correspond to the sinusoidal excitation of the frequencies of 100 to 50 kc/s, since the luminescent decay times are 5 to 10 microsecond in the case of pulse excitation (Sect. 3 (b)).

Now we must consider the luminescent centers in ZnS:Cu, Pb phosphors. From the photoluminescent data the emission peaks of ZnS:Cu phosphors lie at the wavelengths of about 460, 520 and 670 mμ[11]. On the other hand, another peak might exist due to lead activators as indicated by Fonda[12]. In the case of electroluminescence of our samples, however, it is considered that the luminescent centers corresponding to the first two emission bands emit the light prepominantly (blue and green centers), and these features coincide with the results obtained by Waymouth[13] and other workers. Green peaks are predominantly observed at the low frequency sinusoidal excitations and at high temperatures, and blue peaks at high frequencies and low temperatures. Besides, these temperature dependences of the spectral distribution are similar to the case of photoluminescence of ZnS:Cu phosphors (e.g. Tomlinson)[14]. Though the several mechanisms about the problem of colour shift in electroluminescence above mentioned are proposed by Zalm, Curie, Tomlinson, and Goffaux[15] based on some assumptions about luminescent centers, it seems that the critical evidence does not exist yet. Moreover, Burns[16], and Nudelman and Matossi[5] indicated that the color shift of electroluminescence in ZnS phosphor can be explained with the assumption of the different excitation mechanisms in the blue and green centers. They assumed that the blue luminescence is due to the excitation of electron from the ground level to some excited level within this center, followed by an almost immediate direct transition to ground level, and the green luminescence, on the contrary, is due to some phosphorescence processes with a delaying mechanism such as traps or metastable states and with transitions involving the conduction band. In our experiments, however, these excitation processes are not the case, since the most excited electrons may be risen to the conduction band as indicated in the following section.

Therefore the color shift in our samples is probably due to the difference of the recombination process in two types of centers, or the hole migration mechanism. If we assume the hole migration mechanism from blue to green centers as Zalm and others (Klasens and Schön's theory)[17], the followings are necessary to explain the experimental results. (1) the cross section of blue centers for impact ionization is much larger than that of green centers, or (2) the cross section of the filled blue centers for the hole trapping is much larger than that of green centers, if the ionizing process is attained only by the collisions of lattice atoms and fast electrons.

(b) *Brightness waveforms*

As described in Sec. 3 (b) the brightness waveforms of the electroluminescence excited by the short pulse fields are considerably different from the ones excited by the sinusoidal fields. In the brightness waveforms excited by pulse fields the first peaks are much smaller than the second ones, and this result indicates that the recombination process is raised up mainly after the excitation is cut off but not during the excitation. Because the short pulses used in this experiment are the DC pulses, it may be impossible that the reverse field generated by the polarization charges overcomes the externally applied fields.

We can expect also from the smallness of the first peaks that the probability of the excitation, in which electrons transit from the ground state to the excited state and drop immediately to the ground state, is very small. The recombination probability where the accerelated electrons in the 2nd region recombine with the excited centers in this region, may also be small. The transit time of fast electrons necessary to pass the 2nd region might be estimated as:

$$T=\frac{d}{\mu F}, \tag{11}$$

where d is the depth of the 2nd region which is about 10^{-3} cm, μ is the electron mobility which is about 100 cm^2/volt. sec., and

F is the field strength of about 10^6 volt/cm, and so T is about 10^{-11} sec.. As the decay time of the electroluminescence is over 5 microseconds as described in Sec. 3 (d), it may be considered that the greater part of the free electrons are moved to the 3rd region without recombinations.

The asymmetry of the brightness due to the polarity of field applied to the cell may be considered as follows: the luminescence occurs always in the 2nd region which is in the cathode side of the particle, and the emitted light is absorbed or scattered by phosphor powder going through the cell. Therefore if the emission is observed from the cathode side, the brightness may be larger than the reverse case.

From these points of view, this experiment is the direct evidence for the excitation and recombination mechanisms settled in the previous section.

(c) *Voltage dependences of brightness*

The voltage dependences of electroluminescent brightness are closely connected to the voltage dependences of excitation probability of the luminescent centers, which involve the relation between the inner and externally applied fields.

If we assume that the exponential factor in Eq. 10 is independent of the the mechanism of the generation of the primary electrons, the constant factor c is

$$c = c'/A, \tag{12}$$

introducting Eq. 9 to Eq. 10. Therefore the larger the c-value is, the weaker the inner field is.

In our experiments, the c-value in the case of sinusoidal excitation is about 130 $(\text{volts})^{1/2}$ at room temperature, and this value is of the same order as that of Zalm's data. On the other hand, the c-value in the case of pulse excitation is about 250 $(\text{volts})^{1/2}$, and this value is nearly twice as much as in the sinusoidal case. These results seem to be due to the difference of the emitting particles, or the difference of the inner field strength of the same particle in each cases. The c-values of the individual particle of phosphor may be distributed in certain wide range and the particles which have small c-values contribute mainly to the luminescence. There are, however, no reasons why particles having large c-values can emit the light predominantly even in the case of pulse excitations. In any case, it might be considered that the c-values in all particles become larger in the case of pulse excitation than in the sinusoidal case. If the inner field in the 2nd region is weaker in the pulse excitation than in the sinusoidal case even at the same peak voltage, the c-value becomes larger and the luminescent brightness becomes lower in the forme case. This is just the case of our experimental results. That is to say, the strength of the inner field as smaller by about a factor of two in the pulse excitations.

The strength of the inner field might vary with the frequency of applied field, if the dielectric relaxation of dielectric medium of the electroluminescent cell occurs in the frequency range of applied field. In our case, however, this is not true, for in the silicone oil the relaxation may occur only above 10 Mc/s and furthermore the preliminary experiments using binderless cell gave the same results as reported here.

In any case, it might be sure that the reason for the weakness of inner field in the case of pulse excitation is the electronic phenomena in the phosphor particle, that is, the positive space charges in the 2nd region or the polarization field consisting of the trapped electrons in the deep traps in the 3rd region. Assuming the Mott-Schottky type exhaustion barrier in the 2nd region, the maximum field strength is

$$F_{\max} = -AV^{1/2} \tag{13}$$

and

$$A = (8\pi Ne/\mathcal{E})^{1/2}, \tag{14}$$

where V is the applied voltage, N is the space charge density in the barrier and $\mathcal{E}$ is the dielectric constant of the crystal. The field strength is proportional to the square root of the space charge density in this region. Therefore the space charge density in the case of pulse excitation might be one-forth of the density in the case of sinusoidal excitation.

Maeda[18) calculated the strength of the inner field under special assumptions, and indicated that a field strong enough for electroluminescent phenomenon can be obtained, even if there are no space charges in the 2nd region. From our discussions, however, the positive space charges in the 2nd region seem to play an important role in the generation of local intense field, because it seems that there might be no difference of the field strength in two cases according to the Maeda's considerations.

(d) *Dependences of brightness on the pulse duration*

The dependences of the electroluminescent brightness on the pulse duration mentioned in Sect. 3 (e) may involve essentially the transient phenomena in electroluminescent mechanism. It may be considered that the increase of the brightness with the pulse duration is due to the increase of the number of primary electrons. The reason for the increase of primary electrons with the pulse duration may be considered in two cases as follows. First, if we assume that the primary electrons are generated thermally from the donors or traps in the 1st region which may be in the interface layer between the surface conductive layer and ZnS, the number of paimary electrons generated per unit time at the time t after the application of field is expressed by

$$n=n_0 p \exp(-pt) , \tag{15}$$

where

$$p=s \exp\left(-\frac{E}{kT}\right) , \tag{16}$$

where n_0 is the number of electrons in the donors or traps before the application of the field and s is the frequency factor and E is the depth of the donors or traps. Therefore, the electroluminescent brightness increase with the pulse duration τ as

$$\int_0^\tau n dt=n_0(1-\exp(-p\tau)). \tag{17}$$

This equation seems to coincide with our experimental results illustrated in Figs. 13 and 15. The depth of donor or trapping level obtained from the experimental results, however, seem to be too small compared with the trap depth usualy obtained from the glow curve data.[4] Therefore, it might be considered that the shallow donors in the interface, in which the band gap might be considerably smaller than the one of ZnS, are the sources of primary electrons.

Second, if we assume that the primary electrons are generated from the donors or traps by the field-ionization directly, it must be concluded that the field strength in the 1st region increases with the time while the pulse field is applied, and so the longer the time is, the deeper the emptied level is. The analysis of this process is so complex that we consider some simple case. For simplicity we assume that if the field strength overcomes F, the levels lying at depth E are ionized immediately, and the relation between E and F is[13]

$$F=\text{const.}\, E^{3/2}. \tag{18}$$

Moreover, assuming that the distribution of levels in the 1st region is

$$n(E)dE=g(F)dF , \tag{19}$$

and F increases with time as

$$F(t)=F_0+f(t) , \tag{20}$$

where F_0 is the field strength generated instantaneously and $f(t)$ is the one increasing after the application of external field. The electroluminescent brightness may increase as

$$B(t)=B_1\int_0^F g(F)\cdot\exp(-c/F)dF . \tag{21}$$

Putting $F_0 \gg f(t)$, the above equation becomes

$$B(t)=B_2\int_0^f g(F_0+f)\exp(cf)df+B_2' . \tag{22}$$

Now we assume that the function $g(F_0+f)$ is the slowly-varying one, and so Eq. 22 may become

$$B(t)=B_3\int_0^t \exp(cf(t))\cdot\frac{df}{dt}\cdot dt+B_2' . \tag{23}$$

The function $F(t)$, which indicates the process of space charge formation, might be estimated as follows. If we assume that the space charges in the *2nd* region increase by the thermal releasing of the trapped electrons, the space charge density increases as

$$N=N_0+N_T(1-\exp(-pt)) , \tag{24}$$

where N_0 is the space charge density being generated instantaneously and N_T is the density of trapped electrons at $t=0$. As the field strength is expressed in Eq. (13) and (14), the field strength in this case is

$$F=F_0+apt , \tag{25}$$

where a is a constant.

Therefore, the brightness is

$$B(t)=B_0'\int_0^t \exp(capt)dt+B_0'' = B_0\exp(capt)+B_0'' . \tag{26}$$

This equation is clearly inconsistent with our experimental results, and so the mechanism assumed in the former case may contribute to this phenomenon at least in this phosphors. Moreover the experimental results which indicate the invariance of the curve shape with the applied voltages as indicated in Sec. 3 (e), may confirm this conclusion.

The latter case, however, seems to play a certain role in electroluminescent phenomena. For the light output excited by the 0.5 microseconds pulse in duration at room temperature is almost the same as that excited at liquid air temperature; and in the further investigations now in progress,[20] in which very short pulses (almost 30 millimicroseconds in duration) are used, considerable light outputs are still observed. These facts indicate that the primary electrons generated by the direct field-ionization may be effective in some parts of excitation of electroluminescence as discussed by Piper and Williams.

(e) *Decay of electroluminescence*

The study of the luminescent decay in this paper gives us the interesting results in considering not only the recombination process but also the excitation process. As explained in Sec. 3 (c) the luminescent decay obeys the bimolecular law at least in the beginning, and furthermore the constant factors An_0 are almost the same in spite of the different exciting voltages. From the formal interpretation it means that the initial density of the ionized centers at $t=0$ in the 2nd region is nearely independent of the exciting conditions.

The alternative interpretation, in which it is assumed that these decay times are composed of the time necessary to come back to the 2nd region from the 3rd region and the time staying at the excited states of the blue centers, will lead to the inconsistent results with experiments. First, the time necessary to come back to the 2nd region is estimated from the equation similar to Eq. 11, though the field strength by the polarization charges can not be determined precisely. If we assume that the polarization field is as low as 10 volts/cm and the particle size is about 10μ, the transit time is about 1 microsecond. Furthermore, if we assume that the process in which the electrons flow back to the 2nd region is the rate-determining process, the monomolecular law may predominate in the recombination processes as indicated by Zalm. This problem will be discussed later again. Second, if the optical transition of electron from the excited state to the ground state of the luminescent center is the rate-determining process, the luminescent decay must obey the monomolecular law, and moreover the life time of the excited state may be considerably shorter than 1 microsecond as indicated by Mott and Gurney[19].

In any case we shall have to consider more precisely the reason why the bimolecular mechanism predominates the recombination process. Zalm indicated that the phase shift of the peak in the brightness waveform excited by sinusoidal field can be explained under the assumption of monomolecular law. This means that the free electron density flowing back from the 3rd region is considerably smaller than the density of ionized positive centers in the 2nd region and so the electron flow to the 2nd region is the rate-determining process. His assumption, however, loses its validity in the case of small excitation intensity. As indicated in Sec. 4 (d), the excitation probability in the case of pulse field is much smaller than in the case of sinusoidal excitation, although the number of primary electrons seems to be the same order in both cases as shown in Fig. 11. Furthermore, the trapping effect in the 3rd region during the application of the external field may decrease, if the pulse duration is considerably short as discussed later, and so the electrons staying in the 3rd region may come back to the 2nd region instantaneosely as soon as the external field is removed even in the low polarization field.

From these points of view, it may not be impossible that the bimolecular recombination process between the free electrons and ionized centers is the rate-determining one in the case of short pulse field excitations.

Surely it is an interesting fact that the decay time is nearly independent of the voltages of applied field. This fact, however, is explained under the assumptions as follows: (1) the number of primary electrons is greatly larger than the secondary ones generated by impact ionization of luminescent centers, and (2) the recombination cross section of the ionized center is the same as that of primary electron sources which are ionized thermally or directly by the externally applied field. The assumption (1) is justified from Eq. 7 in Sec. 4 even in the case of pulse excitations. On the contrary, there are no foundations to insist on the assumption (2), because the structure of primary electron source is not clarified up to date.

If we assume that there are two kinds of ionized centers and the number of the one is considerably greater than the other, the recombination process is expressed by the following equations,

$$-\frac{dn_1}{dt}=An_1(n_1+n_2)\ ,$$

$$-\frac{dn_2}{dt}=Bn_2(n_1+n_2)\ , \tag{27}$$

where n_1, n_2 and A, B are the densities and the recombination factors of two kinds of centers respectively, and from the above assumption $n_1 \gg n_2$. Therefore we can write approximately,

$$-\frac{dn_1}{dt}=An_1^2\ ,$$

$$-\frac{dn_2}{dt}=Bn_1n_2\ . \tag{28}$$

The solutions of these differential equations are

$$n_1=\frac{N_1}{N_1At+1}\ ,$$

$$n_2=\frac{BN_1N_2}{(N_1At+1)^{B/A}}\ , \tag{29}$$

where N_1, N_2 are the initial values of n_1 and n_2 at $t=0$ respectively. Therefore, the light output from the second centers may decay as:

$$L=\frac{BN_1N_2}{(N_1At+1)^{(B/A)+1}}\ . \tag{30}$$

This Eq. 30 indicates that the decay of light output from the second centers may obey the bimolecular law if the recombination factors A and B are equal under the assumption (2). Furthermore, the decay time becomes independent of the initial density of the second ionized centers, N_2. This means that the decay time does not vary with the applied voltages, if the number of primary electrons N_1 are independent of the applied voltages. As stated in Sec. 4 (c) and (d), it seems that the number of available primary electrons in the excitation is the same, if the temperature and the pulse duration have the definite values.

Of course, the luminescence decay might obey also the bimolecular law, if the recombination factor A is considerably greater than B and the decay of n_1 is very rapid comparing with that of n_2. Furthermore, as the width of exhaustion barrier which coincides with the 2nd region spreads with the applied voltage proportional to its square root, the density of ionized centers may not increase as expected from the light outputs. If we assume that the density of ionized centers is uniform in the 2nd region, the decay time may be expressed as

$$\tau \propto \sqrt{\frac{\sqrt{V}}{I_0}} \tag{31}$$

(for $I_0 \propto n_0^2\sqrt{V}$),

where V is the applied voltage and I_0 is the initial value of light output at $t=0$. As the light output I_1 excited by the pulse of 900 volts in height is 6.5 times larger than I_2 excited by the 600 volts pulse from Fig. 10, so

$$\tau_2 \doteqdot 2.3\tau_1\ , \tag{32}$$

where τ_1 and τ_2 are the decay times corresponding to I_1 and I_2 respectively. The Table II indicates that the decay time does not vary as expected from the above equation especially at high temperature.

In any case, we can estimate the density of centers which plays a role mainly in determining the decay time from Eq. 3. If we assume that the thermal velocity of free electron is 10^7 cm/sec, and the recombination cross section of centers is 10^{-18} cm^2, the density of ionized centers is of the order of 10^{16} cm^{-3}. This value is rather too small and it seems that the recombination cross section is slightly smaller than the value given here.

The trapping effect in the 3rd region may appear in some cases. The free electrons in the 3rd region may decrease with time during the application of field by trapping phenomena as the following equation,

$$-\frac{dn}{dt}=\sigma_T vnN_T\ , \tag{33}$$

where σ_T is the trapping cross section of electron traps, v is the thermal velocity of free electrons and N_T is the trap density. Assuming that $n \ll N_T$,

$$n=n_0\exp(-\sigma vN_Tt)\ . \tag{34}$$

When the externally applied field is removed, the remaining electrons in the conduction band begin to come back to the 2nd region, and the number of free electrons coming back to the 2nd region may decrease with the pulse duration as expected from Eq. 34. Therefore the decay time may be longer for longer pulse duration, as the luminescent decay obeys the bimolecular law. The results illustrated in Fig. 9 may be the case.

The analysis of electroluminescent decay seems to be interesting but considerably difficult problem, as the ionized centers and the electrons are not always distributed uniformly in the material, and the space charge layers and polarization fields might affect the decay time as discussed by Matossi[5] and Frankl[21].

(f) *Build-up characteristics*

As explained in Sec. 3 (g), the build-up of electroluminescence might be due to the trapping phenomena of excited electrons. That is, some part of secondary electrons excited by electron impacts may be trapped in the deep traps in the 3rd region and then they can not come back to the 2nd region for certainly long time comparing with the time from pulse to pulse. Therefore the ionized centers may be left without the radiative recombinations in the 2nd region, and the field strength in this region and so the light output may grow gradually with the number of the repeating pulses, until the stationary state is established.

From the glow experiment of photoluminescence reported before[4], it is clarified that there are two types of electron traps, the depths of which are about 0.35 eV and 0.47 eV respectively (the frequency factor is estimated as $10^{10}\,\text{sec.}^{-1}$ in both traps). The other types deeper than these traps might exist in this phosphor, i.e. surface traps and etc., as the build-up character as illustrated in Fig. 17 (a) could not be observed for a long time after several runs of measurements at room temperature unless the preheating is made.

It is likely, however, the two types of traps above mentioned are effective enough to build-up the electroluminescence at the repeating frequency of 50 kc/s. The results shown in Fig. 17 (b) indicate that the build-up character can be observed still after several runs of measurements at 125°C. This means that the traps, from which the electrons can scape thermally within a comparatively short time at this temperature, may be effective to this character. The probability that an electron escapes to the conduction band from the trap of 0.47 eV depth at 120°C, is estimated as

$$p=s\cdot\exp\left(-\frac{E}{kT}\right)\doteqdot 3\times10^{+3}\,\text{sec}^{-1}\,. \qquad (35)$$

Then these traps seem to be effective in this repeating frequency of exciting pulse of 50 kc/s, though the probability of electron trapping is not determined precisely.

§ 5. Summary

The electroluminescence phenomena in ZnS: Cu, Pb phosphors excited by the short field pulses are investigated and the excitation and the recombination mechanisms are discussed. From the experimental results of emission spectra, brightness waveforms, dependences of light outputs on the applied voltages and pulse durations, decay times, build-up characteristics and their temperature dependences, the following considerations are made: the local intense field generated at the cathode region of particle accerelates the primary electrons and the luminescent centers are impact-ionized by these primary electrons. The field strength may be smaller than in the case of sinusoidal fied excitation and then the excitation efficiency of primary electrons greatly decreases compared with the latter case. The primary electrons are partly generated thermally and partly by the direct field-ionization. The blue luminescent centers are mainly excited and they emit the light predominantly without the hole migration mechanism. Besides, the decay times and the build-up characteristics are affected by the trapping effects in the anode region of phosphor particle.

The author considers that the electroluminescence excited by short field pulse has the complementary nature to the one excited by the sinusoidal field, and further experiments are now in progress.

§ 6. Acknowledgments

The author wishes to thank Professors Y. Suge and T. Inui for their continuous and helpful encouragements, and Mr. K. Sugiyama and M. Wakatuki for their helpful assistances, and Mr. M. Kobayashi for his advices in the measuring equipments.

The author also wishes to thank Mr. T. Toriu of Dai-Nippon Toryo Company for giving him the phosphor samples, and Mr. S. Kawashima of NHK Technical Laboratory for his helpful discussions.

Dielectric Susceptibility Tensor of Cadmium Sulfide

By Taizō MASUMI*

Department of Applied Physics, University of Tokyo, Tokyo, Japan

(Received March 27, 1959)

The components of static dielectric tensor $\|\kappa_{s_{ij}}\|$ of wurtzite cadmium sulfide have been examined. An anisotropy of κ_s was found between the two crystal orientations [$2\bar{1}\bar{1}0$] and [0001], that provides some suggestive knowledges on the lattice vibration spectra of cadmium sulfide and on the scattering mechanisms of electrons in several semiconductors.

A systematic examination on the dielectric susceptibilities over several semiconductors gives us various knowledges about the nature of the binding between constituent atoms of the crystals. Homopolar binding is more important in usual semiconductors than in inoic crystals. In such cases, the dielectric constant measurement provides a sensitive test of the natures of the binding1),2) as well as the elastic constants measurement1),3).

Cadmium sulfide single crystals have been studied up to now about flaky crystals with prefered crystal orientations prepared by vapour phase or sublimation processes at near atmospheric pressures. Kroeger et al4). had performed the capacitance measurements for ribbon-shaped cadmium sulfide crystals at 1 and 100 kc/sec and obtained the low frequency dielectric constant $\kappa_s=11.6\pm1.5$ for insulating specimens. However, it is supposed that the applied field $\boldsymbol{E}$ in their measurements may

An example of experimental values of static dielectric constants of hexagonal cadmium sulfide at room temperatures. * By resonant circuit and at 20°C. (After Taizō Masumi)

have a direction parallel to the crystal orientation $[2\bar{1}\bar{1}0]$ for flaky crystals. Medcalf and Fahrig[5)] have recently developed a method of growing cadmium sulfide single crystals of uniform size, shape and homogeneity from the melt at high pressures and temperatures By using such specimens, the author has been able to find the anisotropy in static dielectric constant of cadmium sulfide single crystals. The present re-examination on the dielectric susceptibility tensor supported by the progresses in crystal growing technique[6)] has an aim to study the lattice vibration spectra and scattering mechanism of electrons in cadmium sulfide.

Samples used for our experiment are not ribbon-shaped crystals, but specimens cleaved, machined and polished from cadmium sulfide ingots produced by the Eagle-Picher Company. Sizes of specimens are of about $0.5\sim0.8\,\mathrm{cm}^2$ in area and $0.07\sim0.5$ cm in thickness (parallel to the $[2\bar{1}\bar{1}0]$ or [0001] direction). Static dielectric constant κ_s is determined by the lumped circuits, that is, by the null method involving some types of capacitance bridge in the medium frequency range or by a resonant circuit for the dielectric measurement in higher region. The whole frequency range extends from 10^2 cps to 50 Mc/sec in our experiments. Particular attentions should be paid on photoconductivity phenomena in the crystal as remarked by Kroeger et al.[4)]. We also used the crystals kept in dark for at least a day before observations.

An example of experimental results on a specimen is shown in Table I for κ_s, where the loss factor $\tan\delta$ has not been studied. These values may involve some degrees of errors because no correction were made for edge effects. Slight increases in observed dielectric constants at lower frequency region may be due to the inhomogeneity in resistivity.

The amounts of impurity atom in the specimens are of the orders of 10^{-4} for zinc and indium and 10^{-5} for silicon. We neglected also the temperature effect that is unlikely to be large.

As shown in Table I, the observed dielectric constants of cadmium sulfide single crystals show a remarkable difference between the $[2\bar{1}\bar{1}0]$ and [0001] directions, while we have not observed any appreciable anisotropy in the (0001) plane. Frequency dependence of κ_s scarecely has been recognized for each direction. The probable values of κ_s over several specimens are found to be as follows;

$$\kappa_{s[2\bar{1}\bar{1}0]}=10.8\pm1.6 \quad \text{at } 15°\text{C}$$

$$\kappa_{s[0001]}=7.8\pm1.4 \quad \text{at } 15°\text{C}$$

$$K_{\kappa_s}=\frac{\kappa_{s[0001]}}{\kappa_{s[2\bar{1}\bar{1}0]}}=0.73 \quad \text{at } 15°\text{C}\,.$$

These results on the dielectric susceptibility tensor of wurtzite type cadmium sulfide suggest us that there exist some anisotropies in the effective charge of constituent ions and/or in the restoring force against their displacements, from which we can easily derive the dispersion relation for the longitudinal optical branch depending on (σ/σ) and also imagine an anisotropic energy surface $\hbar\omega(\sigma)=$const. in σ-space, where σ denotes the phonon wave vector. It may be possible that these situation play some roles in the scattering mechanism anisotropy of electrons in some types of semiconductors[7)-10)]*.

---

*) Some situations parallel with those for cadmium sulfide had been recognized also for semiconducting rutile TiO_2, although they have been rather neglected up to now.

The author would like to express his sincere gratitudes to Professor Y. Suge and Professor T. Inui of Tokyo University for their continual encouragements, and to Professor Y. Uemura of the University for his kind critiques and discussions. Sincere thanks are also, especially, due to Dr. H. Mimura, Dr. T. Tanaka and Dr. M. Kobayashi for their helpful discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 9, SEPTEMBER, 1959

On the Screening of Impurity Potential by Conduction Electrons

By Noboru TAKIMOTO

*Department of Physics, University of Tokyo**

(Received April 15, 1959)

A detailed investigation is made on self-consistent impurity potential in a charge cloud of conduction electrons. It is shown first that the Thomas-Fermi method can be used so as to include a certain correlation effect between the conduction electrons which is ignored in customary theories. The same problem is then treated by the method of Nakajima and Bardeen and Pines and it is shown that it leads to essentially the same result as that obtained by the Thomas-Fermi method. The obtained potential differs from the usual one in the fact that the screening parameter now depends on the way of the scattering. Some discussion is given about the equivalence of the two methods and further possible improvement. The potential thus derived is then used for the calculation of the electric resistance governed by the impurity scattering.

§1. Introduction

The method of Thomas-Fermi (T.F.) has often been used in deriving self-consistent potential due to a lattice imperfection embedded in a sea of conduction electrons. This method is of statistical nature and is based on the assumption that when one is interested in the interaction between one particular electron and a certain lattice imperfection, all the other conduction electrons are in local thermal equilibrium in the field of the imperfection as well as of the particular electrons*, i.e., the heaping up of screening electrons (or holes) is partly due to the thermal contact of these electrons (or holes) with the other degrees of freedom localized around the imperfection. It can also be shown that if the conduction electrons and the imperfection are treated as isolated from any other systems, the same result is obtained for the screening. In this case the screening arises entirely from the adiabatic deformation of the charge distribution of the conduction electrons. However, when the assumption of the local equilibrium or of the adiabatic motion of the screening electrons ceases to be valid**, the T.F. method allows no further refinement. Thus one needs some other method which treats the same problem from a dynamical point of view. A great deal of work has been done from such a point of view for the problem of the electron-phonon interaction, but nothing so far for the problem of the impurity scattering***. In early investigation of the electron-phonon interaction, two alternative assumptions were adopted with regard to the charge distribution of the conduction electrons in the field of thermally distored lattice: Nordheim[1)] assumed it rigid, while Bloch and Bethe[2)] assumed it deformable. However, the difference between the potentials they adopted was only formal.

---

* Present Address: Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai, Japan.

Later, this problem was treated in more detail by Bardeen[3)], who noticed the adiabatic deformation of the charge distribution in the distorted lattice and thus confirmed Bloch-Bethe's assumption. At the same time he derived the self-consistent scattering potential with use of the T.F. method.

More recently, Fröhlich[4)] used a field theoretical technique to treat the adiabatic part of the electron-phonon interaction systematically, and showed that the adiabatic motion of the conduction electrons reduces the phonon velocity to what is actually observed. Fröhlich's work was then extended by Nakajima[5)], who showed that Bardeen's potential can be derived in a more straightforward manner from the original Hamiltonian through a certain transformation. He showed also that Fröhlich's renormalization procedure of the phonon velocity can be extended to include the interaction between the electrons.

Finally, Bardeen and Pines[6)] superposed on the Nakajima's method the collective treatment of Bohm and Pines[7)], and eliminated a great part of the e-e interaction which makes the collective modes. The previous results, however, remained essentially unaltered.

It is clear that the same arguments can be applied to the problem of the impurity scattering, which will be treated in the following. The adiabatic motion of the conduction electrons which reduces the phonon velocity in the electron-phonon case now results in the deformation of their charge distribution in the field of impurity atoms, and this gives rise to the screening effect. The mathematical parallelism between these two cases is almost perfect, and the formulae derived later in this paper can be derived from those for the electron-phonon case by putting ω, the phonon frequency, equal to zero.

This method of obtaining the self-consistent potential resembles the Hartree-Fock's method, but differs from it in that here the method takes account of a certain correlation between electrons automatically. It is shown that the new potential, obtained after some simplifying assumptions, contains the simplest result of the T. F. Method in a certain limit, and that the method can be applied to more general problems to which the T.F. method is hardly applicable.

In § 2, the T.F. method will be recapitulated in such a way available for the later discussions, and all the essential result will be obtained there. In § 3, Nakajima's method will be used to renormalize the impurity potential, and one will see the coincidence of the result with that of § 2. In § 4, the collective treatment will be given along the line similar to that of Bardeen and Pines. The properties of the effective impurity potential thus derived will be discussed fully in two cases where the screening electrons are degenerate (in § 5), and where these are non-degenerate (in § 6). These will be used then for the calculation of the relaxation time of the electric current for both cases (in § 7), and it will be shown that the residual resistance changes only slightly: In metals it is raised a little from the value given by older theories in which the impurity potential is simply screened coulombic. In semi-conductors it will be concluded that the truth lies between two assumptions adopted by Conwell-Weisskopf and Brooks-Herring.

---

* In this statement, the T. F. method is meant not to be the customary one, but one which will be developed in § 2 of this paper. In the customary T. F. method, the effect of the particular electron is ignored.

** At absolute zero of temperature, both assumptions may be equivalent and valid.

*** Unfortunately, the established method at present is not yet so successful as to include the non-adiabatic motion of the screening electrons in an unambiguous manner.

In appendix it will be shown that by the Nakajima's method one can get the screening of the coulomb interaction between conduction electrons without introducing the plasma explicity.

§ 2. The Thomas-Fermi Method

Suppose that an impurity atom is introduced substitutionally into a certain metal and that some of the valence electrons of the atom are released from the atom and itinerate over the crystal as members of the conduction electrons, leaving thus Ze excess ionic charges at the atom. The conduction electrons of the metal are perturbed by this impurity atom.

The perturbations which destroy the periodicity of the crystal are primarily due to the coulomb interaction between the electron in consideration (the Aufelektron) and the excess ionic charges, the excess coulomb interaction between the Aufelektron and those electrons or holes which heap up around the impurity atom. Here the " excess interaction " means the difference in the interaction of the Aufelektron with other electrons when there is the impurity atom and when there is none. Other minor effects are: the difference of Hartree-Fock field of the ionic charges of the impurity atom from that of the mother crystal atom, local strain around the impurity atom and so on.

The first of these is the coulomb interaction $U(r_0)$

$$U(r_0)=-\frac{Ze^2}{r_0} \tag{2.1}$$

with the origin at the impurity atom. The charge distribution of the conduction electrons is affected by the ionic charges Ze and the modified charge distribution which is determined by the potential itself. Thus self-consistency is required between the potential and the charge distribution.

Let $f(H)$ be the distribution function of a conduction electron with one particle Hamiltonian H. The Poisson equation requires

$$\begin{aligned}\Delta U(\boldsymbol{r}_0)=-4\pi e^2\boldsymbol{Tr}[\{f(H_0+U)\\ -f(H_0)\}\delta(\boldsymbol{r}-\boldsymbol{r}_0)]+4\pi Ze^2\delta(\boldsymbol{r}_0),\end{aligned} \tag{2.2}$$

where H_0 is the kinetic energy of a conduction electron, and $\boldsymbol{Tr}$ means the operation

$$\boldsymbol{Tr}[A]=\sum_{k\sigma}\int\psi_k{}^*(\boldsymbol{r})A\psi_k(\boldsymbol{r})\,d\boldsymbol{r}$$

where $\psi_k(\boldsymbol{r})$ is the eigen function of H_0 specified by the wave vector $\boldsymbol{k}$ and σ is the spin coordinate. The first term on the right hand side of (2.2) except the factor $-4\pi e$ represents the difference of the charge density in the presence of the impurity atom from that in its absence. If U in the curely bracket is taken for c-number and only the first term in the expansion of $f(H_0+U)$with the respect to U is retained, Eq. (2.2) gives the well-known formula

$$U(r_0)=-\frac{Ze^2}{r_0}e^{-qr_0}, \tag{2.3}$$

with

$$q^2=4\pi e^2n(\zeta)\ , \tag{2.4}$$

where $n(\zeta)$ is the state density at the Fermi level ζ.

In obtaining (2.3), the Fermi distribution is assumed to be perfectly degenerate. It is reported that the inclusion of the exchange interaction in Eq. (2.2) raises the screening factor q about one half[8]. This seems not to be acceptable, for it is hardly understandable why the exchange term should have any connection with the Poisson equation (2.2). Furthermore, it is probable that the exchange interaction will greatly be reduced if the correlation is included from the start. This will be demonstrated in § 4.

Reflecting the procedure by which it is derived, U given by Eq. (2.3) is to be used only as a c-number, or, what amounts to be the same, as diagonal elements. In other words, it is a potential, as it were, for a test charge, that is, no deformation on the side of the screening electrons in the field of the Aufelektron is considered. Actually, any electron may be picked up from whole conduction electrons as Aufelektron in question, so that this particular electron will be screened by the remaining charges with a hole scooped out by itself, that is, the screening charges are polarized by the Aufelektron, the effect of the screening thus being somewhat diminished. Mathematically, this polarization arises from the off-diagonal elements of U which are ignored in deriving (2.3).

This can be taken care of if U in the function $f(H_0+U)$ is treated as a q-number. In order to expand $f(H_0+U)$ into a power series of U, one writes $f(H_0+U)$ as

$$f(H_0+U)=\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} e^{(H_0+U)s}\phi(s)ds\ , \tag{2.5}$$

where $\phi(s)$ is the Laplace transformation of the distribution function:

$$\phi(s)=\int_0^\infty e^{-sE}f(E)dE\ . \tag{2.6}$$

The integral of (2.5) is performed along the so-called Bromwich path. Now, one can expand $\exp(H_0+U)$ into the ordered exponential series:

$$e^{(H_0+U)s}=e^{H_0 s}+\int_0^s ds' e^{H_0(s-s')}Ue^{H_0 s'}+\cdots\ . \tag{2.7}$$

Then one obtains in the linear approximation,

$$\begin{aligned}&\boldsymbol{Tr}[\{f(H_0+U)-f(H_0)\}\delta(\boldsymbol{r}-\boldsymbol{r}_0)]\\&\quad=\sum_{\boldsymbol{k}\sigma}\sum_{\boldsymbol{k}'}\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}ds\cdot\phi(s)\int_0^s ds'\langle\boldsymbol{k}/e^{H_0(s-s')}Ue^{H_0 s'}/\boldsymbol{k}'\rangle\times\langle\boldsymbol{k}'/\delta(\boldsymbol{r}-\boldsymbol{r}_0)/\boldsymbol{k}\rangle\ ,\end{aligned}$$

where

$$\langle\boldsymbol{k}/\boldsymbol{A}/\boldsymbol{k}'\rangle=\int\psi_{\boldsymbol{k}}^*(\boldsymbol{r})\boldsymbol{A}\psi_{\boldsymbol{k}'}(\boldsymbol{r})\,d\boldsymbol{r}\ ,$$

Let E_k be an eigen value of H_0 with an eigen function ψ_k, then the above expression can be manipulated as follows:

$$\begin{aligned}&\sum_{\boldsymbol{k}\sigma}\sum_{\boldsymbol{k}'}\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}ds\phi(s)\int_0^s ds' e^{E_k(s-s')}\langle\boldsymbol{k}|U|\boldsymbol{k}'\rangle e^{E_{k'}s}\langle\boldsymbol{k}'|\delta(\boldsymbol{r}-\boldsymbol{r}_0)|\boldsymbol{k}\rangle\\&\qquad=\sum_{\boldsymbol{k}\sigma}\sum_{\boldsymbol{k}'}\int_{c-i\infty}^{c+i\infty}ds\phi(s)\frac{e^{E_{k'}s}-e^{E_k s}}{E_{k'}-E_k}\langle\boldsymbol{k}|U|\boldsymbol{k}'\rangle\langle\boldsymbol{k}'|\delta(\boldsymbol{r}-\boldsymbol{r}_0)|\boldsymbol{k}\\&\qquad=\sum_{\boldsymbol{k}\sigma}\sum_{\boldsymbol{k}'}\frac{f(E_{k'})-f(E_k)}{E_{k'}-E_k}\langle\boldsymbol{k}|U|\boldsymbol{k}'\rangle\langle\boldsymbol{k}'|\delta(\boldsymbol{r}-\boldsymbol{r}_0)|\boldsymbol{k}\rangle\ .\end{aligned}\tag{2.8}$$

In the free electron approximation,

$$\langle\boldsymbol{k}|U|\boldsymbol{k}'\rangle=U(\boldsymbol{k}-\boldsymbol{k}')$$

and

$$\langle\boldsymbol{k}'|\delta(\boldsymbol{r}-\boldsymbol{r}_0)|\boldsymbol{k}\rangle=e^{i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{r}_0}\ , \tag{2.9}$$

where $U(\boldsymbol{k}-\boldsymbol{k}')$ is defined by the Fourier transformation of U:

$$U(\boldsymbol{r}_0)=\frac{1}{(2\pi)^3}\int e^{i\kappa\cdot\boldsymbol{r}_0}U(\kappa)d\kappa\ . \tag{2.10}$$

From Eqs. (2.8), (2.9) and (2.10), the Poisson equation is transformed to

$$-\kappa^2U(\kappa)=-4\pi e^2\sum_{\boldsymbol{k}}\frac{f(E_{k-\kappa})-f(E_k)}{E_{k-\kappa}-E_k}U(\kappa)+4\pi Ze^2\ ,$$

whence

$$U(\kappa) = -\frac{4\pi Ze^2}{\kappa^2 + \boldsymbol{H}(\kappa)} ,$$

where

$$\boldsymbol{H}(\kappa) = -4\pi e^2 \sum_{k\sigma} \frac{f(E_{k-\kappa}) - f(E_k)}{E_{k-\kappa} - E_k} . \tag{2.11}$$

A detailed investigation of the potential (2.11) will be postponed to §§ 5 and 6. It is easily shown that in the limit of $\kappa \to 0$, where the polarization effect mentioned above becomes negligible, (2.11) reduces to the screened coulombic form with a screening "constant" (2.4), but for larger κ or for the smaller impact parameter, $\boldsymbol{H}(\kappa)$, the screening parameter, depends on the way of the scattering.

It is reported that the method of Gell-mann and Brueckner leads the same result (2.11) for the impurity potential*). It is interesting to see that a phenomenological theory is equivalent in essence to the orthodox formalism of the many-body problem. This implies that the method of the next section has a very intimate connection with the Gell-mann and Brueckner's method.

§ 3. The Nakajima's Method

This section will be devoted to a formulation of the dynamical method of obtaining the effective impurity potential. Although the method yields after all the same result as obtained by the T.F. method, the procedure is not so straight-forward as the statistical method and there remains a problem unsolved in connection with the invalidity of the adiabatic assumption described in the introduction.

In the following, the problem is treated in the number representation. The Hamiltonian of the electronic system with a proper choice of the base is

$$H^{(1)} = \sum_{k\sigma} E_k n_{k\sigma} + \frac{1}{2} \sum_{\kappa \neq 0} M_\kappa{}^2 \rho_\kappa \rho_{-\kappa} + \sum_{\kappa \neq 0} U_{-\kappa} \rho_\kappa , \tag{3.1}$$

where E_k is the unperturbed energy of a conduction electron with the wave vector $\boldsymbol{k}$ and $n_{k\sigma}$ is the occupation operator of the state specified by $\boldsymbol{k}$, σ. The effective mass expression

$$E = \frac{1}{2m^*} \hbar^2 k^2 , \tag{3.2}$$

is used throughout this paper. ρ_κ is the Fourier component of the density fluctuation

$$\rho_\kappa = \sum_{k\sigma} c_{k-\kappa\sigma}{}^* c_{k\sigma} , \tag{3.3}$$

where $c_{k\sigma}{}^*$ and $c_{\ \sigma}$ are respectively the creation and annihilation operator of the electron $\boldsymbol{k}$, σ, satisfying the anticommutation relations:

$$[c_{k\sigma}{}^*, c_{k'\sigma'}]_+ = \delta_{kk'} \delta_{\sigma\sigma'} , \qquad [c_{k\sigma}{}^*, c_{k'\sigma'}{}^*]_+ = [c_{k\sigma}, c_{k'\sigma'}]_+ = 0 , \tag{3.4}$$

and the relation

$$n_{k\sigma} = c_{k\sigma}{}^* c_{k\sigma} .$$

$M_\kappa{}^2$ is the matrix element of the e-e interaction e^2/r_{12}**) and $U_{-\kappa}$ is that of the bare impurity potential $-Ze^2/r$:

---

*) T. Izuyama, Dissertation. The author is indebted to Dr. T. Izuyama for very valuable discussions about this problem.

**) Actually, the whole e-e interaction should not be included, since a certain part of it is included already for the modification of the electron mass in the crystal. In relation to this, there seems to exist an ambiguity in the choice of the mass of the screening electrons, for, though the effective mass expression (3.2) is adopted here, it can also be considered that the periodic potential of the crystal has little effect on the screening electrons when they are in the limited range around the impurity atom. A detailed investigation of it, however, is beyond the scope of this paper. It is expected that the qualitative conclusions obtained in this paper is not far from the truth.

$$M_\kappa^2=\int\psi_{k-\kappa}^*(\boldsymbol{r}_1)\psi_{k'}^*(\boldsymbol{r}_2)\frac{e^2}{r_{12}}\psi_k(\boldsymbol{r}_1)\psi_{k'-\kappa}(\boldsymbol{r}_2)d\boldsymbol{r}_1d\boldsymbol{r}_2\,,$$

$$U_{-\kappa}=\int\psi_{k-\kappa}^*(\boldsymbol{r})\frac{-Ze^2}{r}\psi_k(\boldsymbol{r})d\boldsymbol{r}\,, \tag{3.5}$$

where $\psi_{\boldsymbol{k}}(\boldsymbol{r})$ is the Bloch function. These matrix elements will be assumed in the following to depends only on the difference κ of wave vectors of initial and final states. In the free electron approximation, they are:

$$M_\kappa^2=\frac{4\pi e^2}{\kappa^2}\quad\text{and}\quad U_{-\kappa}=-\frac{4\pi Ze^2}{\kappa^2}\,, \tag{3.6}$$

which are normalized over the unit volume.

$H^{(1)}$ is divided into three parts:

$$H^{(1)}=H_0+H_c+H_I\,,$$

where

$$H_0=\sum_{k\sigma}E\,n_{k\sigma},\quad H_c=\frac{1}{2}\sum_{\kappa\neq0}M_\kappa^2\rho_\kappa\rho_{-\kappa}\quad\text{and}\quad H_I=\sum_{\kappa\neq0}U_{-\kappa}\rho_\kappa\,. \tag{3.7}$$

Now, it is required to obtain the eigenvalue in a form

$$H^{(1)}e^{iS/\hbar}\Psi_0=Ee^{iS/\hbar}\Psi_0\,, \tag{3.8}$$

where Ψ_0 is the eigenfunction of the unperturbed system H_0, and $\exp(iS/\hbar)$ is a transformation operator. Two transformations can be considered, one associated with H_c and the other with H_I. In this section it is assumed that the former transformation has little effect in determining the effective impurity potential. This is the assumption which Nakajima made tacitly in his derivation of the effective electron-phonon interaction. In the next section both transformations will be carried out in parallel.

The transformed Hamiltonian is expanded in a series of the undetermined operator S:

$$e^{-iS/\hbar}H^{(1)}e^{iS/\hbar}=H^{(1)}-\frac{i}{\hbar}[S,\ H^{(1)}]-\frac{1}{2\hbar^2}[S[S,\ H^{(1)}]]+\cdots\,. \tag{3.9}$$

Now, the first term of the right hand side is written as

$$H^{(1)}=H_0+H_c+H_I^0+(H_I-H_I^0)\,, \tag{3.10}$$

where H_I^0 is the effective impurity potential to be determined.

S is required to satisfy the equation

$$H_I^0-\frac{i}{\hbar}[S,\ H_0]=0 \tag{3.11}$$

and H_I^0 is to be obtained by another equation

$$-\frac{i}{\hbar}[S,\ H_c]+H_I-H_I^0=0\,. \tag{3.12}$$

This can be solved only after making an approximation which will be described later. Two equations (3.11) and (3.12) are combined into a single one:

$$-\frac{i}{\hbar}[S,\ H_0+H_c]+H_I=0$$

This equation implies that one is proceeding with a perturbation calculation with system H_0+H_c as the unperturbed. The effect of the impurity atom is displayed by the operator S which, as Eq. (3.11) indicates, is determined by the renormalized interaction $H_I{}^0$, and the term $-i/\hbar[S, H_c]$ is interpreted as the change of e-e interaction energy in the presence of the impurity atom. The screening effect of the conduction electrons arises from this change. The self-consistency of the treatment is implied by Eq. (3.12), which can be read as follows: The effective potential $H_I{}^0$ is determined by the bare potential H_I together with the correction term $-i/\hbar[S, H_c]$ which arises as a result of the deformation of the charge distribution determined by the effective potential itself.

Let the effective potential be expressed as

$$H_I{}^0=\sum_{k\sigma}\sum_{\kappa} U^0(\boldsymbol{k}-\kappa,\ \boldsymbol{k})c_{k-\kappa\sigma}{}^*c_{k\sigma}\ . \tag{3.13}$$

It turns out that the single parameter κ does not suffice this time to specify the effective potential.

It can easily be shown that the operator

$$-\frac{i}{\hbar}S=\sum_{k\sigma}\sum_{\kappa}\frac{U^0(k-\kappa,\ k)}{E_{k-\kappa}-E_k}c_{k-\kappa\sigma}{}^*c_{k\sigma}\ , \tag{3.14}$$

satisfies Eq. (3.11). Substitution of this into the commutator of (3.12) gives

$$\begin{aligned}\frac{i}{\hbar}[S,\ H_c]=&\sum_{k\sigma}\sum_{\kappa}\frac{U^0(\boldsymbol{k}-\kappa,\ \boldsymbol{k})}{E_{k-\kappa}-E_k}\frac{1}{2}\sum_{\kappa'}M_{\kappa'}{}^2\\&\times\{(c_{k-\kappa\sigma}{}^*c_{k+\kappa'\sigma}-c_{k-\kappa-\kappa'}c_{k\sigma})\sum_{k'\sigma'}c_{k'\sigma'}{}^*c_{k'-\kappa'\sigma'}\\&+\sum_{k'\sigma'}c_{k'-\kappa'\sigma'}{}^*c_{k'\sigma'}(c_{k-\kappa\sigma}{}^*c_{k-\kappa'\sigma}-c_{k+\kappa'-\kappa\sigma}c_{k\sigma})\}\ .\end{aligned} \tag{3.15}$$

According to Bardeen and Pines, the approximation to retain only the diagonal terms in the round bracket in (3.15) gives the Hartree's approximation[*]. In addition to this, there are two other diagonal combinations which represent the exchange effect. These three terms give the final equation which must be solved to give the self-consistent potential $U(\boldsymbol{k}-\kappa,\ \boldsymbol{k})$. This is

$$\begin{aligned}M_\kappa{}^2\sum_{k'\sigma'}&\frac{U(\boldsymbol{k}'-\kappa,\ \boldsymbol{k}')}{E_{k'-\kappa}-E_{k'}}(n_{k'-\kappa'\sigma'}-n_{k'\sigma'})+\sum_{\kappa'}M_{\kappa'}{}^2\frac{U^0(\boldsymbol{k}-\kappa,\ \boldsymbol{k})}{E_{k-\kappa}-E_k}\\&\times(n_{k-\kappa-\kappa'\sigma}-n_{k-\kappa'\sigma})+\sum_{k'}M_{k'-\kappa}{}^2\frac{U^0(\boldsymbol{k}'-\kappa,\ \boldsymbol{k}')}{E_{k'-\kappa}-E_{k'}}(n_{k'\sigma}-n_{k'-\kappa\sigma})\\&+U_{-\kappa}-U^0(\boldsymbol{k}-\kappa,\ \boldsymbol{k})=0\ .\end{aligned} \tag{3.16}$$

This is a set of algebraic equation with infinite variables, actually the integral equation, so that it is hopeless to obtain its general solution. If two exchange terms are omitted, it is simplified to

$$M_\kappa{}^2\sum_{k'\sigma'}\frac{U^0(\boldsymbol{k}'-\kappa,\ \boldsymbol{k}')}{E_{k'-\kappa}-E_{k'}}(n_{k'-\kappa\sigma}-n_{k'\sigma})+U_{-\kappa}-U^0(\boldsymbol{k}-\kappa,\ \boldsymbol{k})=0\ .$$

In this approximation, indices other than κ can be suppressed from U^0:

$$M_\kappa{}^2\sum_{k'\sigma'}\frac{n_{k'-\kappa\sigma'}-n_{k'\sigma'}}{E_{k'-\kappa}-E_{k'}}U_{-\kappa}{}^0+U_{-\kappa}-U_{-\kappa}{}^0=0\ , \tag{3.17}$$

whence one obtains finally

---

[*] Bohm and Pines[7] remarked also that this is nothing but the random phase approximation adopted by themselves in deriving the equation of motion for the density fluctuation ρ_κ.

$$U_{-\kappa}{}^{0}=\frac{U_{-\kappa}}{1-M_{\kappa}{}^{2}\sum\limits_{k\sigma}(n_{k-\kappa\sigma}-n_{k\sigma})/(E_{k-\kappa}-E_{k})} \qquad (=U_{\kappa}{}^{0})\,. \tag{3.18}$$

When the distribution function is substituted into operator $n_{k\sigma}$ (3.18) reduces to (2.11). As for the convergence of the series expansion (3.9), the same argument as given in the electron-phonon case holds here, too, that is, one can choose an energy interval ΔE in such a way that the energy denominator in (3.14) is restricted to be larger than this, but the omission of terms with denominators smaller than this has little influence on the result, while the series (3.9) converges rapidly. ΔE can properly be chosen if the alloy is dilute enough.

The above argument has, however, no physical base and ΔE has been chosen only for the mathematical convenience. According to the method developed in this section, one cannot treat the screening of that part of interaction which, in the form of the matrix elements, connects any two states whose wave vectors differ very little from each other, or, in other words, which associates with nearly forward scattering. For such a mode of scattering, the assumption of the adiabatic motion of the screening electrons will be invalid, and it is required to investigate in detail the mechanisms which cause the non-adiabatic motion. Unfortunately, no theory is established at present which allows to treat such a ploblem. Up to the second order perturbation which is a main object of this paper, the ambiguity in the choice of ΔE has no direct concern with the results.

After all, the transformed Hamiltonian is written as:

$$\begin{aligned} e^{-iS/\hbar}H^{(1)}e^{iS/\hbar}= & \sum_{k\sigma}E_{k}n_{k\sigma}+\sum_{\langle k\sigma,\kappa\rangle}\sum U_{\kappa}{}^{0}c_{k-\kappa\sigma}c_{k\sigma} \\ & +\frac{1}{2}\sum_{\kappa}M_{\kappa}{}^{2}\rho_{\kappa}\rho_{-\kappa}-\frac{i}{\hbar}[S,\ H_{I}]+\text{higher order terms}, \end{aligned} \tag{3.19}$$

where $\langle k\sigma,\ \kappa\rangle$ means to take summation over those $\boldsymbol{k}$ and σ for which

$$|E_{k-\kappa}-E_{k}|<\Delta E\,, \tag{3.20}$$

or, in other words, only those processes which corresponds to the real scattering are retained in the summation. This term cannot be eliminated by transformation without causing divergence of the seried (3.9)*).

Thus for not too small κ's, one has seen the coincidence of the results of the two methods. This is reasonable, because for such κ's, the screening is mainly determined by the dynamical properties of the system consisting of the conduction electrons and the impurity atom. It is for smaller κ's that each method, the satistical one of § 2 and the dynamical one of § 3, has its own feature and will yield different result from each other.

Similar procedures employed in this section can be applied to eliminate or to renormalize the higher order term $-i/\hbar\ [S,\ H_I]$ and so on, but this will not be done here.

§ 4. The Collective Treatment

The effective potential (3.18) is derived as a solution of Eq. (3.12) after making the random phase approximation and on the supposition that exchange terms would have no essential effects. The latter supposition is highly probable, because the coulomb interaction will reduce to a great extent the chance for any two electrons to get near each other. In case of the electron-phonon interaction, Bardeen and Pines[6] showed this by introducing the collective coordinates. This method will be use here for the problem in hand in a somewhat different manner, but of course the principle is the same. The starting Hamiltonian is

---

*) Strictly speaking, the summation in the denominator of Eq. (3.18) must be carried out under the restriction:

$$|F_{k-\kappa}-E_{k}|>\Delta E$$

which is, however, omitted there for brevity.

$$H=H^{(1)}+\frac{1}{2}\sum_{|\kappa|<\kappa_c} P_\kappa^* P_\kappa-\sum_{|\kappa|<\kappa_c} M_\kappa^2 P_\kappa \rho_\kappa\,, \tag{4.1}$$

with the subsidiary condition

$$P_\kappa \psi=0\,, \quad (P_\kappa^*=P_{-\kappa}) \tag{4.2}$$

$H^{(1)}$ is defined by (3.1) and κ_c is the critical wave vector as usual.

If the function ψ satisfies tee subsidiary conduction (4.2) strictly, the eigen values of the new Hamiltonian are the same as those of $H^{(1)}$. Now, consider a canonical transformation $\exp(iS'/\hbar)$ by which H is transformed to

$$e^{-iS'/\hbar} H e^{iS'/\hbar}\,. \tag{4.3}$$

Let S' be given as

$$S'=\sum_{|\kappa|<\kappa_c} (M_\kappa \rho_{-\kappa}+\mathcal{E}_\kappa v_\kappa) Q_\kappa\,, \tag{4.4}$$

where Q_κ is a quantity conjugate to P_κ, i.e., there exists a relation $[Q_\kappa,\ P_\kappa]=i\hbar\delta_{\kappa\kappa'}$, and $Q_\kappa^*=Q_{-\kappa}$. $\mathcal{E}_\kappa$ is a constant chosen so that the following two equations hold:

$$e^{-iS'/\hbar} P_\kappa e^{iS'/\hbar}=P_\kappa+M_\kappa \rho_{-\kappa}+v_\kappa\,, \qquad e^{-iS'/\hbar} P_\kappa^* e^{iS'/\hbar}=P_\kappa^*+M_\kappa \rho_{-\kappa}-v_\kappa\,. \tag{4.5}$$

With use of the random phase approximation, the transformed Hamiltonian is

$$\begin{aligned} e^{-iS'/\hbar} H e^{iS'/\hbar} &=\sum_{k\sigma} E_k n_{k\sigma}+\frac{1}{2}\sum_{|\kappa|<\kappa_c} \{P_\kappa^* P_\kappa+\omega_p^2 Q_\kappa^* Q_\kappa\} \\ &\quad -\frac{1}{2}\sum_{|\kappa|<\kappa_c} v_\kappa v_{-\kappa}+\sum_{|\kappa|<\kappa_c} (U_\kappa-\mathcal{E}_\kappa v_\kappa)\rho_\kappa+\sum_{|\kappa|<\kappa_c} \frac{1}{i\hbar} M_\kappa Q_\kappa \sum_{k\sigma} (E_{k-\kappa}-E_k) c_{k\sigma}^* c_{k-\kappa\sigma} \\ &\quad +\sum_{|\kappa|>\kappa_c} U_\kappa \rho_\kappa+\frac{1}{2}\sum_{|\kappa|>\kappa_c} M_\kappa^2 \rho_\kappa \rho_{-\kappa}\,, \end{aligned} \tag{4.6}$$

where ω_p is the well-known plasma frequency, $\omega_p^2=4\pi ne^2/m^*$. The third term represents the shift of the zero point energy of the system and need not be considered any more*). The fifth term represents the plasma-electron interaction which can be eliminated by another transformation, which however, has no concern with the impurity scattering problem. All the other therms have obvious meanings.

Let U_κ^0 be defined by

$$U_\kappa^0=U_\kappa-\mathcal{E}_\kappa v_\kappa M_\kappa\,, \tag{4.7}$$

then U_κ^0 represents the effective impurity potential to be determined.

The subsidiary condition (4.2) is also transformed to

$$(P_\kappa+M_\kappa \rho_{-\kappa}+\mathcal{E}_\kappa v_\kappa)\psi=0$$

From now on, the procedures are similar to those of the previous section. A transformation $\exp(iS/\hbar)$ is required to eliminate the virtual part of the impurity potential. This time, however, the problem must be divided into tow parts. For $|\kappa|>\kappa_c$, the required transformation is the same as that generated by (3.14) and the same equation (3.16) follows**). Now, two exchange terms cannot be omitted without appropriate reasoning, so that the equation is very hard to solve. In the lack of the exact treatment, it is assumed that the omission is allowed and one can use (3.18) in this case. For $|\kappa|<\kappa_c$, the transformation is just what is defined by (3.14) with $U^0(\boldsymbol{k}-\kappa,\ \boldsymbol{k})$ there replaced by U_κ^0 defined by (4.7). Then the transformed Hamiltonian is

---

*) In the electron-phonon case, the corresponding term reduces the phonon frequency.

**) It must be kept in mind that now in (3.16) all the exchange terms with long wave length M_κ with $|\kappa|<\kappa_c$ are eliminated as a result of the canonical transformation (4.4).

$$e^{-iS/\hbar}e^{-iS'/\hbar}He^{iS'/\hbar}e^{iS/\hbar}=\sum_{k\sigma}E_kn_{k\sigma}+\frac{1}{2}\sum_{|\kappa|<\kappa}(P_\kappa^*P_\kappa+\omega_p^2Q_\kappa^*Q_\kappa)$$

$$+\sum_{|\kappa|<\kappa_c}\frac{1}{i\hbar}M_\kappa Q_\kappa\sum_{k\sigma}(E_{k-k}-E_\kappa)c_{k\sigma}^*c_{k-\kappa\sigma}$$

$$+\sum_{<|\kappa|<\kappa_c>}U_\kappa^0\rho_\kappa+\sum_{<|\kappa|>\kappa_c>}U_\kappa^0\rho_\nu+\frac{1}{2}\sum_{|\kappa|>\kappa_c}M_\kappa^2\rho_\kappa\rho_{-\kappa}+\text{higher order terms.} \qquad (4.9)$$

Again, $\langle|\kappa|<\kappa_c\rangle$ and $\langle|\kappa|>\kappa_c\rangle$ mean to retain in the summation those terms which corresponds to the real processes. U_κ^0 for $|\kappa|>\kappa_c$ has, as assumed above, the expression (3.18), while U_κ^0 for $|\kappa|<\kappa_c$ is still undetermined. The subsidiary condition is transformed further to

$$\left(P_\kappa+M_\kappa\rho_{-\kappa}-\frac{i}{\hbar}[S,\ \rho_{-\kappa}]+\mathcal{E}_\kappa v_\kappa+\text{higher order terms}\right)\psi=0\ ,$$

where

$$-\frac{iS}{\hbar}=\sum_{k\sigma}\sum_{\kappa}\frac{U_{-\kappa}^0}{E_k-E_{k-\kappa}}c_{k-\kappa\sigma}^*\,c_{k\sigma}\ .$$

After calculating the commutator and making the random phase approximation, one obtains

$$\left\{P_\kappa+M_\kappa\rho_{-\kappa}+\mathcal{E}_\kappa v_\kappa+\sum_{k\sigma}\frac{M_\kappa U_\kappa^0}{E_k-E_{k-\kappa}}(n_{k-\kappa\sigma}-n_{k\sigma})+\text{higher order terms}\right\}\psi=0$$

v_κ is chosen in such a way that there exists no coupling between the impurity atom and the plasma through the subsidiary condition. This is achieved if the following equation holds.

$$v_\kappa=\mathcal{E}_\kappa^{-1}\sum_{k\sigma}\frac{M_\kappa U_\kappa^0}{E_k-E_{k-\kappa}}(n_{k-\kappa\sigma}-n_{k\sigma})\ . \qquad (4.10)$$

Then the subsidiary condition in the lowest order approximation is

$$(P_\kappa+M_\kappa\rho_{-\kappa})\psi=0\ , \qquad (4.11)$$

which is the same as that when there is no impurity atom. (4.7) and (4.10) give

$$\frac{U_\kappa^0-U_\kappa}{M_\kappa}=\mathcal{E}_\kappa^2\sum_{k\sigma}\frac{M_\kappa U_\kappa^0}{E_k-E_{k-\kappa}}(n_{k-\kappa\sigma}-n_{k\sigma})$$

and from $\mathcal{E}_\kappa^2=1$ one obtains finally

$$U_\kappa^0=\frac{U_\kappa^0}{1-M_\kappa^2\sum_{k\sigma}(n_{k-\kappa\sigma}-n_{k\sigma})/(E_{k-\kappa}-E_k)}\ , \qquad (4.12)$$

which is the same as (3.18). Thus the e-e interaction is for the most part eliminated to make the plasma. Non the less its screening effect is essentially the same as in the Nakajima's method. As is desired, there exists on coupling between the impurity atom and the plasma through the subsidiary condition, so it seems that the effective impurity potential derived will not depend so much on the extent to which the wave function satisfies this condition.

§ 5. The Effective Potential in Metals

In this section, a detailed investigation of the effective impurity potential (3.18) is made for the case where the conduction electrons are degenerate.

Let I_κ be defined as

$$I_\kappa=-\sum_{k\sigma}\frac{n_{k-\kappa\sigma}-n_{k\sigma}}{E_{k-\kappa}-E_k}\ . \qquad (5.1)$$

In the limit of small κ, or for nearly forward scattering, I_κ can easily be calculated:

$$I_\kappa=-\sum_{k\sigma}\frac{f_{k-\kappa}-f_k}{E_{k-\kappa}-E_k}$$
$$\doteqdot-\sum_{k\sigma}\frac{\partial f}{\partial E_k}$$
$$\doteqdot n(\zeta)\ , \tag{5.2}$$

where f_k is the Fermi distribution which is substituted into $n_{k\sigma}$ in (5.1), and $n(\zeta)$ is the state density including the spin state at the Fermi level*.

Then from Eqs. (3.18), (5.2) and (3.6), one obtains the self-consistent impurity potential

$$U_\kappa{}^0=\frac{-4\pi Ze^2}{\kappa^2+q^2}\ , \tag{5.3}$$

where q is the screening constant given by (2.4). Thus in the limit of the forward scattering, or, as will be pointed out later, if the polarization of the screening electrons is ignored, one is led to exactly the same result as that of the simplest T.F. method. It is obvious that the effect of this polarization is larger for the larger κ or for the smaller impact parameter. This comes out from the exact calculation of I_κ, which can be carried out in the free electron approximation and in perfectly degenerate case. The final result is

$$I_\kappa=n(\zeta)G\left(\frac{\kappa}{2k_0}\right)\ , \tag{5.4}$$

where

$$G(x)=\frac{1}{2}\left[1+\frac{1}{2x}(1-x)\log\left|\frac{1+x}{1-x}\right|\right]\ ,$$
$$\kappa=|\kappa| \tag{5.5}$$

and k_0 is the absolute value of the Fermi wave vector. The effective potential is then

$$U_\kappa{}^0=\frac{-4\pi Ze^2}{\kappa^2+q^2G(\kappa/2k_0)}\ . \tag{5.6}$$

The expression of the potential in ordinary space, or the Fourier transformation of (5.6) cannot be obtained analytically, but it approaches, for small r, to the bare coulomb type more rapidly than (2.3) does.

The function $G(x)$ has the following expansion formulae:

$$G(x)=1-\frac{x^2}{1.3}-\frac{x^4}{3.5}-\cdots\quad\text{for } x<1, \tag{5.7a}$$

$$G(x)=\frac{x^{-2}}{1.3}+\frac{x^{-4}}{3.5}+\cdots\quad\text{for } x>1. \tag{5.7b}$$

In Fig. 1, $G(x)$ is plotted as a function of x. As one may have anticipated, the screening parameter $G(x)$ is a monotonically decreasing function of the argument x. Namely, the effect of the screening diminishes as the impact parameter decreases. For the straight backward scattering ($x=1$), the screening parameter is exactly one half of the semi-classical value (2.4)**.

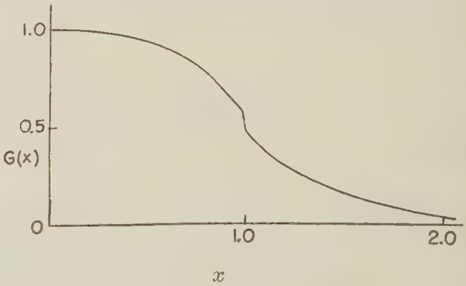

Fig. 1. $G(x)$ as a function of x.

All the quantitative result obtained so far have been based on the free electron approximation and effects of the band structure has been ignored, so one is not in a position to derive any conclusion about the interband effect. It is likely, however, that when the impurity potential induces the interband transition or similar effects, the matrix elements to be used, for example, for the calculation of the transition probability will not be those originated from the classical potential (2.3), but will be rather those obtained from the bare coulomb potential.

It is easily shown that the effect of temperature is to modify the screening parameter by a factor of order of kT/ζ, where k is the Boltzmann constant and T is the absolute temperature, and hence is quite negligible in ordinary metals at ordinary temperature.

§ 6. The Effective Potential in Semi-Conductors

In this section, a detailed investigation of the effective potential (3.18) is made in the case where the screening electrons obey the Boltzmann statistics. U_κ and $M_\kappa{}^2$ in (3.18) is redefined by

---

* For such κ's, (5.1) is not strictly valid (cf. § 3).

** Strictly speaking, the value of κ for which $x=1$ holds lies in the region where (4.12) cannot be used off-hand, because in this region exchange effect cannot be omitted without further justification.

$$U_\kappa = -4\pi Ze^2/\kappa^2\mathcal{E}\ ,$$
$$M_\kappa{}^2 = 4\pi e^2/\kappa^2\mathcal{E}\ , \tag{6.1}$$

where $\mathcal{E}$ is the static dielectric constant of the material.

Now, the Boltzmann distribution

$$f_k = \frac{e^{-\beta E_k}}{Z}$$

with

$$\beta = 1/kT \tag{6.2}$$

is substituted into $n_{k\sigma}$ in (5.1)*). Z is a function of T though the equation

$$\sum_{k\sigma} f_k = n\ , \tag{6.3}$$

where n is the number of the conduction electrons in the crystal.

In the following two limiting cases, I_κ can be expanded into power series:

Case A; $kT \gg \hbar^2\kappa^2/2m^* = E_\kappa$,

$$I_\kappa = \frac{n}{kT}\left[1 - \frac{1}{6}\left(\frac{E_\kappa}{kT}\right) + \frac{1}{6}\left(\frac{E_\kappa}{kT}\right)^2 - \cdots\right]. \tag{6.5a}$$

Case B; $kT \ll E_\kappa$,

$$I_\kappa = \frac{n}{kT}\left[\left(\frac{kT}{E_\kappa}\right) + 2\left(\frac{kT}{E_\kappa}\right)^2 + 12\left(\frac{kT}{E_\kappa}\right)^2 + \cdots\right]. \tag{6.4b}$$

In deriving Eqs. (6.4a) and (6.4b), the relation (6.3) was used. (6.4a) is valid for nearly forward scattering, and (6.4b) for large angle scattering of those electrons whose energy is much larger than the thermal average value. If only the first term of the series (6.4a) is retained, the effective potential has the simplest form

$$U_\kappa{}^0 = \frac{-4\pi Ze^2}{\kappa^2 + q_D{}^2}\ , \tag{6.5}$$

where

$$q_D{}^2 = \frac{4\pi ne^2}{kT} \tag{6.6}$$

is the screening constant. (6.5) is nothing but the Debye-Hückel potential and $q_D{}^{-1}$ is the Debye length. Thus again in the limit of the forward scattering in which the polarization effect is negligible, the result agrees with that of the simplest T.F. method.

The exact calculation of I_κ leads

$$I_\kappa = -\sum_{k\sigma} \frac{n_{k-\kappa\sigma} - n_{k\sigma}}{E_{k-\kappa} - E_k}$$
$$= \sum_{k\sigma} n_{k\sigma}\left(\frac{1}{E_{k-\kappa} - E_k} - \frac{1}{E_k - E_{k+\kappa}}\right)$$
$$\frac{m^*}{\lambda Z\pi^2\hbar^2\kappa}\int_0^\infty dt\cdot xe^{-\lambda\kappa^2}\log\left|\frac{x+\xi}{x-\xi}\right|\ , \tag{6.7}$$

where

$$\xi^2 = \frac{\lambda\kappa^2}{4} = \frac{E_\kappa}{4kT} \tag{6.8}$$

and

$$\lambda = \frac{\hbar^2}{2m^*kT}\ .$$

With use of the relation

$$\sum_{k\sigma} \frac{e^{-\lambda\kappa^2}}{Z} = \frac{1}{4\pi^{3/2}Z\lambda^{3/2}} = n\ , \tag{6.9}$$

one obtains

$$I_\kappa = \frac{n}{kT}F(\xi) \tag{6.10}$$

where

$$F(\xi) = \frac{1}{\sqrt{\pi}}\cdot\frac{1}{\xi}\int_0^\infty dx\cdot xe^{-\kappa^2}\log\left|\frac{x+\xi}{x-\xi}\right|. \tag{6.11}$$

The effective impurity potential is

$$U_\kappa{}^0 = \frac{-4\pi Ze^2}{\kappa^2 + q_D{}^2F(\xi)}\ . \tag{6.12}$$

The function $F(\xi)$, or the screening parameter, is evaluated numerically and is plotted against ξ in Fig. 2.

The variation of $F(\xi)$ with respect to κ is understandable by the argument given in § 5. Its variation with respect to the temperature is in the reverse. This will be due to the fact that at high temperatures, the electrons (or holes) are hard to heap up around the

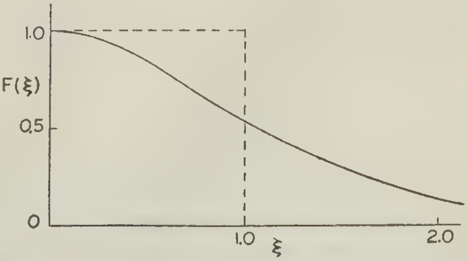

Fig. 2. $F(\xi)$ as a function of ξ. In calculating the electric resistance in § 7, $F(\xi)$ is replaced by the dashed line.

---

*) It will be very hard to comprehend what sort of approximation it is to take the ensemble average over the electron distribution in the denominator of (3.18). The same question is applicable to the case of metals except when the conduction electrons are perfectly degenerate.

impurity atom owing to the temperature agitation.

It is expected that the temperature and the carrier concentration dependence of the electric resistance will differ from those in which the Debye-Hückel potential (6.5) is used. This difference, however, may hardly be checked by experiment, because other factors may have much stronger temperature and concentration dependence. A detailed examination will be made in the next section.

§ 7. The Effect of the New Potential on the Electric Conductivity

The relaxation time τ_k of the electric current j_k is[9]

$$\frac{1}{\tau_k}=\frac{\pi Nc}{\hbar}\sum_{k'}|\langle \boldsymbol{k}|U|\boldsymbol{k}'\rangle|^2(1-\cos\theta)\delta(E_k-E_{k'}), \tag{7.1}$$

where c is the atomic concentration of the impurity atom, N is the number of the lattice points in the crystal, θ is the scattering angle and U is the impurity potential which is given by (5.6) for metals and (6.12) for semi-conductors. In the following, τ_k is calculated for each case separately.

Case I: *Degenerate Case.*

Substitution of (5.6) into (7.1) gives after the integration of angular variables

$$\frac{1}{\tau_k}=\frac{\pi(Ze^2)^2m^*Nc}{\hbar^3k^3}\boldsymbol{I}(\alpha)\ , \tag{7.2}$$

where

$$\boldsymbol{I}(\alpha)=2\int_0^1\frac{x^3}{\{x^2+\alpha^2G(x)\}^2}dx \tag{7.3a}$$

and

$$\alpha=q/2k\ ,$$
$$k=|\boldsymbol{k}|\ . \tag{7.3b}$$

The electric conductivity σ is

$$\sigma=\frac{ne^2}{m^*}\tau_{k_0}$$
$$=\frac{\nu\hbar^3k_0^3}{\pi cm^*(Ze)^2\boldsymbol{I}(\alpha_0)}\ , \tag{7.4}$$

where ν is the number of the free electron per atom, k_0 is the Fermi wave-length and $\alpha^0=q/2k_0$. The integration (7.3a) cannot be carried out analytically, but if only first two terms in the expansion (5.7a) are retained it can be done to give

$$\boldsymbol{I}(\alpha_0)=\frac{1}{(1-\alpha_0/3)^2}$$
$$\times\left[\log\left(1+\frac{1-(\alpha_0^2/3)}{\alpha_0^2}\right)+\frac{1}{1+(\alpha_0^2)/(1-\alpha_0^2/3)}\right]. \tag{7.5}$$

If only the first term of (5.5a) is retained, one obtains the well-known formula of the residual resistance in which (7.5) is replaced by

$$\boldsymbol{I}'(\alpha_0)=\log\left(1+\frac{1}{\alpha_0^2}\right)-\frac{1}{1+\alpha_0^2}\ . \tag{7.6}$$

For a numerical example, let us consider metallic copper for which $\alpha_0\sim0.8$ and $I(\alpha_0)/I'(\alpha_0)\sim1.2$\*), so that the residual resistance is raised by about this factor, as can be expected qualitatively.

Case II. *Non-Degenerate Case*

Substitution of (6.2) into (7.4) and the integration over the angular variables give

$$\frac{1}{\tau_k}=\frac{\pi(Ze^2)^2m^*Nc}{\varepsilon^2\hbar^3k^3}2\int_0^{\sqrt{\eta}}\frac{x^3}{\{x^2+\gamma^2F(x)\}^2}dx, \tag{7.7}$$

where

$$F(x)=\frac{1}{\sqrt{\pi}}\cdot\frac{1}{x}\int_0^\infty dy\cdot ye^{-y^2}\log\left|\frac{y+x}{y-x}\right|,$$
$$\gamma^2=\frac{\pi ne^2\hbar^2}{(kT)^22m^*\varepsilon^2} \tag{7.8}$$
$$\eta=\frac{E_\kappa}{kT}\ .$$

The electric conductivity is given by

$$\sigma=\beta\sum_{k\sigma}j_{kx}^2\frac{e^{-\beta E_k}}{Z}\tau_{\boldsymbol{k}}\ , \tag{7.9}$$

where j_{kx} is the x-component of the electric current. Substituting (7.7) into (7.9) and carrying out the integration over $\boldsymbol{k}$, one obtains

$$\sigma=\frac{2^{5/2}\varepsilon^2\nu(kT)^{3/2}}{3m^{*1/2}\pi^{3/2}(Ze)^2}\int_0^\infty \alpha\eta\cdot\eta^3e^{-\eta}\frac{1}{J_\gamma(\sqrt{\eta})}\ , \tag{7.10}$$

where

$$J_\gamma(\sqrt{\eta})=2\int_0^{\sqrt{\eta}}\frac{x^2}{\{x^2+\gamma^2F(x)\}^2}dx\ . \tag{7.11}$$

The integrand of (7.13) with $J_\gamma(\sqrt{\eta})$ removed has a sharp maximum at $\eta=3$, while $J_\gamma(\sqrt{\eta})$ is a slowly varying function, so the integration can be performed approximately by putting $J_\gamma(\sqrt{\eta})$ constant $J_\gamma(\sqrt{3})$. This means that the electrons which have the largest contrubution to the conductivity are those whose energy is twice the average kinetic energy.

---

*) Taken from ref. 8).

After this one obtains

$$\sigma=\frac{2^{7/2}\mathcal{E}^2\nu(kT)^{3/2}}{m^{*1/2}\pi^{3/2}(Ze)^2 J_\gamma(\sqrt{3})}\,. \tag{7.12}$$

Now, three cases are considered: These are Conwell-Weisskopf's, Brooks-Herring's and the present case which are treated separately.

[I] Conwell-Weisskopf's Formula.

Conwell and Weisskopf used the bare coulomb potential as the scattering potential. This corresponds to the case $\gamma=0$ in (7.11). In this case, the integration (7.10) diverges. They avoided this by introducing a lower limit in the integration over x, which, from the classical dynamics, is written

$$x=2k\sqrt{\frac{\eta}{1+(2\mathcal{E}kTd\eta^2/Ze^2)^2}}\,,$$

where d is the average distance between the impurity atoms. This yields

$$J_0(\sqrt{3})=\log\left(1+\left(\frac{6\mathcal{E}kTd}{Ze^2}\right)^2\right). \tag{7.13}$$

(7.13) and (7.12) give the Conwell-Weisskpf's formula[10].

[II] Brooks-Herring's formula.

Brooks and Herring[11] used for U in (7.1) the Debye-Hückel potential (6.5). This corresponds to the case $F(\xi)=1$ in (7.7). In this case $J_\gamma(\sqrt{3})$ is easily calculated and is given by

$$J_\gamma(\sqrt{3})=\log\left(1+\frac{3}{\gamma^2}\right)-\frac{1}{1+3/\gamma^2}\,. \tag{7.14}$$

(7.14) and (7.12) give the Brooks-Herring's formula.

[III] The Present Case.

The analytical integration of (7.10) is hopeless, so the potential is simplified by putting

$$F(x)=1 \text{ for } 0<x<1,$$
$$=0 \text{ for } x>1.$$

This corresponds to replacing the screening parameter $F(x)$ plotted in Fig. 2 by a simple step function plotted there also by a dashed line. Then the integration is elementarily carried out and the result is

$$J_\gamma(\sqrt{3}=\log\left(3+\frac{3}{\gamma^2}\right)-\frac{1}{1+1/\gamma^2}\,. \tag{7.15}$$

For the typical values of parameters such as m^*, $\mathcal{E}$ and for the simple case $n=N$, the function $J_\gamma(\sqrt{3})$ is numerically calculated for each case and plotted against n for constant T (Fig. 3) and against T for constant n (Fig. 4).

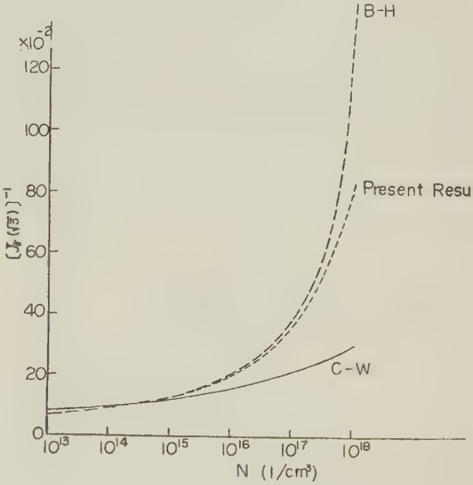

Fig. 3. $[J_\gamma(\sqrt{3})]^{-1}$ as a function of N. Values; $\varepsilon=16.1$, $T=80$, $Z=1$ and $m^*=m/4$ are chosen. Without common factors, the electron mobility is proportional to $[J_\gamma(\sqrt{3})]^{-1}$.

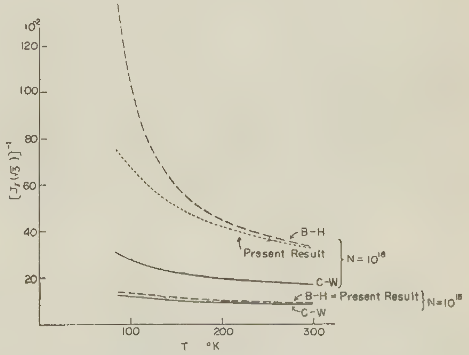

Fig. 4. $[J_\gamma(\sqrt{3})]^{-1}$ as a function of T. Values; $\varepsilon=16.1$, $Z=1$ and $m^*=m/4$ are chosen.

According to Fig. 3, the present potential yields the electron mobility in the lower concentration region nearly equal to what B–H's case yields. In the lowest concentration region, both results nearly coincide with C–W's case. As the carrier concentration increases, however, these three begin to deviate from one another and the new result lies between the older two. The interpretation is as follows: At the lower concentration there are few screening electrons, so that the impurity potential is nearly coulombic and its effect is rather over the long range. Consequently, the fraction which nearly forward scattering processes possess in the total cross section is overwhelmingly large and hence the polarization effect is negligible. As the concentration increases, the screening becomes much more effective and the effect of the impurity atom is limited in the short range. The large angle scattering then tends to possess a larger fraction in the total cross section and at the same time the reduction of the screening parameter tends to be effective on the phenomenon. The last is the reason why the present potential yields the result which lies between the older two. The screening effect was under-estimated by Conwell and Weisskopf, while over-estimated by Brooks and Herring.

Fig. 4 indicates similar features. These features may be suggested as a possible effect which is conspicuous for large γ.

§ 8. Summary and Discussions

The method of Thomas-Fermi was used to show that the requirement of the self-consistency was extended to include a certain correlation effect between the conduction electrons. The effective potential derived was shown to contain the result of the simplest T.F. method in the limit of the forward scattering. Actually, the screening parameter depends on the way of the scattering in such a way that it decreases as a impact parameter decreases. This is due to the polarization of the screening electrons by the colliding electron.

The method of Bardeen and Pines, applied to the problem of the impurity potential, was shown to yield entirely the same results as the T.F. method within the scope of this paper.

The effect of the new potential on the electric resistance was shown to be rather little in the lowest order of approximation. In case of metals, it is raised slightly from the value known so far. In case of semi-conductors, it was concluded that the truth lies between the two assumptions adopted hitherto.

All the problem was treated in the free electron approximation except that the effective mass was used. It seems at first sight that the procedures can directly be extended to the cases in which the band structure of the material is included. However, it is not obvious whether such an extension is realistic or not, and this question cannot be answered unless the problem is reconstructed in a more fundamental formalism in which the ion core field, the impurity potential and the field due to the conduction electrons are treated all in equal importance.

In calculating the electric resistance in § 7, the assumption was tacitly made that the transformation which led to the effective potential had no influence on the electric current operators. This assumption has an intimate relation with the discussion given in § 3 on the convergence of the expansion (3.9), and cannot be examined before the method of treating the non-adiabatic motion of the screening electrons is established.

Apart from that, two approximations were made. One is the random phase approximation made in solving Eq. (3.12). This approximation may at first sight have been justified, for the results agreed with those of the T.F. method. One may also think that the random phase approximation is quivalent to the procedure of taking the ensemble average in the statistical treatment as the T.F. method. However, a little reflexion shows that this is not the case, because what were omitted as a result of this approximation are very complicated interaction terms which cannot be treated by the T.F. method. It will be very cumbersome to justify this approximation more clearly, but such an attempt is desirable.

Another approximation, or rather the assumption is that the exchange terms play no essential role in determining the self-consistent potential. This assumption was made in § 3 without any reasoning. In § 4, the introduction of the collective coordinates eliminates the long range part of the exchange interaction, but there still remains the short range part which cannot be ignored without further justification. It is required to treat the exchange terms more properly.

Thus to the extent of this paper, the dynamical method is equivalent to the T.F. method, and cannot be claimed to have made much progress in determining the effective interaction. Still it is more general than the T.F. method in exhibiting the assumptions and approximations on which the T.F. method is established, and in finding out the problems which future theory must solve and the T.F. method could never do.

Though the dynamical method is not yet so well established, it is systematic within its limit of validity, and there are some problems to which the method can be applied. One of them is the screening of magnetic interaction by conduction electrons, which will be discussed in a forthcoming paper.

Acknowledgment

The author wishes to thank Profs. R. Kubo and Y. Uemura and members of their laboratories for much stimulating discussion, especially Dr. H. Hasegawa for his continual encouragement throughout this work.

Appendix

The screening of the Coulomb interaction in metals by the Nakajima's method

In this appendix, it is shown that in metals the screening of the coulomb interaction between the conduction electrons is derived by the method of § 3. The procedure is similar to that used by Bohm and Pines in their earlier investigations on this subject, but the result differs in the fact that the correlation is more properly treated and the effective potential, if derived correctly, depends on the way of the interaction.

The Hamiltonian of the system is

$$H_0=\sum_{k\sigma} E_k n_{k\sigma}+\frac{1}{2}\sum_{\kappa} M_\kappa{}^2\rho_\kappa\rho_{-\kappa}\,. \tag{A.1}$$

Let the first term be H_0 and the second H_I.

Again a transformation is made

$$e^{-iS/\hbar}He^{iS/\hbar}=H-\frac{i}{\hbar}[S,\ H]-\frac{1}{2\hbar^2}[S[S,\ H]]+\cdots\,. \tag{A.2}$$

It is required that S satisfies the equation

$$H_I{}^0-\frac{i}{\hbar}[S,\ H_0]=0\,. \tag{A.3}$$

$H_I{}^0$ is the undetermined interaction which is expressed in a form

$$H_I{}^0=\frac{1}{2}\sum_{k\sigma}\sum_{k'\sigma'}\sum_{k} M^0(\boldsymbol{k},\ \boldsymbol{k}',\ \kappa)c_{k-\kappa\sigma}{}^*c_{k\sigma}c_{k'\sigma'}{}^*c_{k'-\kappa\sigma'}\,.$$

$M^0(\boldsymbol{k},\ \boldsymbol{k}',\ \kappa)$ is to be determined by another equation

$$-\frac{i}{\hbar}[S,\ H_I{}^0]+H_I-H_I{}^0=0\,. \tag{A.4}$$

The solution of (A.3) is

$$-\frac{i}{\hbar}S=\sum_{k\sigma}\sum_{k'\sigma'}\sum_{\kappa}\frac{M^0(\boldsymbol{k},\ \boldsymbol{k}',\ \kappa)}{E_{k-\kappa}-E_k+E_{k'}-E_{k'-\kappa}}c_{k-\kappa\sigma}{}^*c_{k\sigma}c_{k'\sigma'}{}^*c_{k'-\kappa\sigma}\,. \tag{A.5}$$

With use of this, (A.4) is explicity written down and after the random phase approximation is made and exchange terms are dropped out, one obtains the equation

$$M_\kappa{}^2\sum_{k'\sigma'}\Big\{\{M^0(\boldsymbol{k}',\ \boldsymbol{k}_2,\ \kappa)\frac{n_{k'\sigma'}-n_{k'-\kappa\sigma'}}{E_{k_1-\kappa}-E_{k_1}+E_{k'}-E_{k'-\kappa}}$$
$$+M^0(\boldsymbol{k}_1,\ \boldsymbol{k}',\ \kappa)\frac{n_{k'\sigma'}-n_{k'-\kappa\sigma'}}{E_{k_2-\kappa}-E_{k_2}+E_{k'}-E_{k'-\kappa}}\Big\}+M_\kappa{}^2-M^0(\boldsymbol{k}_1,\ \boldsymbol{k}_2,\ \kappa)=0\,. \tag{A.6}$$

Even this equation is difficult to solve. So the problem is simplified by taking only those scattering processes in which two electrons collide with each other, each electron conserving its energy throughout the process. In this case, single parameter κ suffices to specify the effective potential M^0. (A.6) is then much simplified to

$$2M_\kappa^2\sum_{k'\sigma'}\frac{n_{k'\sigma'}-n_{k'-\kappa\sigma}}{E_{k'}-E_{k'-\kappa}}M_\kappa^0+M_\kappa^2-M_\kappa^0=0\ ,$$

whence

$$M_\kappa^0=\frac{M_\kappa^2}{1-2M_\kappa^2\sum(n_{k\sigma}-n_{k-\kappa\sigma})/(E_k-E_{k-\kappa})}\ . \tag{A.7}$$

For small κ,

$$M_\kappa^0=\frac{4\pi e^2}{\kappa^2+2q^2}\ , \tag{A.8}$$

where q is the screening constant defined by (2.5). The simplifying assumptions used for the derivation of (A.7) seems to hold actually to some extent on account of the high degeneracy of the conduction electrons as well as of the Pauli principle. The trouble with the exchange terms may arise from the treatment in which the coulomb and the exchange effects are equally important. The introduction of the correlation hole prior to the treatment of the exchange may reduce the latter effect. This will be the central principle of Bohm and Pine's theory. As for the mathematical regior of the method, anything convincing cannot be said without studying the effects of higher order terms and of the subsidiary condition.

Properties of Semiconductive Barium Titanates

By Osamu SABURI

Technical Laboratory, Murata Manufacturing Co.

(Received April 23, 1959)

The resistivity of barium titanate which is usually of the order of $10^9 \sim 10^{12}$ ohm-cm, may be remarkably reduced with suitable control in valency. The valency-controlled barium titanate, whose resistivity is of the order of $10 \sim 10^4$ ohm-cm at room temperature, shows anomalous positive character in the temperature dependency of the resistivity. For example, the resistivity of barium titanate containing 0.1 mol. percent of cerium abruptly changes by 10^4 between 120°C and 150°C.

Some semiconductive properties and their relations to the crystal transition and the composition of the materials are reviewed, for the valency-controlled barium titanates, and assumptions are proposed for the role of additives on the reduction of the resistivity of the barium titanates.

§ 1. Introduction

The anomaly in resistivity-temperature character of barium titanate was first reported by H. A. Sauer and S. S. Flaschen as positive temperature coefficient of resistance thermistor materials1). They described positive resistivity-temperature characters and their voltage dependencies for some valency-controlled barium titanates. Similar study was done by G. G. Harman for barium titanate containing samarium2).

This paper first attempts to show what kind of additives may be effective upon the reduction of the resistivity of barium titanates.

Sauer et al. already reported that those cations whose valencies are higher than the host ions are only effective substituents for producing semiconductive barium titanates. However, should any substitution occur in ionic crystal, we might generally expect that an impurity level in the energy band would be produced and hence bring any influence on conduction properties. From this point of view, several cations were picked up as substituents in our experiment, which were supposed to be close to Ba^{+2} or Ti^{+4} in their sizes and have higher or lower valency than Ba^{+2} or Ti^{+4}.

Assumptions for the mechanism of the conductivity in the barium titanates may be available from those experimental results.

The effects of quantities on the resistivity and crystal structure for those additives which is effective upon reducing the resistivity, the effects of the deviation from the stoichiometry for some valency-controlled barium titanates will be also explained.

Our another attempt is to show the relation between crystal transition and positive temperature character of resistivity of the valency-controlled barium titanates, with the data obtained for the barium titanates and barium-strontium titanates containing proper additives.

Furthermore, some dielectric properties and semiconductive properties of titled materials, such as frequency spectra of resistivity and dielectric constant, rectification phenomena, thermo-e.m.f., Hall e.m.f. will be shown with the effects of different electrode materials.

The barium titanates of low resistivity will be referred as semiconductive barium titanates in the following descriptions.

§ 2. Preparation of Samples and Methods of Measurements

The methods of preparing samples were mainly the same as those for ceramics, except that specially purified raw materials were used.

As the base material, we used barium-titanyl-oxalate which had been precipitated from barium chloride and titanium tetra-chloride dropped into oxalic acid3), where the purity of each raw material was of the order of 99.99%.

The additive cations were basically introduced in the forms of oxalates, so far as they were available. In case the oxalate of the cation to be introduced was water soluble or not available, oxide or chloride of the cation was used.

The base materials and the additives were throughly mixed with a pot-mill of polyethylene, with adequate amount of barium carbonate or titanium dioxide to compensate the deviation from the stoichiometry caused by the additives.

The mixed materials were fired in alumina crucibles at about 1000°C. for 1 hr.. After firing, the materials usually turned white (occasionally very slightly colored) and, formed very brittle lumps.

The lumps were crushed and pressed into discs of 20 mm in diameter and about 2 mm in thickness, under the hydraulic pressure of 600 kg/cm², unless otherwise mentioned.

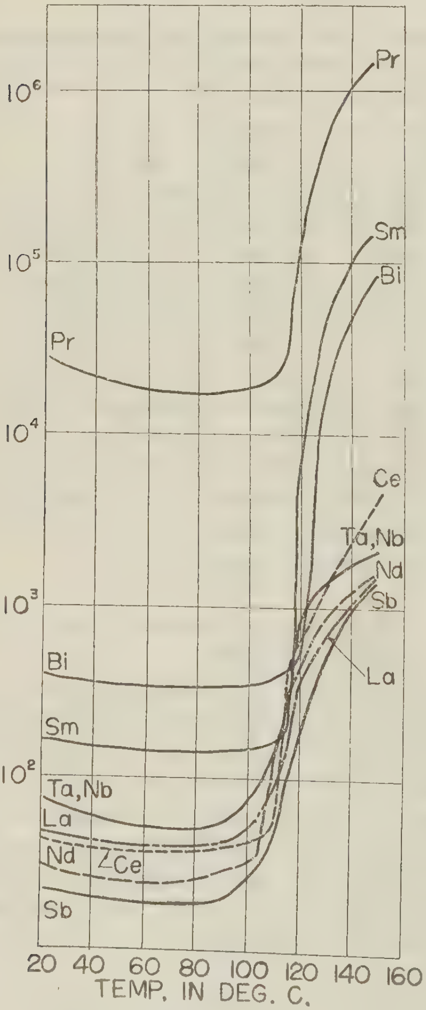

Fig. 1. Resistivity-temperature characters of semiconductive barium titanates containing various additives.

Those discs were fired at 1350°C~1400°C for 2 hrs. in an electric furnace with carborundum heating elements, where high alumina saggers and zirconia sand were used, and the atmosphere was not specially controlled.

Resistivity was determined by a direct measurement of the current flowing through the sample under impressed voltage of 0.01~0.1 V/mm. Provided that indium amalgam electrodes were used, the resistivity measured by the above mentioned method coincided with the value measured by 4-probe method.

For the measurements of dielectric properties, an impedance bridge and a Q-meter were used.

Hall voltages were measured with the apparatus of the sensitivity of 1 μV, which had been reported by J. J. Donoghue et al.⁴⁾.

Lattice constants were estimated with a recording X-ray diffractometer with $K\alpha_1$ of copper target.

§ 3. Experimental Results

1. *The effects of the kinds of the additives*

Each additives of 0.3 molecular percent of the mother material was introduced for studying the effects of the kinds of the additives.

Among various kinds of additives that were surveyed, Bi, Ce, La, Nb, Nd, Pr, Sb, Sm and Ta were effective upon the reduction of the resistivity of the barium titanate and those samples containing one of the above

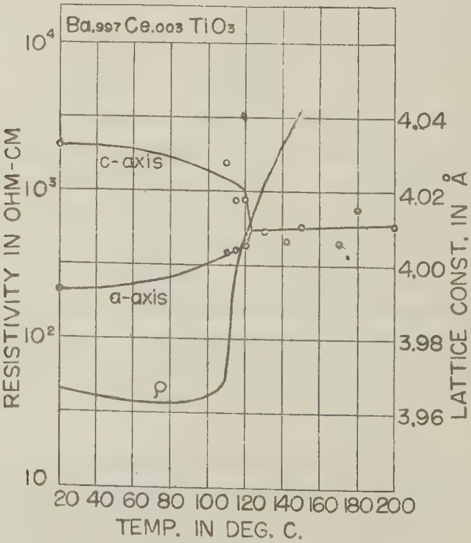

Fig. 2. Correspondence of the anomaly in the resistivity-temperature character to the crystal transition.

mentioned additives showed anomalous positive temperature character of resistivity as illustrated in Fig. 1. One example of the correspondencies of the anomalies in the resistivity-temperature characters with the transitions in crystal structures is shown in Fig. 2 for the barium titanate containing 0.3 mol. % of Ce.

Table I. Ceramic and electric properties of barium titanates containing various additives.

Properties of introduced element			Properties of the specimen including the element				
Element	Valencies	Ionic radii	Color	Shrinkage	Lattice const. at 25°C		Resistivity at 25°C
					a-axis	c-axis	
—	—	Å	—	%	Å	Å	ohm-cm

Zn	+2	0.74	light yellow	81.3	3.9920	4.0196	3.7×10^{10}

On the other hand, for the barium titanates containing one of Ag, Co, Ga, Mo, Mn, V, W and Zn, resistivity was not appreciably reduced and the anomaly in the resistivity-temperature character as caused by Bi, Ce or others could never be observed.

Those specimens whose resistivities were remarkably reduced were characterized with bluish color. Color, lattice constant and resistivity at room temperature are shown in Table I, for every specimen mentioned here.

2. *The effects of the quantity of the additives*

The effects of the quantity of the additives were studied for the barium titanates containing La or Ce, which had turned out to be effective for reducing the resistivity.

The result shown in Fig. 3 tells us that the barium titanates containing La or Ce of less than 0.05 mol. %, and those containing La or Ce of more than 0.5 mol. % show comparatively higher resistivity. The anomalous positive temperature character of resistivity as shown in Fig. 1, was not apparent for those specimens of high resistivity.

Fig. 3 also tells us that the tetragonal lattice of barium titanate tends to cubic at room temperature with increasing quantity of La or Ce.

The variation of the positive temperature character of resistivity with the variation of the content of La or Ce is shown in Fig. 4. From this result, we may suppose that the optimum quantity of the additives would be about 0.3 mol. % for obtaining lowest resistivity, and that the optimum one would be about 0.1 mol. % for obtaining highest positive temperature coefficient of resistivity.

3. *The effects of the deviation from the stoichiometry for the barium titanates*

It has been known that the properties of barium titanate are greatly affected by the deviation from the stoichiometry, that is the deviation from the unity of the molecular ratio of Ba:Ti. The effects of the deviation were checked for the semiconductive barium titanates.

Experimental results are shown in Fig. 5, for the barium titanates containing 0.3 mol. % of La or 0.1 mol. % of Ce with excess Ba or

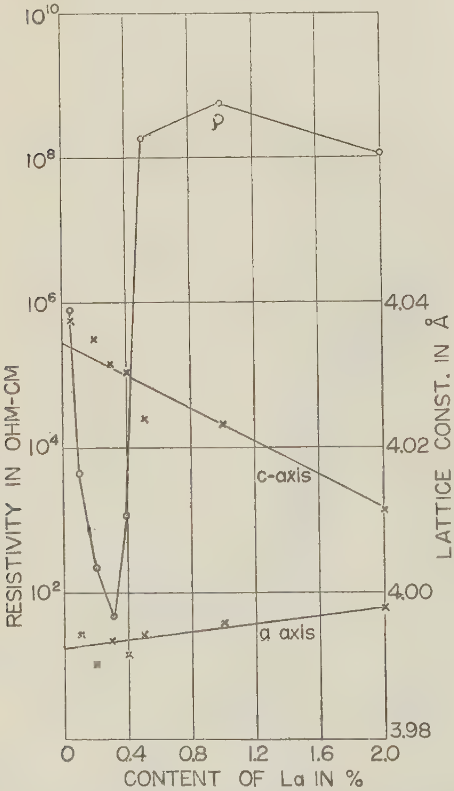

Fig. 3 (a). Dependencies of resistivity and lattice constants on the content of La.

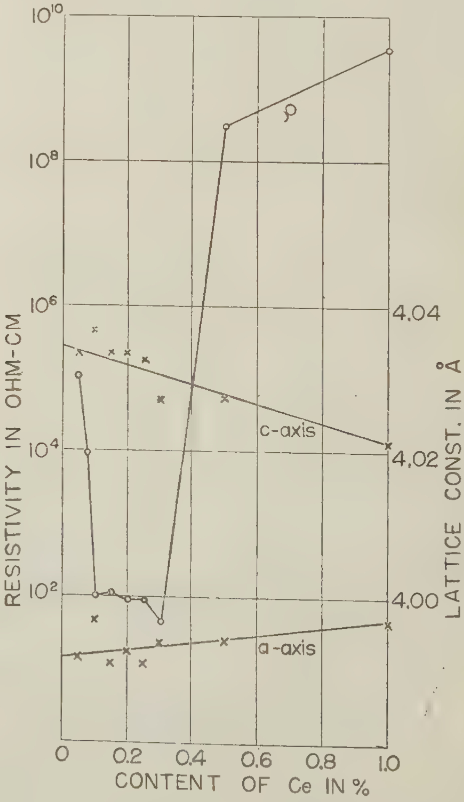

Fig. 3 (b). Dependencies of resistivity and lattice constants on the content of Ce.

Ti. With the results shown in Fig. 5, we may conclude that the deviation from the stoichiometry has not much influence upon the resistivity-temperature character.

4. *Properties of the barium-strontium titanate with Ce*

As is well known, increasing quantity of strontium causes decreasing Curie temperature in barium-strontium titanate system. Should the anomaly of resistivity in the semiconductive barium titanate happen with the the transition in crystal structure, one might expect that the temperature where the resistivity anomaly happens will shift with the variation of the content of strontium in semiconductive barium-strontium titanate system.

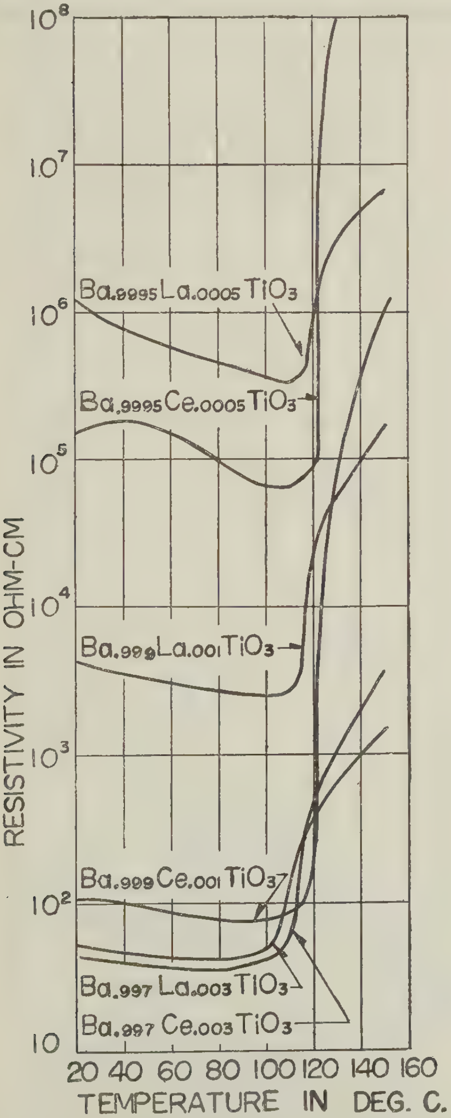

Fig. 4. Dependencies of resistivity-temperature characters on the content of La or Ce.

Fig. 6 illustrates a series of resistivity-temperature characters for the specimens with different content of strontium, and shifting of crystal transition point with the content of strontium.

The expected correspondence of the anomaly in resistivity with the crystal transition is observed in Fig. 6.

5. *Properties of reduced barium titanates*

Even no additions are introduced, the resistivity of barium titanate can be remarkably reduced with suitable reduction (making deficits of oxygen atoms), that is, with heating in vacuum or hydrogen atmosphere.

Pure barium titanate fired in air is usually yellow and has considerably high resistivity, however, its color turns bluish and its resistivity is lowered after the reduction treatment.

If the reduction is not so heavy, the treated barium titanate shows an anomalous positive temperature character of resistivity. But, if

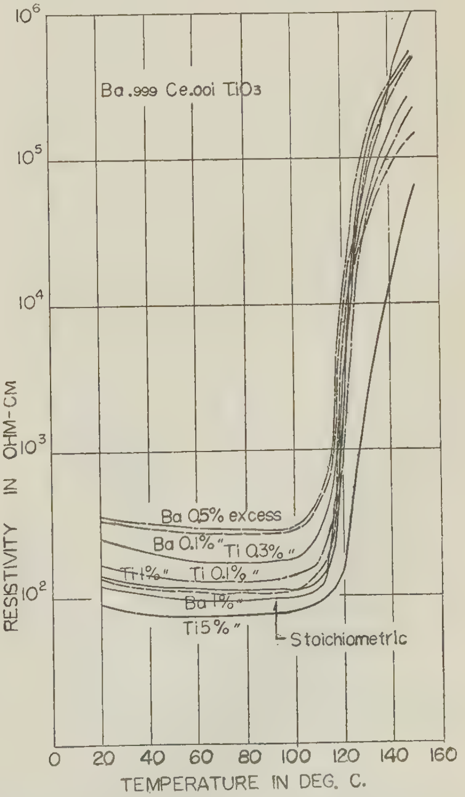

Fig. 5 (a). Dependencies of resistivity-temperature characters on the deviations from stoichiometry.

the reduction becomes much heavier, the positive character becomes poor, or can even no more be observed.

Such behavior of barium titanate is illustrated in Fig. 7. The specimens were reduced in hydrogen atmosphere at the conditions written in the figure.

6. *Properties of valency-controlled single crystals.*

The properties of barium titanates mentioned above are all concerned with the ceramics, that is the barium titanates in polycrystal states.

One might wonder what behavior could be observed for single crystals. To answer this question, some measurements were done with valency-controlled barium titanates in singles crystal states.

Specimens were single crystals of butterfly type (about 15 mm at longest sides) which had been grown from barium titanate melted in potassium fluoride. Method of producing single crystals was the one reported by Remeika⁵⁾, except that iron was not introduced but barium titanate powder containing 0.3 mol. % of La, Sb, Nd or Ce was used as raw material. Though we can not expect that the same amounts of additives as in the raw materials would be introduced into single crystals, we can expect that a certain amount of each additive was introduced into the crystals, inferring from their color (dark greyish green for the ones containing La, Sb or Nd, dark yellow for the ones containing Ce).

The resistivity of these single crystals is considerably high; typical temperature characters for them are shown in Fig. 8, where no similar anomaly in resistivity as reported for polycrystals is observed.

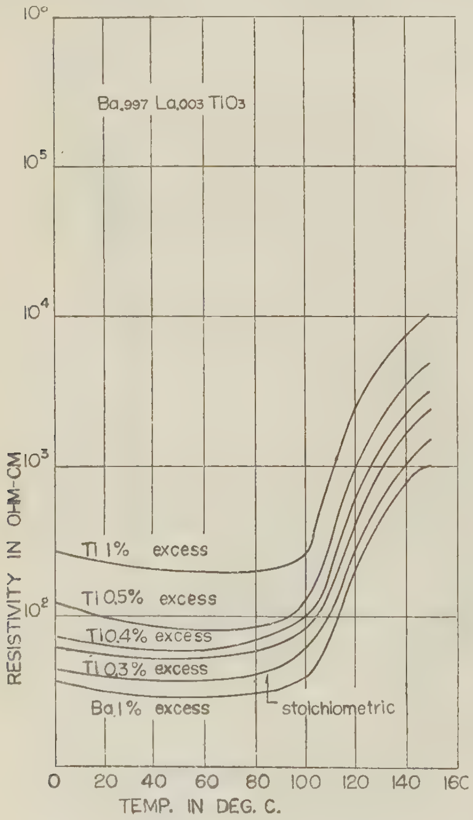

Fig. 5(b). Dependencies of resistivity-temperature characters on the deviations from stoichiometry.

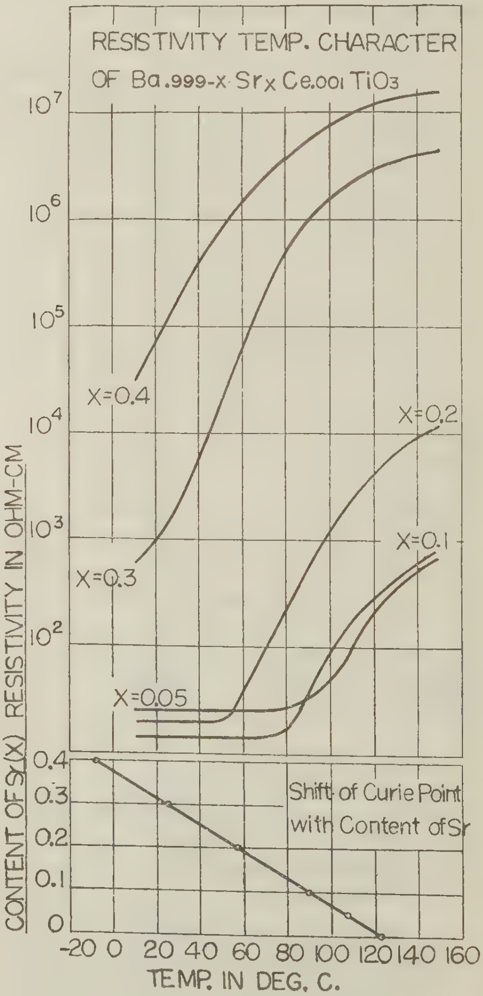

Fig. 6. Variation of resistivity-temperature curve and shift of Curie point with content of Sr in Ba–Sr titanate system.

7. *The resistivity-temperature characters in the extended temperature region*

Typical resistivity-temperature characters of semiconductive barium titanates in the extended temperature region are shown in Fig. 9, where the measurements were done between −70°C and +400°C.

Until the temperature gets t_1, the resistivity decreases with increasing temperature as usually shown in common semiconductors. The resistivity abruptly increases at the temperature just above t_1, and its rate of change amounts as much as 10^4. However, when the temperature exceeds t_2, the resistivity begins again to fall with increasing temperature, where logarithm of resistivity is proportional to the inverse absolute temperature.

The temperature t_1 depends upon the composition of the barium titanates, as it corresponds to the crystal anomaly as shown in Fig. 2 and Fig. 6. Whereas, the temperature t_2 is not so much affected by the composition but is equally about 200°C for every specimen. The activation energies gotten from the inclinations of log. resistivity *vs.* 1/absolute temperature curve are about 0.03 to 0.15 eV for temperature region below t_1, and are about 0.8 to 1.46 eV for temperature region above

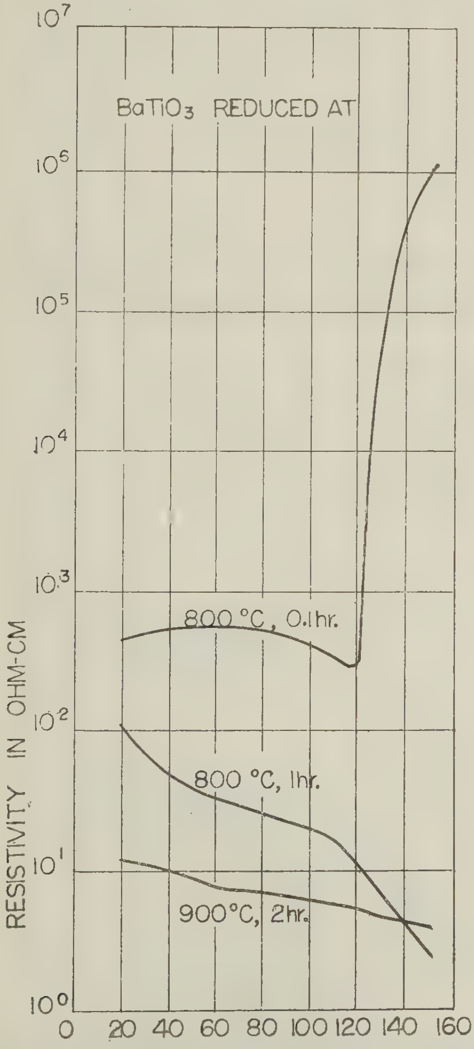

Fig. 7. Resistivity-temperature characters of reduced barium titanates.

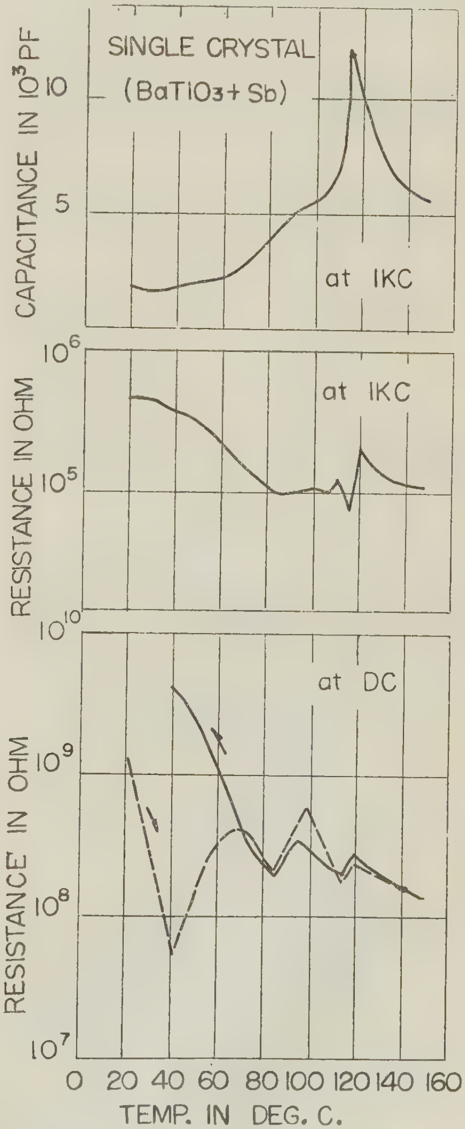

Fig. 8. Temperature characters of resistance at DC, capacitance and parallel resistance of a single crystal of valency-controlled barium titanate with Sb.

t_2. The temperature coefficients of the resistivity in the temperature region between t_1 and t_2 are about 8 to 60%/°C, as calculated with the equation:

Temperature coefficient:

$$\alpha=(1/0.434\Delta t)\log R_1/R_2\,.$$

8. *The voltage dependency of the resistivity and the effects of the electrode materials on the contact resistance*

In this study, the measurements of resistance, unless otherwise mentioned, consisted of the direct measurements of current through the specimens under a certain impressed voltage (2 probe method).

The comparison of the results of 2 probe method with those of 4 probe method and the voltage dependency of the resistivity are illustrated in Fig. 10, when ohmic electrodes of indium-amalgam were used, and the arrangement for 4-probe method was as shown

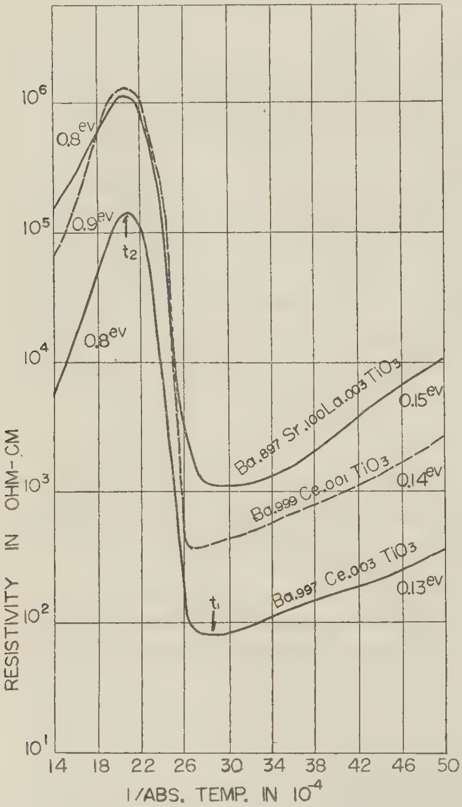

Fig. 9. Resistivity-temperature characters in extended temperature region.

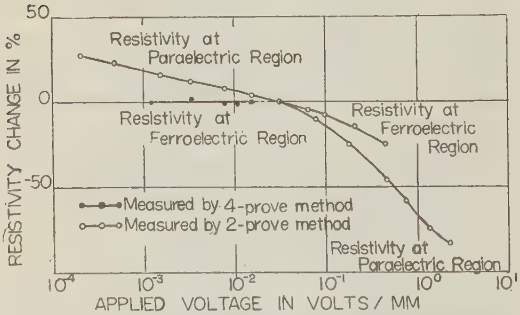

Fig. 10. Voltage dependendies of resistivity in ferroelectric and paraelectric regions.

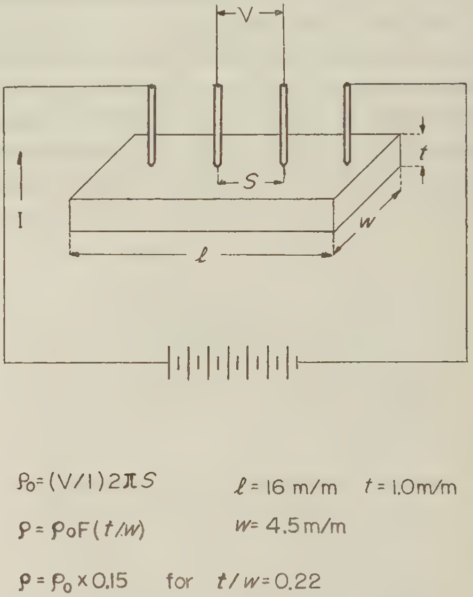

Fig. 11. Arrangement for the 4-pobe method of measurement of resistivity.

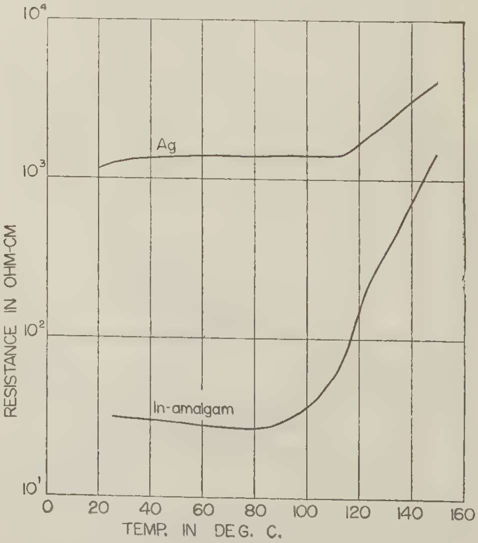

Fig. 12. Apparent resistance-temperature characters shown in the specimen with silver electrodes and in the specimen with indium-amalgam electrodes.

in Fig. 11.

Fig. 10 tells us that for certain voltages (0.01~0.1 volt/mm) the value measured with 2-probe method coincide with those measured with 4-probe method fairly well, and that the resistivity is more voltage sensitive in paraelectric region than in ferroelectric region.

All measurements with resistivity reported in this paper were done at the impressed voltage of 0.01~0.1 volt/mm, and with indium-amalgam electrodes.

Some materials show higher contact resistance than indium-amalgam, as shown in Fig. 12, which result was obtained for fired-silver electrodes.

9. *Frequency spectra of resistivity and dielectric constant for the semiconductive barium titanates*

In this section, the resistivity (ρ) and dielectric constant (ε) and their frequency depend-

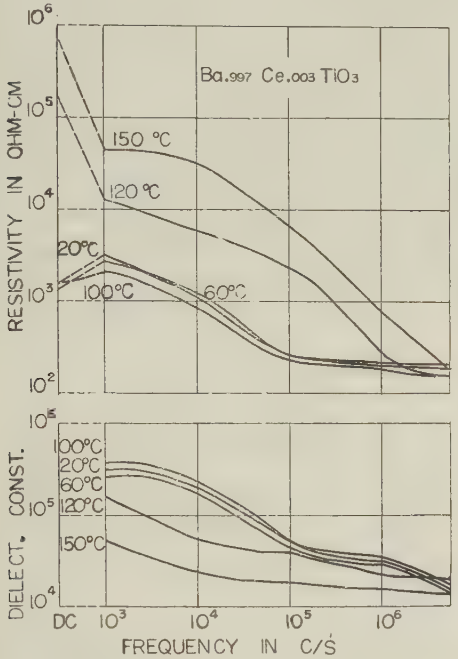

Fig. 13. Frequency character of resistivity and dielectric constant for the semiconductive barium titanate with 0.3 mol. % of Ce.

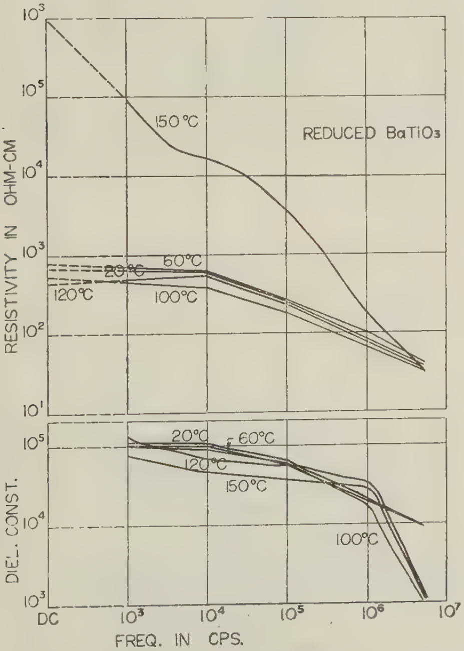

Fig. 14. Frequency character of resistivity and dielectric constant for the reduced semiconductive barium titanate.

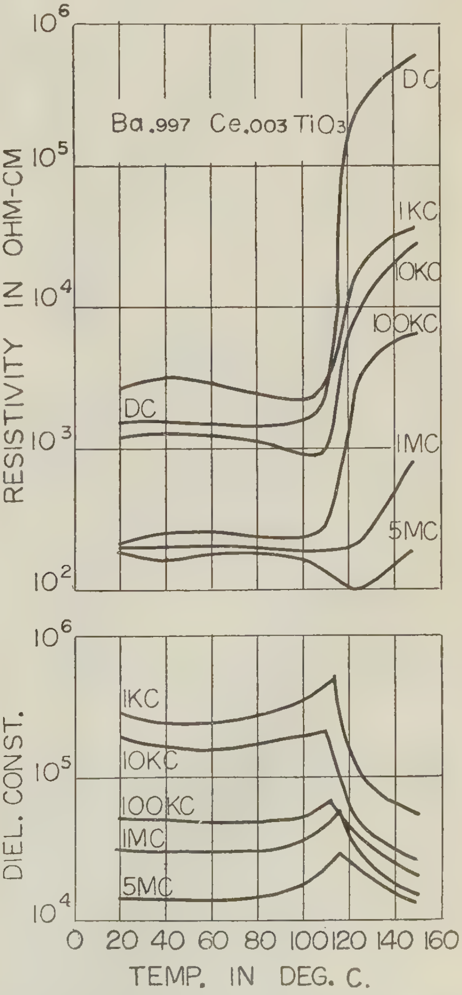

Fig. 15. Temperature character of resistivity and dielectric constant for the semiconductive barium titanate with 0.3 mol. % of Ce.

encies will be explained for typical semiconductive barium titanates with ohmic electrodes, ρ and ε are calculated from the measured parallel resistance and parallel capacitance.

Fig. 13 shows the frequency spectra of ρ and ε for barium titanate containing 0.1 mol. % of Ce, and Fig. 14 shows those for weakly reduced barium titanate.

Fig. 13 and Fig. 14 are rearranged in Fig. 15 and Fig. 16 respectively, with the frequencies as the parameter. The temperature dependencies of ρ and ε with the frequencies as the parameter for $Ba_{.999}Ce_{.001}TiO_3$ and $Ba_{.897}Sr_{.100}La_{.003}TiO_3$ are respectively shown in Fig. 17 and Fig. 18. A dispersion is observed at lower frequency region for every sample, and the positive temperature character decreases with increasing frequency.

10. *Thermo-e.m.f. for the semiconductive barium titanates*

The thermo-e.m.f.s for some representative semiconductive barium titanates were measured as total thermo-e.m.f.s against copper, with cold junction maintained at 15°C and hot junction elevated up to 415°C. Experimental results are as shown in Fig. 19, the e.m.f. per degree $(d\theta/dT)$ appears constant in each specimen for the referred whole tem-

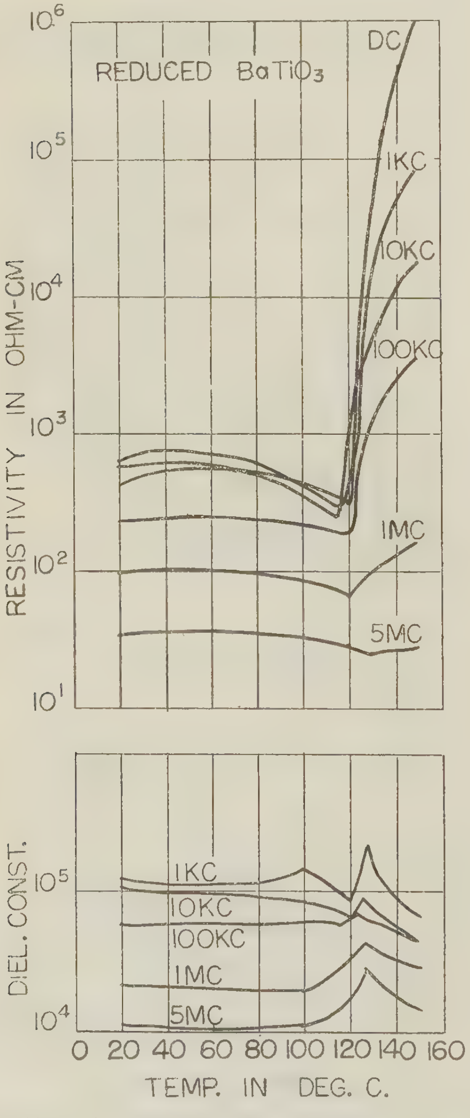

Fig. 16. Temperature character of resistivity and dielectric constant for the reduced semiconductive barium titanate.

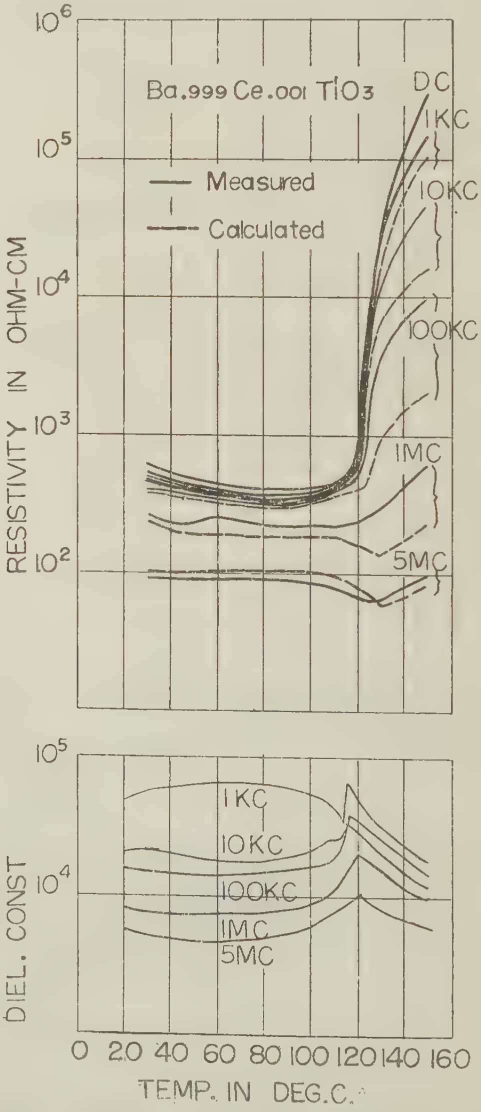

Fig. 17. Temperature character of resistivity and dielectric constant for the semiconductive barium titanate with 0.1 mol % of Ce.

perature region including Curie point. The value of $d\theta/dT$ is about 690 to 860μV/°C which depends upon the material. The sign of the generated e.m.f. indicates that those materials are N-type semiconductors.

11. *Rectifying phenomena in the semiconductive barium titanates*

With the semiconductive barium titanate with ohmic electrode on one surface and non-ohmic electrode on the other, a certain rectifying phenomenon may be observed. Fig. 20 shows an example of this phenomenon when fired silver and indium-amalgam electrodes were used, where the maximum ratio of forward to backward current is about 600. Semiconductive barium titanates are proved to be N-type also from the direction of easy flow at the rectifying contact.

12. *Hall effects in the semiconductive barium titanates*

In spite of the endeavor to detect a small e.m.f. using sensitive apparatus, no accurate value of Hall constant has been obtained for the semiconductive barium titanates, as the

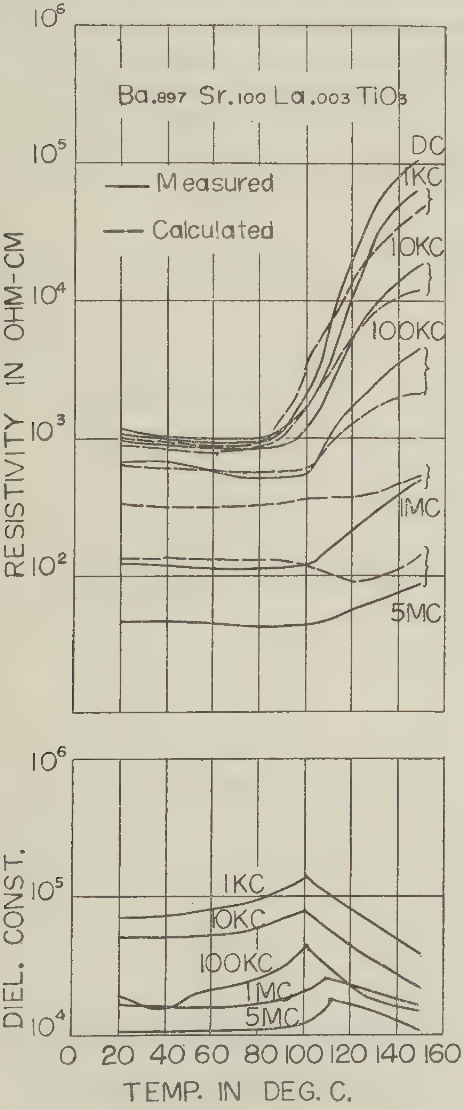

Fig. 18. Temperature characters of resistivity and dielectric constant for the semiconductive barium-strontium titanate.

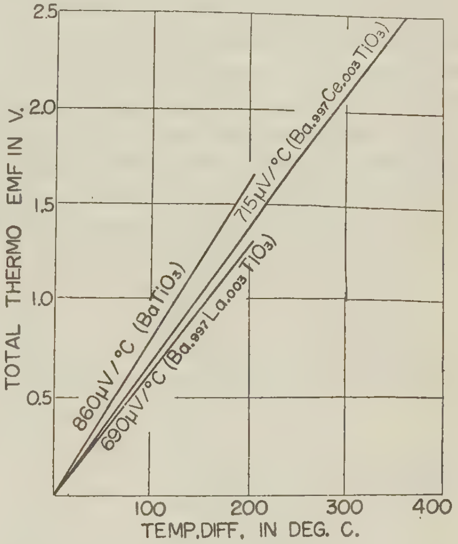

Fig. 19. Thermo e.m.f. in semiconductive barium titanates.

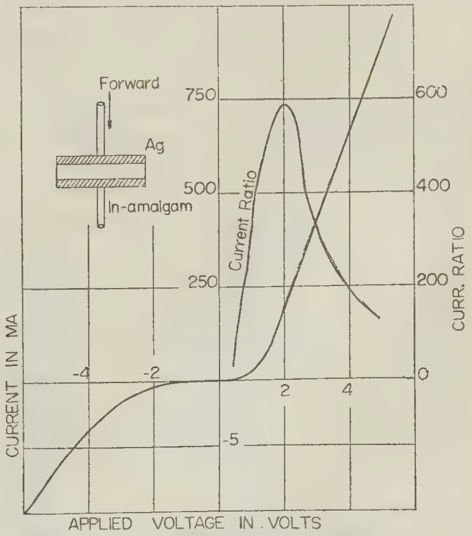

Fig. 20. Rectifying character of semiconductive barium titanates.

generated e.m.f. is very small and interfered with considerably strong noise. However, the order of magnitude of the Hall constant value is estimated at about 10^{-2} cm^3/coulomb, at room temperature, and the sign of Hall e.m.f. indicates that those materials are N-type.

13. *Behaviors of the semiconductive barium titanates with silver electrodes*

As mentioned in section 7, some electrode materials put on barium titanates show high contact resistance. Here, some characters of barium titanates with silver electrodes fired on both surfaces of them will be briefly surveyed, though these characters should not be considered to be proper to the barium titanates.

The resistance shown with silver electrodes greatly depends upon the applied voltage as illustrated in Fig. 21.

The apparent capacity shown with this specimen considerably depends upon frequency, as illustrated in Fig. 22. Fig. 23 and Fig. 24 respectively illustrate examples of the effects of d.c. biasing voltage and those of impressed a.c. voltage upon the apparent capacity and dissipation factor for the specimen with silver electrodes.

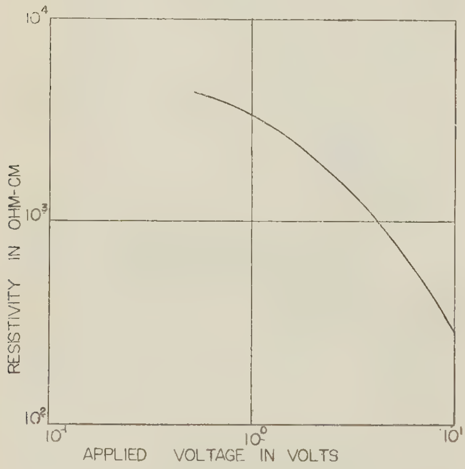

Fig. 21. Voltage dependency of contact resistance for semiconductive barium titanate with silver electrodes.

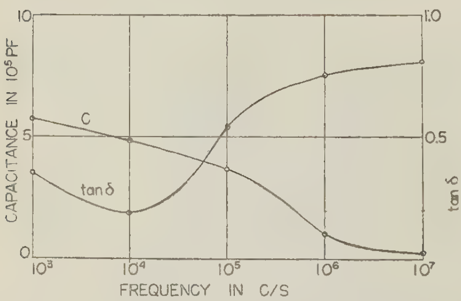

Fig. 22. Frequency characters of capacitance and tan δ shown by the semiconductive barium titanate with silver electrodes.

§ 4. Discussions

1. *Mechanism of generation of the conductivity in the barium titanates*

Fig. 25 shows the proposed substitutions of various cations for Ba^{+2} or Ti^{+4}. For example, we choose Ag^{+1}, Sb^{+3}, La^{+3}, Ce^{+3}, Pr^{+3}, Bi^{+3} and Th^{+4} as the substituents for Ba^{+2}. Cations written above Ba^{+2} or Ti^{+4} are those which have smaller valencies than the host ions, and cations written below Ba^{+2} or Ti^{+4} are those which have larger valencies than

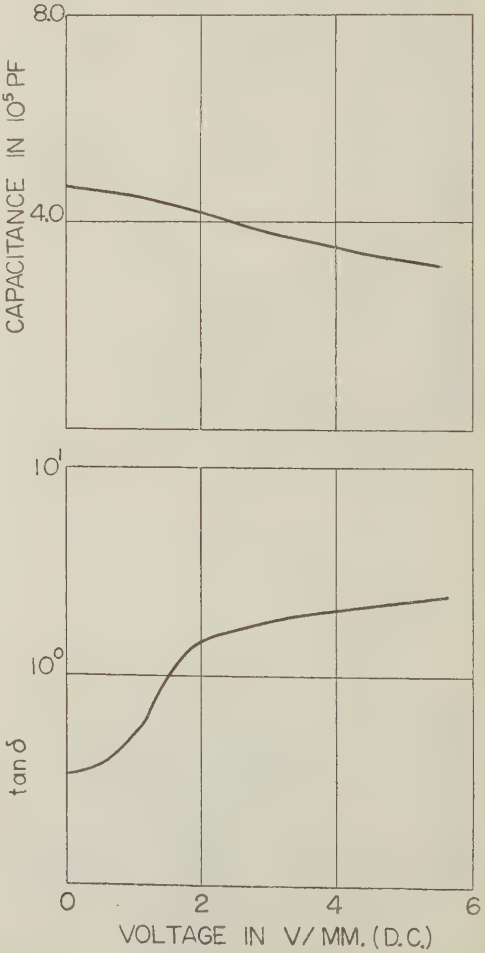

Fig. 23. D.C. bias voltage effects on capacitance and tan δ for the semiconductive barium titanate with silver electrodes.

the host ions. The cations surrounded by the bold squares are the ones that have appeared to be effective for reducing the resistivity of barium titanates in our experiment.

Referring to Fig. 25, we may conclude that the effective cations for reducing the resistivity should have larger valencies than the host ions. Th^{+4}, V^{+5}, Mo^{+6}, W^{+6} and Mn^{+6} seem to oppose this conclusion. However, Mn, V, Mo and W have more than two valency states, and we might assume that they were introduced into Ti site with the valencies of not more than four. Furthermore, Th^{+4} ion which was expected to occupy the Ba site might actually entered into Ti site.

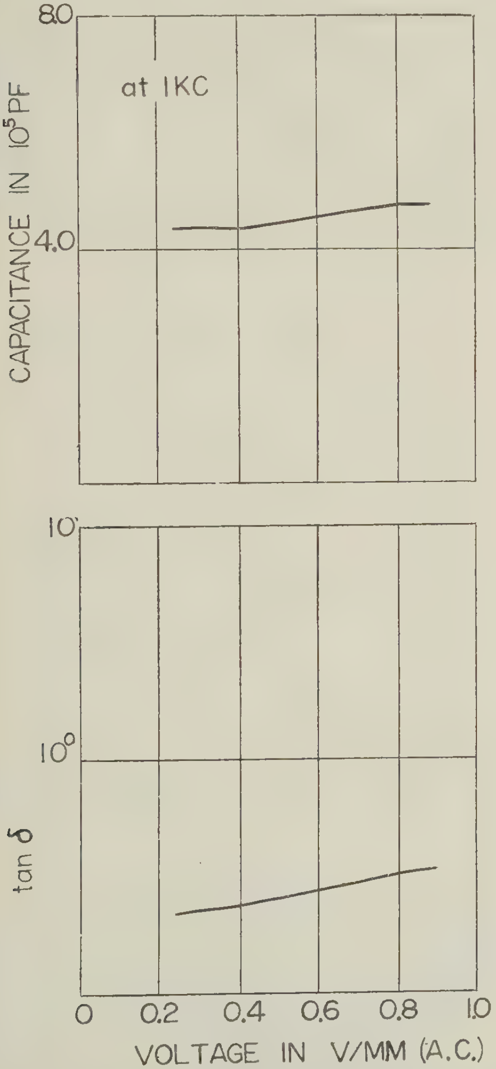

Fig. 24. A.C. applied voltage effects on capacitance and tan δ for the semiconductive barium titanate with silver electrodes.

Of course, these mechanisms are only of assumption, and should be validated with the determination of the valency states of the introduced cations.

The bluish colors of semiconductive barium titanates suggest the existences of Ti^{+3} ions, as they are popular in reduced TiO_2 crystals.

Should these assumptions be true, we may suppose the following process of substitution,

$$Ba^{+2}Ti^{+4}O_3^{-2}+xLa=Ba_{1-x}^{+2}La_x^{+3}Ti_{1-x}^{+4}Ti_x^{+3}O_3^{-2}$$

$$Ba^{+2}Ti^{+4}O_3^{-2}+xTa=Ba^{+2}Ti_{1-2x}^{+4}Ti_x^{+3}Ta_x^{+5}O_3^{-2},$$

and in case of reduction without any additives,

$$Ba^{+2}Ti^{+4}O_3^{-2}-xO=Ba^{+2}Ti_{1-2x}^{+4}Ti_{2x}^{+3}O_{3-x}^{-2}.$$

And we may suppose that the conductivity is caused by the electron exchange between Ti^{+4} and Ti^{+3}. The fact that the semiconductive barium titanates are N-type seems to support the above mechanism of producing available electrons.

Experimental results shown in Fig. 2 and Fig. 6 tell us that the anomalous positive temperature character of resistivity corresponds to the crystal transition, as the resistivity-temperature characters are always raised just below the Curie points.

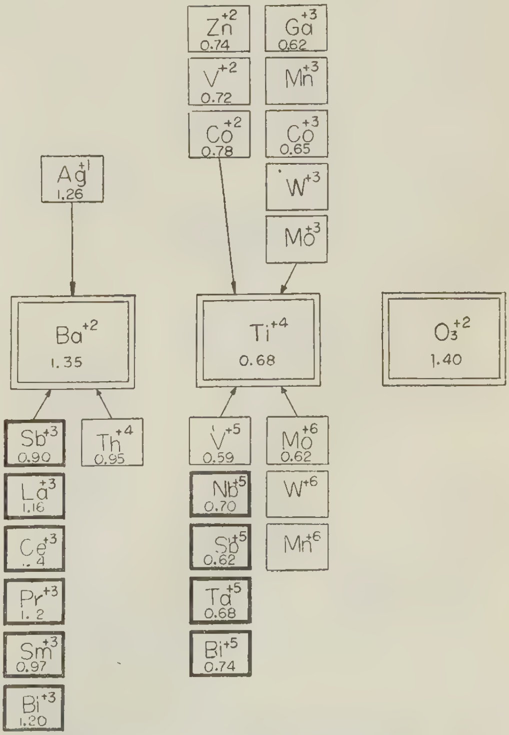

Fig. 25. Intended substitutions for Ba and Ti ions.

Though we may predict the anomalous temperature character of resistivity produced with a certain cooperation of the conduction and the crystal transition, detailed mechanism of the cooperation has not been clarified.

2. *Semiconductive properties of the barium titanates*

The semiconductive barium titanates are identified as N-type from the experimental results for thermo-e.m.f., rectification, and also from those for Hall voltage.

The activation energy below the temperature t_1 as low as 0.03 eV to 0.15 eV denotes the existance of high donor level.

It seems somewhat queer that the thermo-e.m.f.: $d\theta/dT$ is independent of temperature in the temperature region including the Curie point; the depth of the Fermi level: ΔE_f is about 0.24 eV to 0.28 eV as calculated from the value of $d\theta/dT$ with the relation:

$$\frac{d\theta}{dT} = \pm\left[\frac{\Delta E_f}{eT} + \frac{2k}{e}\right],$$

where T is assumed to be 273°K.

3. *Frequency spectra of ρ and ε for the semiconductive barium titanates*

Here we discuss the frequency spectra of ρ and ε shown by the barium titanates with indium-amalgam electrodes, that is, the character regarded as proper to the semiconductive materials. As shown in Fig. 15, Fig. 16, Fig. 17 and Fig. 18, the resistivity-temperature character in the neighbor of the Curie point is steepest at d.c., and is apt to become less steep with increasing frequency. However, this phenomenon should be considered as caused by our method of measuring parallel resistance and parallel capacitance. Generally, we may denote the equivalent circuit of these conductive specimen with the network shown by Fig. 26, where R_0 denotes the leakage resistance that corresponds to the actual conductance as shown at d.c., C_p denotes the apparent capacity, R_p denotes purely alternative losses in concerning with C_p. These R_0, C_p and R_p are of course functions of temperature and frequency.

Now, roughly assuming that the dielectric tangent, $\tan\delta = 1/\omega C_p R_p$, is constant and in-

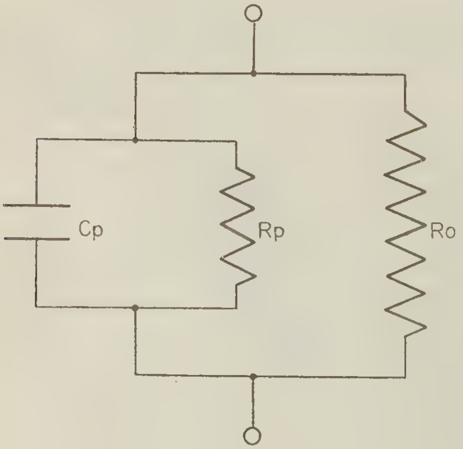

Fig. 26. Equivalent circuit for semiconductive barium titanates with ohmic contacts.

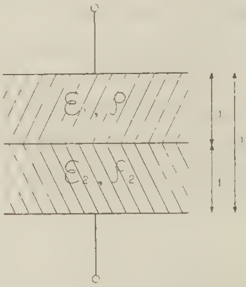

Fig. 27. Double layers.

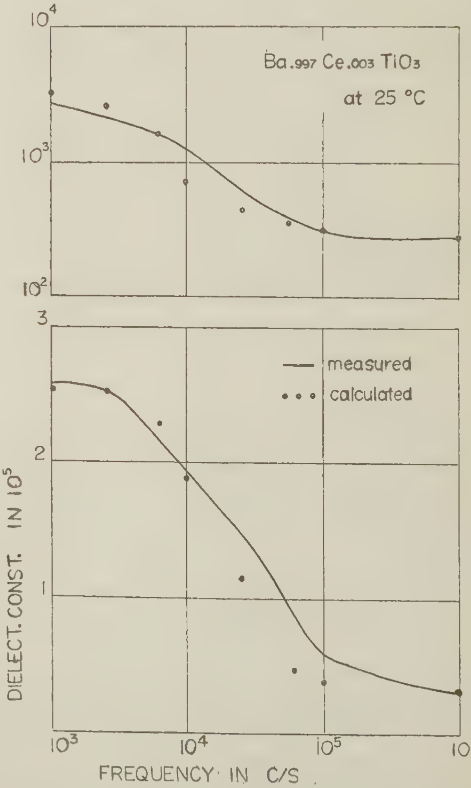

Fig. 28. Comparison of measured value and calculated value for the dispersions in resistivity and dielectric constant.

dependent of the frequency, we may calculate the resistivity-temperature character at each frequency from the assumed value of $\tan\delta$ and the resistivity-temperature character at d.c. The calculated results are shown in Fig. 17 and Fig. 18 as dotted lines, and fairly good coincidence of them with the measured values suggest us that the resistivity-temperature character observed at d.c. would be maintained still at 5 Mc.

Some of the dielectric dispersions shown in Fig. 13 and Fig. 14 may be explained as that caused with interfacial polarization, though not all of them can be done. Here we imagine double layers as shown in Fig. 27, for the measured character of Fig. 28 which is abstracted from Fig. 13. Assuming d_1/d_2 is equal to unity, we may have the calculated values shown in Fig. 28 by dots, with values: $\mathcal{E}_1=2.5\times10^4$, $\rho_1=2.75\times10^4$ ohm-cm, $\mathcal{E}_2=4.3\times10^5$ and $\rho_2=2.5\times10^3$ ohm-cm. The coincidence of calculated and measured value suggests the validity of this explanation for this case.

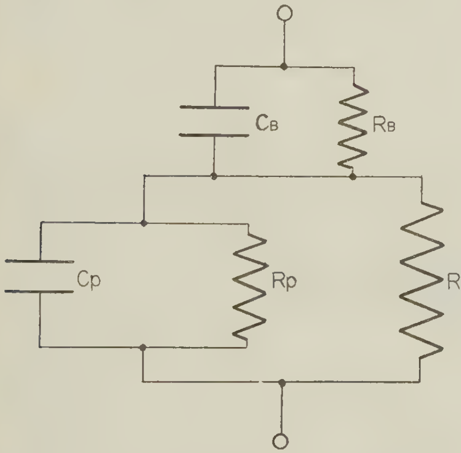

Fig. 29. Equivalent circuit for semiconductive barium titanates with non-ohmic contacts.

4. *Barrier layers*

From various results as shown in Fig. 21, Fig. 22, Fig. 23 and Fig. 24, we may reasonably suppose the existence of barrier layer at the contacts of silver and semiconductor for the specimen with silver electrodes, in which case the equivalent circuit should be written as Fig. 29. Barrier capacitance amounts about $4.4\times10^{-1}\mu$F/cm^2 and barrier conductance is about 1×10^{-3} mho/cm^2.

5. *Various effects on producing semiconductive barium titanates*

Each additive has its own optimum quantity for producing semiconductive barium titanate of minimum resistivity, as shown in Fig. 3. Close care should be paid for weighing the raw materials, as the optimum quantities are critical. The reason why the excess amounts of additives tend to make the barium titanate an insulator is a problem still to be studied.

On the other hand, the deviation from the stoichiometry is not critical as known from Fig. 5. Additional experiment informed us that the forming pressure of green body is also not critical as shown in Fig. 30, which was obtained for $Ba_{.999}Ce_{.001}TiO_3$.

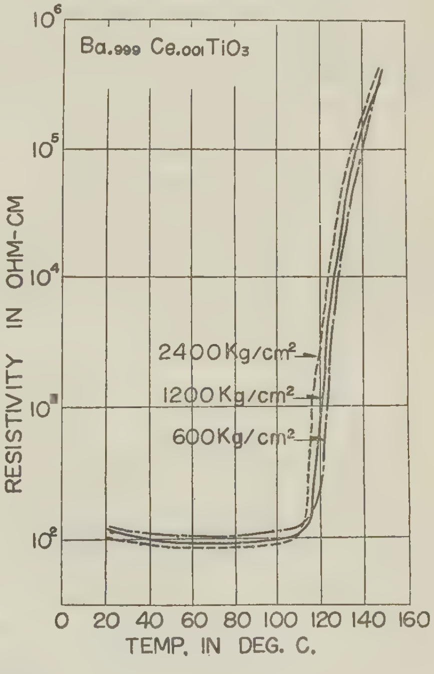

Fig. 30. Effect of forming pressure on resistivity-temperature character.

§5. Conclusion

The conductivity of semiconductive barium titanates is supposed to be produced by the control of valency of Ti^{+4} ions, generating Ti^{+3} ions which present available electrons.

The mechanism for the generation of the anomalous positive temperature character is still not clear, however, it is obvious that the anomaly in resistivity is just caused with the transition in the crystal.

The similar anomaly in resistivity would be predicted in other crystals which have any crystal transition and of which constituent ions possess more than two valency states.

Lead titanate, lead zirconate, barium zirconate titanate are the examples of these expected crystals, though we have not yet obtained successful results for them.

Those barium titanates with positive temperature character of resistivity are not only of interest from the stand point of solid state physics but also important for practical applications.

Thermally sensitive resistor which was hitherto characterized with negative temperature coefficient is now available with great positive temperature coefficient. Thermally non-sensitive resistor may also be available, utilizing suitable compositions and temperature region. Besides, applications for arrester, regulator, barrier capacitor, non-destructive rectifier are also predicted.

Acknowledgement

The investigation has been begun with valuable suggestion of Dr. Kiyoshi Abe, Professor Emeritus of Kyoto University.

The writer wishes to express his gratitude to Dr. K. Abe and Dr. Tetsuro Tanaka, Professor of Kyoto University, for the incessant direction and encouraging advices.

He also wishes to thank Mr. Akira Kawabata and Mr. Toshio Iguchi, members of Institute for Chemical Research, Kyoto University, Mr. Kikuo Wakino, Juichiro Ozawa, chief researchers of Murata Technical Laboratory, for their helpful suggestions and cooperation.

He is much indebted to Mr. Takami Tanaka, Mr. Toshihiro Iwatsuki, Researchers in Murata Tech. Lab. in their interests and endeavors in measurements and preparations of specimens.

On the Theory of Thermoelectricity

By Jan TAUC

Institute of Technical Physics, Czechoslovak
Academy of Sciences, Praha, Czechoslovakia

(Received April 24, 1959)

The meaning of the inner electrical field inside a two band semiconductor the gap of which depends on temperature is discussed in connection with the theory of the thermoelectromotive force in such semiconductors.

In a recent paper Haga1) discusses the theory of the thermoelectromotive force in a two band semiconductor. In this note, I wish to communicate a few remarks on some questions mentioned in his paper.

The definition of an electric field in a two band semiconductor the gap of which is not constant is ambiguous in a similar sense as e. g. the electrochemical potential $-e\varphi+\mu$ cannot be in all cases decomposed into an electrical part $-e\varphi$ and chemical part μ; this problem is discussed in textbooks on thermodynamics (cf. e. g.2)). In a semiconductor, the decomposition is possible as we can calculate the chemical potential μ from the concentrations of electrons using the Fermi-

Dirac statistics. If the gap ε_g is not constant, one has to consider three parts of the potential acting on the electron which one cannot, without an appropriate theory, determine separately.

However, it is always possible to write the current density equations in the form:

$$i_x^{(k)} = \frac{\sigma^{(k)}}{e}\left(eE_x + T\frac{d(\mu_a/T)}{dx} + Q_a^{*(k)}\frac{1}{T}\frac{dT}{dx}\right) \quad (1)$$

This form can be justified by general considerations of the thermodynamics of irreversibe processes (see 3)). Here E_x denotes the electric field, μ_a is the chemical potential measured as illustrated in Fig. 1, $Q_a{}^{*(k)}$ are heats of transfer of electrons ($k=1$) or holes ($k=2$); the index a means that the quantities are measured from an arbitrary zero energy level. The second term in Eq. (1) may be considered in a certain sense as an "inner" force which together with the third term gives rise to the electric field, the integral of which can be measured as the thermo-electromotive force.

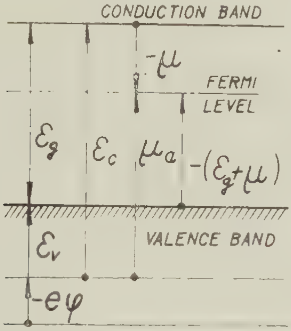

Fig. 1. Energy levels.

The chemical potential can be written as the sum $\mu_a = \varepsilon_c + \mu = \varepsilon_v + \varepsilon_g + \mu$ (μ has the same meaning as in ref. 1)). The heat of transfer can be written $Q_a{}^{*(1)} = \varepsilon_c + Q^{*(1)}$, $Q_a{}^{*(2)} = \varepsilon_v - Q^{*(2)}$, where $Q^{*(1)}$, $Q^{*(2)}$ are the kinetic energies of transfer of electrons and holes which are given by the equations:

$$Q^{*(k)} = \frac{K_2^{(k)}}{K_1^{(k)}} \quad (2)$$

(for K_1, K_2 see ref. 1)).
